Preface

Continuing a tradition established in 2003, the XXII International Conference on Building Pathology and Construction Repair (CINPAR 2026) brought the international community together at Instituto Superior Técnico, University of Lisbon, Portugal, from 15 to 17 July 2026. This volume contains the scientific and technical contributions presented at the conference.

Over its first 21 editions, CINPAR grew into an international meeting place for researchers, engineers, architects, construction professionals, public authorities, and students. Its in-person and virtual editions have been hosted in Brazil, Argentina, Portugal, Chile, Italy, and Türkiye. This history bears witness to the strength of the CINPAR community and to the lasting importance of the questions that led to the conference's creation more than two decades ago.

Those questions are, if anything, more urgent today. Urbanisation and population growth continue to increase the demand for buildings and infrastructure. At the same time, much of the existing built environment is ageing and needs to be assessed, maintained, adapted, and strengthened. Natural and human-induced hazards place further pressure on structures and communities, often revealing vulnerabilities that have developed over many years.

There are also compelling environmental, economic, and cultural reasons to make better use of what has already been built. Extending the service life of existing assets can reduce the consumption of materials and other resources, while the conservation of historic buildings protects values that cannot be replaced. In many cases, demolition and reconstruction are neither economically realistic nor environmentally or culturally acceptable.

The future of the construction sector will therefore depend as much on how we care for existing buildings and infrastructure as on what we build anew. Successful intervention requires a sound understanding of materials, structural systems, deterioration processes, and the methods available for inspection, testing, and assessment. It also requires repair and strengthening solutions that are effective, durable, and compatible with the original construction. Technical knowledge alone is not enough: appropriate standards, responsible management, and close cooperation between research and practice are equally important.

It was within this context that CINPAR 2026 received 212 abstracts, resulting in the acceptance of 154 full papers. The scientific programme comprised 42 sessions: 32 general sessions, three technical sessions, four keynote sessions, and three thematic sessions. These figures are a clear indication of the scale of the conference and of the range of work currently being undertaken in building pathology, rehabilitation, and construction repair.

The papers in these proceedings are organised under eight themes: Inspection and Defects; Materials and Techniques; Natural Hazards; Infrastructure; Design Projects and Rehabilitation Works; Built Heritage; Management and Standards; and Research and Recent Developments. The contributions cover a wide field. They examine diagnostic and non-destructive testing methods, the behaviour and characterisation of construction materials, structural assessment, hazard mitigation, and the conservation of historic buildings. They also present new repair technologies, case studies of rehabilitation projects, and research on the management and long-term performance of the built environment.

The keynote lectures and thematic sessions gave particular attention to questions that are likely to shape the field in the coming years. These included automated and large-scale non-destructive testing, integrated methods for assessing existing and historic structures, the seismic behaviour and strengthening of traditional construction, and the use of digital technologies in the diagnosis of building pathology. The discussions showed the value of bringing scientific research, professional experience, and technological development into closer contact. They also reminded us that interventions must respond not only to questions of safety and durability, but also to the character and cultural significance of the buildings concerned.

These proceedings are the result of the work of a broad international community. We hope they will be useful to researchers, practitioners, students, asset owners, public authorities, and others responsible for the care of buildings, infrastructure, and built heritage. Beyond recording the work presented in Lisbon, we hope the volume will encourage further discussion, research, and cooperation.

We sincerely thank the authors for choosing CINPAR 2026 as the forum in which to present their work. We are also grateful to the members of the Scientific Committee for the time, care, and expertise they devoted to evaluating the submitted contributions. Our thanks extend to the keynote speakers, thematic-session organisers, session chairs, and participants, whose involvement gave substance and energy to the scientific programme.

The conference would not have been possible without the commitment of the International Organising Committee, the Local Organising Committee, and the Honorary Committee, together with the work of many colleagues and volunteers. We are deeply grateful to our sponsors—hci, Instituto Nova Engenharia, Kerakoll, JETSJ, Imperalum, OZ, and STAP—whose generous support played an essential part in making CINPAR 2026 possible. We also thank our institutional supporters for their valued cooperation, and our media partners for helping to extend the reach of the conference.

We hope that the discussions begun at CINPAR 2026 will continue long after the conference itself. May these proceedings support new research, encourage lasting cooperation, and help advance the thoughtful and responsible care of our built environment.

Tiago Miguel Ferreira

Chair of CINPAR 2026

On behalf of the Organising Committee

COMMITTEES

International Organising Committee

Tiago Miguel Ferreira, IST, Portugal (Chairman)
Ana Mafalda Matos, FEUP, Portugal
Esequiel Mesquita, UFC, Brazil
Humberto Varum, FEUP, Portugal
Lais Costa, UFC, Brazil
Monica Garcez, UFRGS, Brazil
Mylene Vieira, UFC, Brazil

Honorary Committee

The Honorary Committee of CINPAR consists of distinguished individuals who have made substantial contributions to the development and continuation of the congress over the years. Their inclusion acknowledges the dedication and efforts of those who have helped shape the history and standing of CINPAR.

Francisco Carvalho, UVA, Brazil (Founder of CINPAR)
Alexandre Bertini, UFC, Brazil
Ángel Oshiro (in memoriam), UTN, Argentina
Eduardo Ballán, UCJC, Spain
Esequiel Mesquita, UFC, Brazil
Gibson Meira, IFPB, Brazil
Hector Cardozo, USalta, Argentina
Humberto Varum, FEUP, Portugal
Jeferson Marinho, URCA, Brazil
Jorge Sota, UTN, Argentina
María Positieri, UTN, Argentina
María Soledad Gómez, PUC, Chile
Monica Garcez, UFRGS, Brazil
Petr Stepánek, BRNO, Czech Republic

Local Organising Committee

Development of 3D-Printed Conductive Mortar Electrodes for Smart Bricks ... 548

Natural Hazards 558

The Use of Aerial Surveying for Land Regularization Purposes and the Right to The City: The Case of Dorothy Stang in the Federal District 559
Monitoring of Geological Risk Areas Using UAVs with High-Precision Aerial Photogrammetry Support: The Case of Sol Nascente, Section 3, Federal District, Brazil 570
From Risk Assessment to Mitigation and Emergency Planning for Multiple Natural Hazards in Urban Built Environments: A Mesoscale, User-Dynamicsbased Framework 584
Physical Vulnerability to Floods in Historic Urban Areas: A Building-Scale Assessment Approach 596
Watershed as a Basis for Heritage Vulnerability Assessment of Historic Urban Landscapes 605
A Structured Methodology for Post-Fire Structural Assessment and Rehabilitation of Unreinforced Masonry Housing in Seismic Regions 617
Assessment of the Impact of Mining Activities with Particular Focus on Mining Tremors Affecting Masonry Structures 629
Seismic Vulnerability Assessment of a Heritage Unreinforced Masonry Building: Pushover Analysis 630
Análise da Reconstrução da Infraestrutura Escolar do Rio Grande do Sul Decorrente dos Efeitos do Desastre Climático Ocorrido em 2024 641
GeoAI Resilience-Based Approach for Critical Assets Under Natural Hazards 653
Climate Resilience Skills for Cultural Heritage Buildings: A European Educational Framework Developed through the ECOHERITAGE Project 664

Infrastructure 677

Surface Distress Evaluation of Interlocking Concrete Block Pavements Using the Pavement Condition Index (PCI): A Case Study in Brazil 678
A Computational Tool Based on Artificial Neural Networks for Supporting PCI Evaluation in Interlocking Concrete Block Pavements 690
Analysis of the Influence of Rainfall Variability on Asphalt Pavement Deterioration: A Case Study Based on Functional Condition Surveys 700
Impact of Structural Pathologies on Property Market Value 712
Failure Mechanisms of the Partial Collapse of the South Road Axis (Eixo Rodoviário Sul) in Brasilia 723
Procedure for Assessing the Dynamic Resistance of Existing Bridge Structures Located in Seismically Active Mining Areas 733
Thermal Behavior of Urban Pavements Under the Influence of Tree Shading: Implications for Pavement Performance and Durability 734
Classes de Agressividade do Concreto no Brasil: Influência Regional, Patologias e Implicações em Projeto 746
Impact of Defects on the Deflection Response of Interlocking Pavements 757
Infrastructure, Architecture, and Tourism Urbanization: Digital Modeling of the Impacts of the Sabiaguaba Environmental and Gastronomic Complex, Fortaleza, Ceará, Brazil 766
Pathological Manifestations in Building Structures: Evaluation of Causes, Impacts on Durability, and Intervention Costs 778
Analysis of Pathological Manifestations Resulting from Prolonged Work Stoppage in Public Educational Construction: Impacts on the Execution of Coatings 788
Análise da Expansão da Infraestrutura Urbana de Brasília. Aspectos da Reabilitação de Viadutos no Trevo de Triagem Norte 799
Avaliação de Vulnerabilidade Sísmica de Escolas de Lisboa: Da Priorização à Escala Urbana à Análise Estrutural Detalhada 810

Design Projects and Rehabilitation Works 822

Decarbonizing Built Heritage: A Technical-Qualitative Assessment of Integrated Retrofit Strategies at the BMCC 823
Improving Daylight and Energy Efficiency in University Buildings: A Study of the Darcy Ribeiro Campus at the University of Brasilia - Brazil 835
A Resilience Clock for Residential Buildings: Age- and Hazard-Conditioned Fragility and Functional Loss via SFD(t) × UHS(TR) 847
Seismic Assessment and Strengthening of the Church of Santo Tomás de Aquino in Rondocan, Peru 859
Integration of an HBIM Model with Thermographic and Damage Image Analysis Based on Computer Vision 870

Built Heritage 882

Structural Fire Risk in Historic Urban Districts: A Component-Based Analysis of its Relationship with Multidimensional Poverty 883
Análise Patológica de Edificação Histórica com Proposta de Reabilitação: Um estudo de caso no Estado do Ceará, Brasil 884
Desafios na Reabilitação de Edificações no Brasil: A Formação Acadêmica como Elemento-Chave para a Qualidade das Intervenções 893
Semantic Structuring of Generic HBIM Elements for Building Systems 902
Caracterização de Chacotas Históricas a Partir de Classificação Análoga de Rochas Sedimentares Através de Microscopia por Luz Polarizada 914
Argumentación en Contra del Uso de Revoques Texturados Plásticos en Fachadas Patrimoniales. El Caso del Museo Provincial de Bellas Artes de Santa Fe (Argentina) 926
HBIM-Driven Management of Diagnostic Information: A Proof of Concept 938
Challenges in Data Collection for the Development of Maintenance Plans for Historic Buildings for Cultural use Integrated with HBIM Models 951
Residual Mechanical Properties of Masonry Materials After Exposure to High Temperatures 963
From Theory to Practice: Expert Views on Vulnerability of URM Buildings 975
Integration of an HBIM Digital Model with GPR Data Interpreted Using Machine Learning 986
Lime Mortars with Fibres and Residues for the Sustainable Rehabilitation of Wattle and Daub Walls 998
O Sítio Histórico de Sobral, Brasil: A Importância do Tombamento pelo IPHAN na Requalificação de Edificações e Espaços Urbanos 1010
Componentes Pré-Fabricados de Argamassa Armada: Quadro Analítico dos Danos em um CAIC em Goiânia 1022
Architectural Documentation of the San Sebastian Church 1034
Integração entre Tradição e Inovação: Desafios para Aplicação da Madeira Laminada Colada em Patrimônios Edificados 1046
Benchmarking Traditional Earthen Construction Technologies for Sustainable and Affordable Housing in Tanzania 1058
Underground Intervention in a Historic Building: Structural Compatibility and Heritage Preservation at the Museu Paulista 1070
Modelagem Digital do Museu da Imagem e do Som a Partir de Nuvem de Pontos 1082
Social Tourism and Modern Heritage: Digital Documentation and Conservation of the SESC Garanhuns Holiday Camp (1956), Brazil 1092
Integrating Computer Vision and Machine Learning for Detection of Damage in Historic Buildings 1102
Electromechanical Self-Sensing Behavior of Lime Mortars with Carbon Nanotubes and Microfibers 1114
Geophysical Characterization of Historic Masonry Using Ground-Penetrating Radar (GPR) 1127

Damage Mapping of a 50's Building as a Strategy for Maintenance ... 1138
Digital Documentation of Cultural Heritage Based on High-Resolution Scanning ... 1150
Point Clouds Beyond BIM: Aesthetic Composition and Montage Techniques for Immersive Room Films in Heritage Education ... 1160
Adaptive vs. Uniform Decimation: A Quantitative Analysis of 3D Mesh Optimization for HBIM ... 1172
HBIM for Modeling a Cultural Heritage Asset Using a Hybrid Scan-to-BIM Workflow: Challenges and Insights from the Pinacoteca do Ceará ... 1182
A Multi-Sensor Acquisition Framework for Built Heritage Documentation: Application at the Church of Nossa Senhora da Conceição de Almofala ... 1193
Wattle and daub (tabique) mortars in Northern Portugal ... 1206
Framework for Assessing and Mapping Degradation Risks in Historic Building Facades ... 1214
Incorporation of Eggshell Residues in Lime Mortars for Rehabilitation of Wattle and Daub Walls ... 1224
Mapping Technical Façade Elements Under Low-intensity Seismicity to Support Risk-informed Urban Decision-Making ... 1233
Large-Scale Seismic Vulnerability Assessment of Masonry Buildings: A Critical Appraisal of Index-based Methods ... 1245
Retrofitting Techniques Applied to Chilean Masonry Towers: A Preliminary Typological Survey of Four Case Studies ... 1257
Material Parameter updating Based on Operational Modal Analysis (OMA): Application to the Sciri Tower ... 1268
Metodologia Digital Integrada para a Conservação do Património Construído: da Reconstrução Virtual ao Fabrico Aditivo ... 1279
Porto Historical Heritage - Digital Twins and Underground Excavation Works ... 1287
Unveiling hybrid two-way out-of-plane response of existing unreinforced masonry structures through extensive shake-table testing ... 1299

Management and Standards ... 1311

Conceptual Model of Resilient Decision-Making for PDHR in Critical Zones ... 1312
Heritage Management and the Progressive Deterioration of an Earthen Troje in Mexico City ... 1325
Proposed Adaptation of the GUT Criticality Matrix for the Maintenance Management of Concrete Pavements in Fuel Stations: A Comparative Approach between Mechanical Damage and Chemical Attack ... 1337
Data Structuring and Systemic Failure Analysis in Built Asset Management: Application to Fire Detection and Suppression System Maintenance ... 1349
Leveraging Data Analytics to Manage Visitor Flows in Heritage Sites ... 1361
Study of Strategies for the Evaluation of Metal Structures Under Fire Action ... 1373

Research and Recent Developments ... 1383

Corrosion Assessment for Prestressed Steel Strands Based on Experimental Data and Numerical Analysis ... 1384
Optimising Resource Value Extraction in Demolition and Rehabilitation: A Digital Twin-Transition Approach - EU Horizon DISCOVER project ... 1396
Análise Química por Fluorescência de Raios X Portátil em Metal do Passado ... 1408
Proposal for an Optimal Timing for Maintenance and Rehabilitation Strategies on Interlocking Pavements ... 1420
Influence of Construction and Demolition Waste as Fine Aggregate Replacement on the Performance of Self-Compacting Mortars ... 1431
Durabilidade da Cor em Concretos Pigmentados Pretos: Avaliação do Comportamento Cromático sob Envelhecimento Acelerado ... 1439
Band Gap Tuning of 1D Phononic Crystals for Subway Vibration Mitigation: A Parametric Study of Periodic Foundations and Barriers ... 1453
Discrete Element-based Particle Modelling Optimization for Stone Masonry Wall's Structural Assessment ... 1465

Abstract: Continuous and systematic monitoring of built heritage surfaces is essential for effective conservation, as it enables the early detection of defects and timely interventions, resulting not only in improved preservation outcomes but also in a more efficient management of resources. However, current inspection techniques are often time-consuming and strongly dependent on the professional expertise, especially when invasive quantitative analyses are not feasible and assessments rely primarily on qualitative observations. In this context, Hyperspectral (HS) Imaging is gaining increasing relevance in the heritage field, as it allows physicochemical information to be associated with each image pixel of a surface. This study proposes a hierarchical and hybrid methodology that combines statistical analysis, Deep Learning (DL), and Machine Learning (ML) techniques applied to HS imaging data for the automatic classification of heritage surface alterations and defects. First, Independent Component Analysis (ICA) is employed as a statistical dimensionality reduction technique to enhance informative spectral patterns related to surface degradation. A selected ICA component is then used as input to a U-Net Convolutional Neural Network (CNN), which is trained to identify and segment macro-scale degraded areas on historical surfaces. Subsequently, a Random Forest (RF) classifier is applied to the original HS data, restricted to the regions detected by the U-Net, to discriminate specific degradation typologies. This multi-stage strategy enables the spatial identification of surface alterations and defects, and the workflow is further extended to the metric quantification of the detected areas by exploiting the Ground Sampling Distance (GSD). Although the classification is currently restricted to a single material and two specific types of degradation, and notwithstanding challenges posed by surface roughness and cast shadows, preliminary results are promising and suggest that the proposed approach has the potential to support conservation professionals in the rapid detection and quantification of built heritage surface alterations and defects.

Keywords: Built Heritage, Defect Detection, Automatic Inspection, Remote Sensing, Hyperspectral Imaging

1. Introduction

The proper conservation of built heritage relies on the effective management of restoration processes. Restoration should not be regarded as a last-resort intervention to prevent the loss of an asset, but rather, it should form part of a continuous maintenance strategy that is as minimally invasive as possible. To enable this approach, continuous maintenance must be supported by equally continuous monitoring. A preventive rather than curative approach to conservation contributes to a more efficient allocation and management of resources, as it allows for timely interventions and reduces the need for extensive and costly restoration actions (A Vandesande and Van Balen 2018; ICOMOS 2011; Aziliz Vandesande et al. 2018; Della Torre 2021).

However, such an approach is not always feasible, as monitoring entails time-consuming procedures conducted by specialised professionals. Furthermore, techniques aimed at obtaining precise quantitative data (e.g., destructive analyses) may be invasive and therefore unsuitable for historic built surfaces (Valença, Gonçalves, and Júlio 2013).

For these reasons, the development of new methods and procedures that allow these analyses to be conducted in a highly automated manner is of primary importance.

The widespread adoption of Artificial Intelligence (AI) has enabled the development of automatic classification procedures, such as the classification of image data through Machine Learning (ML) and Deep Learning (DL) techniques, which are now employed across a broad range of fields. These include, for instance, medicine (Cai, Gao, and Zhao 2020) and food quality control processes (Liu et al. 2025), as well as the building sector and the field of restoration, where they support the automatic mapping of decay phenomena.

The application of AI models to the classification of alterations on heritage surfaces via images is increasingly becoming a consolidated practice. This approach is progressively extending beyond purely research contexts toward operational applications and has been the subject of several review studies (Giannuzzi and Fatiguso 2024; Mishra 2021; Fiorucci et al. 2020).

However, recent advancements do not rely solely on traditional imaging approaches based on RGB data, but increasingly exploit additional spectral wavelengths extending beyond the visible range, such as MultiSpectral (MS) and HyperSpectral (HS) imagery. By investigating further portions of the electromagnetic spectrum, these techniques enable the detection of features that are not discernible to the naked eye and allow the extraction of relevant physicochemical information, thus providing quantitative data acquired through non-contact measurements (Mukhtar, Arbabi, and Viegas 2025).

The acquisition of these additional spectral channels, which in the case of HS imaging can reach hundreds of wavelengths, generates high-dimensional datasets whose management and interpretation through conventional manual procedures become practically unfeasible (Donoho 2000). In this context, AI-based methodologies emerge not merely as supportive tools, but as essential frameworks for the effective processing and interpretation of high-dimensional spectral information (Datta et al. 2022).

Examples of advanced imaging techniques combined with AI-based pipelines for the detection of alterations and decay on heritage surfaces are reported in the literature. For instance, González Manich et al. (González Manich et al. 2016) employed HS imaging to acquire data from a portion of the façade of Glasgow Cathedral (UK). In their study, small Regions Of Interest (ROIs) corresponding to different types of decay were selected to train a Support Vector Machine (SVM) classifier for the automatic segmentation of the acquired image. The results were compared with a manual mapping procedure which, although slightly more accurate, required significantly longer processing times (hours versus minutes). Similarly, Zahiri et al. (Zahiri et al. 2022) classified materials on the façade of a historic building in Bergen (Norway) using a supervised ML algorithm based on Partial Least Squares Discriminant Analysis (PLSDA). The study compared the performance of MS and HS acquisitions, demonstrating the superiority of HS data due to the higher spectral resolution and richer spectral information recorded. Another contribution is provided by Li et al. (Li et al. 2024), who acquired HS imaging data from the Dazu Rock Carvings (China) and processed the dataset using four different supervised ML algorithms to automatically classify and segment decay phenomena such as delamination, efflorescence, crust formation, and biological colonisation, achieving classification accuracies of up to 98%.

Although previous studies have demonstrated that HS imaging combined with AI techniques can detect even millimetric alterations with promising results, they frequently focus on the application and comparison of distinct models, treating them as separate analytical solutions. Moreover, most contributions conclude with the identification and segmentation of decay phenomena, without further translating these results into operationally meaningful outputs.

In this perspective, the present study proposes a hierarchical multi-step framework that integrates statistical approaches, ML and DL techniques within a unified workflow aimed at enhancing the classification of decay phenomena basing on HS images. Furthermore, it introduces a methodological procedure for converting pixel-based outputs into dimensional data, thereby enabling the quantitative estimation of degraded surface areas and supporting more practical decision-making processes.

The present study does not aim to deliver a universally applicable model but introduces a hybrid, hierarchical methodological framework for classifying surface degradation phenomena. To demonstrate the proposed workflow, an experimental heritage case study is presented: although the current application focuses on a specific surface material and two distinct types of degradation, it serves to validate the feasibility of the hierarchical approach and the on-site acquisition procedure. This initial implementation establishes a framework that can be further scaled and adapted to more complex heritage scenarios in future research. Thus, given the limited dataset, the proposed approach is not intended for immediate general use, but rather as a methodological foundation that can be refined and expanded in future work.

The manuscript is structured as follows: *Section 2* presents the selected case study for data acquisition, along with a description of the data collection procedures. *Section 3* describes the proposed methodological framework, providing a preliminary overview in *Section 3.1* and a detailed description of each step from *Sections 3.2* to *3.5*. *Section 4* reports the results of applying the methodology to the case study data, and finally, *Section 5* is dedicated to conclusions.

2. Case study and data acquisition

The selected heritage site for this study is the façade of one of the most important Christian sites in Italy, the *Basilica of the Holy House* in Loreto, in the Marche Region (central Italy). Commissioned in the XVI century by the Archbishop of the nearby city of Recanati, the Basilica houses a smaller inner structure traditionally believed to be the house of the Virgin, brought from Nazareth by flying angels (Santarelli 2014, 1999). The façade is constructed of Istrian stone and is divided into three sections by pairs of pillars (Fig. 1a). The HS images used in this study were acquired on the base of one of these pillar pairs, specifically the third from the left (Fig. 1b), which exhibits several forms of decay, the most evident being cracks and incoherent patching with cement mortar.

Figure 1 – The façade of the Basilica of the Holy House of Loreto (left) and the selected stone base chosen for analysis (right)

HS images acquisition was performed using a Cubert ULTRIS X20 Plus camera (Cubert n.d.), featuring 164 spectral bands with a spectral sampling of 4 nm over a range from 350 to 1000 nm, thus covering part of the UV-A region as well as the entire visible and near-infrared (NIR) spectrum. Owing to the integration of a panchromatic camera, the instrument enables a pansharpening procedure that upscales the spectral images from a spatial resolution of 410 × 410 px to 1886 × 1886 px, allowing the capture of sub-millimetre details.

Since HS acquisition requires stable radiometric conditions and thus consistent illumination, measurements were conducted on a clear-sky day when direct sunlight did not strike the façade in order to avoid cast shadows and localised dark areas.

Images were acquired at close range to ensure high spatial definition. The HS camera was positioned at a distance of 155 cm from the selected area and moved horizontally on a line by 50 cm between successive acquisitions. Vertically, the acquisition started from a height of 70 cm and proceeded upward (120, 170 cm), resulting in a total of 24 HS images.

Prior to acquisition, the camera was calibrated through white, dark, and distance calibration procedures (Shaikh et al. 2021; Hugemann 2010; Del Pozo et al. 2017). White calibration consisted of acquiring a full-frame image of a 50 × 50 cm reference panel with 99% reflectance, used to convert the arbitrary digital numbers recorded by the instrument into reflectance values. Dark calibration accounts for the dark current noise internally generated by the sensor and was performed by covering the camera lenses. Finally, distance calibration corrects the parallax effect caused by the multi-array configuration of the instrument. This procedure was carried out using an asymmetric checkerboard panel, whose black–white intersections are detected by an integrated image registration algorithm to spatially align the images recorded by the different lenses.

The acquisition setup is pictured in Figure 2.

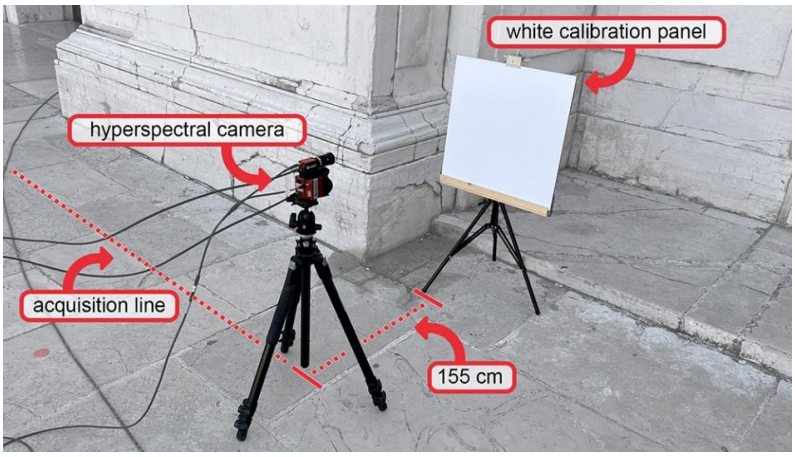

Figure 2 – Hyperspectral images acquisition setup

3. Materials and methods

3.1 Method overview

The present chapter is devoted to the description of the procedures underlying the proposed method for classifying decay phenomena within the collected HS image dataset. This subsection, in particular, provides an overview of the methodological framework, which is described in detail in the following subsections (Fig. 3).

The first step (*Section 3.2*) involves image preprocessing through a statistical technique, namely Independent Component Analysis (ICA), aimed at reducing data complexity and enhancing relevant features associated with macro-scale decay patterns. The second step (*Section 3.3*) consists of identifying the macro-area to be analysed in greater detail through a DL approach based on a Convolutional Neural Network (CNN). Subsequently (*Section 3.4*), the selected area is further investigated using a supervised ML procedure, specifically a Random Forest (RF) classifier. Finally (*Section 3.5*), the resulting image-based outputs are converted into dimensional data by exploiting the Ground Sampling Distance (GSD), thereby providing a practical tool to support professionals in the quantitative assessment of detailed decay areas.

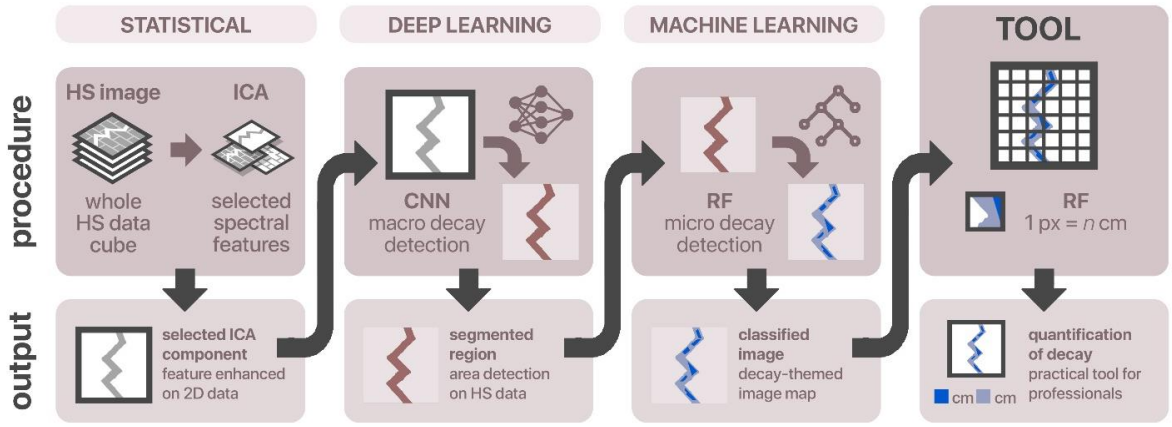

Figure 3 – Schematic overview of the proposed methodology for decay detection

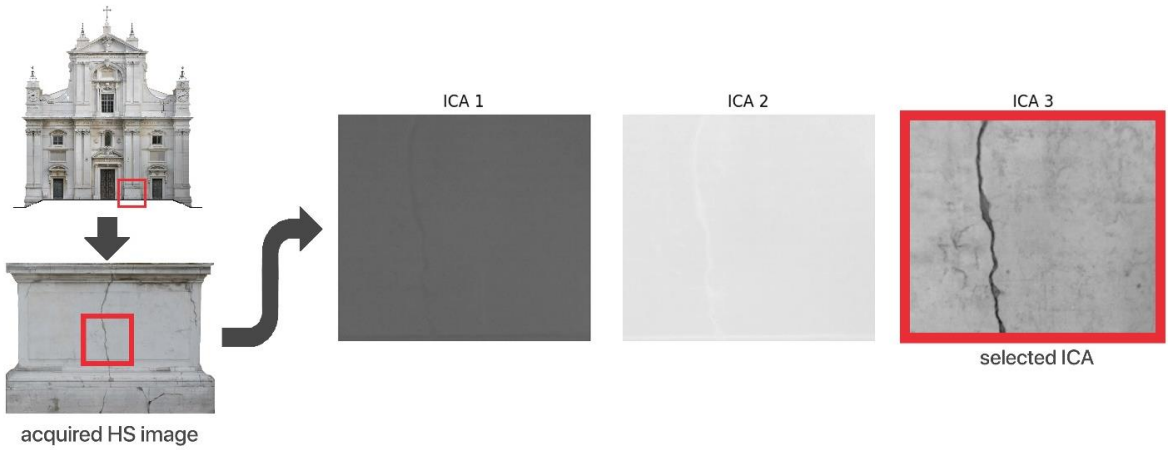
3.2 Preprocessing: dimensionality reduction

HS imaging data are intrinsically information-rich, as each pixel is represented by a reflectance value for every wavelength recorded by the sensor (164 spectral bands in the present case). Consequently, each pixel can be interpreted as a high-dimensional vector in spectral space. While this constitutes a valuable source of information, it also results in a high-dimensional dataset characterised by strong inter-band correlation and substantial redundancy. Such characteristics increase computational burden and may hinder classification performance, even when advanced AI-based methods are employed (Donoho 2000; Pei, Huang, and Zhou 2023). Therefore, a preliminary dimensionality reduction step is typically required, either through projection onto a reduced set of components or through the selection of the most informative transformed features.



In HS analysis, widely adopted mathematical approaches for dimensionality reduction include Principal Component Analysis (PCA) and ICA (Kuras et al. 2021; Kale et al. 2017). Both methods treat each pixel as a spectral vector and aim to transform the original correlated space into a more compact representation. PCA identifies orthogonal directions (*principal components*) along which the variance of the data is maximised. By projecting the data onto these directions, PCA removes linear correlation between spectral bands while preserving most of the overall variance. The resulting components are uncorrelated linear combinations of the original bands (Kale et al. 2017; Greenacre et al. 2022). ICA, by contrast, seeks statistically independent and non-Gaussian components under the assumption of linear mixing. Rather than merely decorrelating the data, ICA attempts to separate the observed signals into underlying independent sources (Kale et al. 2017; Naik and Kumar 2011). Consequently, ICA may provide a representation that is more interpretable when the spectral signal arises from the combination of distinct physical or material contributions.

In the present study, ICA was applied to HS images with the aim of distinguishing macro-scale decay areas from non-degraded regions. The algorithm was used to extract three independent components, corresponding to statistically independent spectral sources. These components were subsequently reshaped into 2D spatial maps, i.e., grayscale images where each pixel represents the intensity of the corresponding component, highlighting areas where it is most discriminative (Fig. 4). Prior to ICA execution, a normalisation step was performed to minimise the influence of varying illumination conditions. Among them, the component exhibiting the highest spatial contrast between degraded and non-degraded areas was selected as input for the subsequent stage (*Section 3.3*). This choice was guided by interpretability and spatial discriminative capability rather than by purely statistical criteria. The adoption of a single ICA-derived image enabled a

substantial reduction of spectral dimensionality while preserving the spatial patterns most relevant for macro-scale degradation segmentation.

Figure 4 –ICA-elaborated images extracted from one of the acquired hyperspectral images

3.3 Where? Macro-scale decay detection

ICA preprocessing allowed for data simplification and the separation of the acquired image into a 2D map of altered and non-altered areas. The next step involves defining a method for the automatic identification of these macroareas, without human intervention. CNNs are DL-based tools commonly employed for this purpose, performing image segmentation by extracting hierarchical features and comparing them with a labeled training set to classify image regions (Courville, Goodfellow, and Bengio 2016).

For this study, a pre-trained U-Net for crack detection was selected for macro-decay identification due to its ability to preserve fine details through its encoder-decoder architecture (Jiangtao, Ruhaiyem, and Panpan 2025). Applied to the ICA-processed 2D image, the U-Net enabled the automatic spatial segmentation of the macro-altered area (Fig. 5), providing spatial context on which to perform the subsequen step (*Section 3.4*).

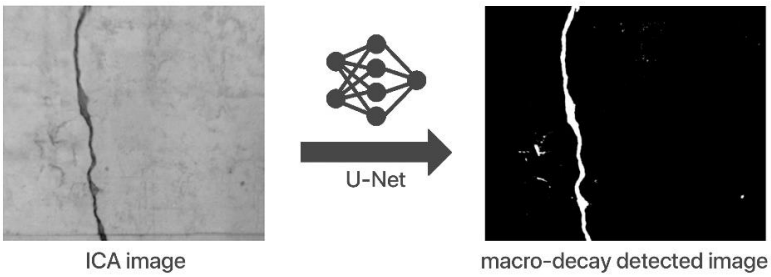


Figure 5 –Segmented area of macro-decay detected by the U-Net on the ICA-elaborated image

3.4 What? Supervised classification of micro-scale decay

The previous section enabled the identification of the area for detailed classification of smaller-scale decay on the original HS images. This step was useful to limit the investigation to a well-defined region, reducing computational effort while providing more precise information regarding the location and type of decay.

Decay classification within the detected area was performed using a supervised ML algorithm. In particular, RF was chosen due to its simplicity, low computational requirements, and robustness with small datasets. In RF, the training dataset (in this case, HS pixels) is split into subsets that are randomly assigned to individual decision trees. Each tree casts a vote for the classification, and the final category is determined by majority vote (Ilehag et al. 2017).

For this purpose, a representative HS image of micro-decay (incoherent patching with cement mortar inside cracks) was selected, and ROIs were labeled as "patch" or "crack" (unpatched areas). This labeled dataset of HS pixels was then used for training the classifier, whose results and performance are described in *Section 4*.

3.5 How much? Quantification of decay

Up to this point, the procedure allowed for the automatic detection and classification of decay, but its quantification remains challenging. Raw HS images lack an intrinsic scale, and irregularly shaped areas are not easily measurable without approximation. However, since the HS camera functions like a standard camera with additional spectral channels, it is possible to compute the real-world dimensions of the detected regions using the GDS.

GSD is a common concept in remote sensing that defines the actual size of a single pixel in metres (Felipe-García, Hernández-López, and Lerma 2012). For a camera with a given Field Of View (FOV) and a known distance (D) from an object, the physical size of the scene along one axis can be estimated as (Eq. 1):

$$\text{Scene size} = 2 \cdot D \cdot \tan(\frac{FOV}{2}) \quad (1)$$

The GSD, i.e., the real-world size of a single pixel, is then obtained by dividing the scene size by the number of pixels (N_{pixels}) along that axis (Eq. 2) and finally, the area of a given decay type can be calculated by multiplying the number of pixels in the corresponding mask ($N_{pixels,mask}$) by the area of a single pixel given by its GDS on the x and y directions (Eq. 3):

$$\text{GDS} = \frac{GDS}{N_{pixels}} \quad (2)$$

$$\text{Decay area} = N_{pixels,mask} \cdot GDS_x \cdot GDS_y \quad (3)$$

This approach allows for the quantification of micro-decay regions in real-world units, providing a reliable estimate of the altered surface.

4. Results

The application of the proposed workflow to the collected dataset produced results consistent with those shown in Fig. 6. Macro-scale decay features (major cracks) were successfully detected in the HS images, and micro-scale decay patterns (incoherent cement mortar patches) were accurately classified. In addition to the segmented images, a legend reporting the identified decay forms and their quantitative measurements was generated.

The RF model, trained on a representative image including both forms of decay, was subsequently tested on the remaining 23 acquired images after masking the macro-scale areas of interest using the U-Net. When compared with ground truth decay masks, the model achieved accuracy values up to 74% for the detection of cracks and 83% for patches under favourable illumination conditions.

However, this performance was primarily observed in the central portion of the stone base, where illumination was relatively uniform. In the upper and lower areas, classification performance heavily decreased (Fig. 7).

In these regions, the presence of mouldings introduces variations in illumination, resulting in cast shadows, which, although limited in intensity, negatively affect both macro-scale detection through the U-Net and the subsequent micro-scale classification. Although HS acquisitions were conducted under carefully controlled lighting conditions and a normalisation step was applied prior to ICA processing to mitigate illumination variability, residual lighting heterogeneity influenced the final classification results.

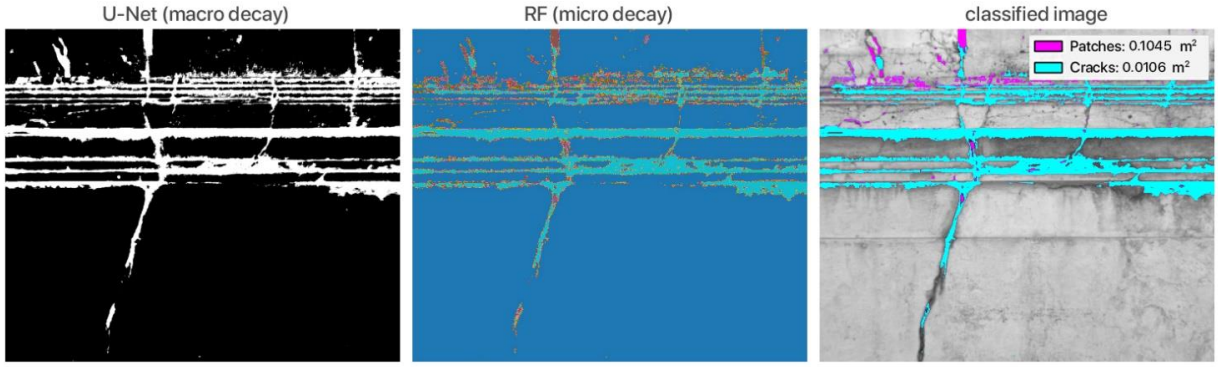

Figure 7 – Macro-scale decay classification using the U-Net, micro-scale classification using the RF classifier, and final classified image including quantitative measurement of decay areas on an image affected by shadows

5. Conclusion

Effective monitoring strategies, both in terms of accuracy and time-efficiency, are of paramount importance to guarantee the early detection of criticalities on built heritage surfaces, thus enabling timely interventions and the avoidance of invasive and costly operations. In this perspective, AI-based automated pipelines for the classification of heritage surface images are currently a hot topic in the literature. Within this context, the application of these pipelines to advanced imagery, such as HS imaging data, is of great interest and is currently under development.

This study aimed to contribute to this field of research by proposing a hierachical methodological framework that combines different approaches: prior statistical pre-processing through ICA, the identification of macro-decay areas through a U-Net segmentation and the detailed classification of alterations within these areas using supervised RF classification. The proposed workflow also includes a method for the metric quantification of the classified surfaces exploiting the concept of GDS, thus providing professionals with a tool capable of

quantifying the extent of alterations, useful when such measurements are required for restoration material estimation or administrative documentation.

Although the first results are promising, they remain moderate, and the procedure shows limitations when dealing with noisy datasets or suboptimal illumination conditions, which is a critical issue widely reported in the literature, particularly for on-field applications (Themistocleous et al. 2020; Hemmleb et al. 2006; McCoy 2005). Future work could evaluate the impact of different solar angles on classification accuracy and investigate whether preliminary surface cleaning, such as dust removal, reduces light scattering. Additionally, approaches to enhance illumination conditions through the use of supportive artificial lighting could be explored. However, implementing lighting conditions in the field presents significant logistical challenges, including complex architectural and urban contexts that hinder the acquisition setup, or the portability of heavy equipment. Furthermore, specific lamp types like halogen sources, which are essential for collecting reliable HS imaging data due to their continuous spectrum, are increasingly difficult to source, as they have been largely phased out of the market due to energy efficiency regulations.

Moreover, since the present study aimed primarily at proposing a methodological framework rather than achieving a perfect solution, the experimental dataset was very limited, constrained to only two types of decay (cracks and patches) on a single material (Istrian stone). Future studies should expand this framework to a broader range of material and degradation patterns. Indeed comprehensive material and decay spectral libraries of heritage surfaces are currently lacking and are required and need to enhance models' generalisaiton (Zahiri et al. 2022). Additionally, U-Net performance was limited in detecting cracks, but procedures focusing on the identification of different macro-decay types (e.g., stains) could be explored.

Despite these limitations, the present study represents a valuable contribution towards the automatic classification of decay on heritage surfaces through HS imaging.

Acknowledgments

The authors would like to express their gratitude to the Superintendence for Archaeology, Fine Arts and Landscape for the Provinces of Ancona and Pesaro e Urbino and to the Pontifical Sanctuary of the Holy House of Loreto for their valuable cooperation and for providing access for data collection. This research received no external funding.

Pathological Manifestations in Residential Construction: Warranty Assessment in Fortaleza – CE.

Allefy Teles SAMPAIO[1], Willlames DE ALBUQUERQUE[2], Eliana BARRETO[3]

[1] Universidade de Pernambuco, Recife, Brasil, ats1@poli.br
[2] Universidade de Pernambuco, Recife, Brasil, was@poli.br2
[3] Universidade de Pernambuco / Universidade Católica de Pernambuco, Recife, Brasil, eliana@poli.brl3

Abstract: This article analyzes the pathological manifestations identified in a vertical condominium development located in Fortaleza, Ceará, focusing on the technical assessment of construction warranty periods and conditions. The methodology employed is based on systematic building inspection, the application of non-destructive testing, and documentary analysis of design drawings and owner's manuals, with ABNT NBR 16747:2020 as the central normative support. The results highlight the prevalence of cracks in ribbed slabs, infiltration in basements, and failures in anchoring systems, raising the technical-legal debate between construction defects and loss of warranty due to absence of preventive maintenance. The climatic context of Fortaleza — bioclimatic zone 8, high humidity, and coastal environmental aggressiveness — is identified as a factor that accelerates the progression of pathologies. The conclusion points to the need for systematized inspection protocols and greater rigor in construction site supervision as instruments for prevention and mitigation of damage.

Keywords: Building pathology; Building inspection; Construction warranty; Pathological manifestations.

1. Introduction

Brazilian residential housing production in recent decades has been marked by cycles of accelerated expansion, driven by federal financing programs and by the growth in demand for vertical condominium units in major urban centers. This intense pace of production, often associated with compressed timelines and the adoption of lower-cost construction solutions, created favorable conditions for the early emergence of pathological manifestations in buildings delivered to the market. Recent studies have demonstrated that the incidence of anomalies in residential buildings in Brazil is high and that much of these occurrences originate from verifiable failures in the design and execution phases (Bauer; Pavon; Oliveira, 2019).

The relevance of this topic transcends the technical dimension and reaches the legal field, since Brazilian law — through the Civil Code (art. 618) and the Consumer Protection Code — imposes objective liability on construction companies and developers for the soundness, safety, and habitability of delivered works. The interface between these legal provisions and the technical criteria established by ABNT NBR 15575:2013 — Performance Standard for Residential Buildings — configures a field of permanent tension between the interests of users and those of construction companies, making the technical assessment of warranties an instrument of growing importance in the context of national diagnostic engineering (Pujadas; Oliveira; Neto, 2021).

In this scenario, building inspection emerges as a central methodology for the identification, classification, and diagnosis of pathological manifestations, allowing the technical distinction between construction defects — for which the builder is responsible — and deterioration resulting from the absence of preventive maintenance — for which the user or the condominium is responsible. This distinction, apparently simple in its conceptual formulation, proves to be complex in practice, requiring the qualified

professional to master rigorous investigation methods and possess in-depth knowledge of the degradation mechanisms of construction systems (Bauer; Pavon; Oliveira, 2019).

Fortaleza, capital of the state of Ceará, presents climatic characteristics that confer singularity to the behavior of buildings in its territory and that justify the conduct of specific studies on building pathology in this context. The city is located in bioclimatic zone 8, according to ABNT NBR 15220:2005, being marked by average annual temperatures exceeding 26°C, average relative air humidity around 78%, intense solar radiation, and a rainfall regime concentrated in the first half of the year. These climatic factors act synergistically as potentiating agents of pathological manifestations, especially those related to moisture, concrete carbonation, and degradation of waterproofing systems (Silva; Brito; Gaspar, 2020).

The environmental aggressiveness of the northeastern coast, characterized by high concentration of chloride ions in the marine atmosphere, represents an additional risk factor for the durability of reinforced concrete structures. The penetration of chlorides through concrete, accelerated by the presence of cracks and by the low quality of rebar coverage, triggers electrochemical corrosion processes that compromise the structural integrity of buildings within periods shorter than the service life established by current technical standards (Medeiros; Helene; Grochoski, 2021). This situation is aggravated by the combination of high temperature and high relative humidity, conditions that intensify the deterioration reactions of concrete and coating materials (Carasek; Cascudo; Scartezini, 2019).

Given this context, the present work aims to identify and analyze the pathological manifestations present in a vertical condominium development in Fortaleza-CE, evaluating their origin, degree of risk, and classification within the warranty periods established by applicable legislation and technical standards. The research seeks to contribute to the advancement of knowledge on building pathology in the northeastern climatic context and to the improvement of building inspection processes as an instrument of asset management and conflict resolution within the scope of construction warranties.

2. Methodology

This research is configured as a case study of applied nature, with qualitative and quantitative approach, of descriptive and analytical character. The object of analysis is a vertical condominium development for residential use, located in the municipality of Fortaleza, Ceará, delivered less than five years before the inspection date. The development comprises multiple towers, with basement intended for parking, ground floor with common use areas, and typical floors with residential units.

The inspection constitutes the central method of this research, understood as the set of technical procedures intended for the assessment of the conditions of use, maintenance, and performance of a building, with a view to identifying anomalies, diagnosing their causes, and formulating technical recommendations. As highlighted by Bauer, Pavon, and Oliveira (2019), systematized building inspection represents a significant methodological advance over traditional inspections, as it incorporates objective criteria for risk classification and requires the responsible professional to adopt a multidisciplinary approach that integrates knowledge of structures, installations, coatings, and maintenance management.

The inspection process was structured in four sequential and interdependent stages. The first consisted of documentary research, with analysis of architectural, structural, hydrosanitary, and waterproofing projects, verification of the Owner's Manual and Common Areas Manual delivered by the construction company, and consultation of the work's Descriptive Memorial. Documentary analysis prior to field inspection is pointed out by Pujadas, Oliveira, and Neto (2021) as an indispensable stage for the correct interpretation of identified anomalies, as it allows comparison between what was executed and what was designed, and identification of conformity deviations that might otherwise be erroneously attributed to use or maintenance.

The second stage corresponded to systematic visual inspection, conducted by a qualified civil engineer in all common areas of the development — basement, ground floor, roofs, facades, and circulation areas — with standardized photographic recording of all identified anomalies. Visual inspection, although it is the

primary method for diagnosing anomalies, should be complemented by specific tests when the complexity or severity of anomalies so requires (Carasek; Cascudo; Scartezini, 2019). This complementation was carried out in the third stage, dedicated to the application of non-destructive testing (NDT), which included: percussion with rubber hammer to identify detachment in ceramic and mortar coatings; surface moisture measurement with digital hygrometer; thermographic analysis by infrared camera for mapping of hidden infiltrations; and measurement of crack opening with fissurometer and graduated magnifying glass. Infrared thermography, in particular, has been highlighted by recent literature as a highly effective tool in the diagnosis of hidden infiltrations and coating detachment on facades, allowing the identification of anomalies not visible to the naked eye with precision and without destructive intervention in the building (Bauer; Pavon; Oliveira, 2019).

The fourth and final stage consisted of the classification and assessment of anomalies, conducted according to two complementary criteria. Regarding origin, pathological manifestations were classified as endogenous (design, materials, or execution), exogenous (external agents), or functional (inadequate use or absence of maintenance), following the taxonomy widely adopted in national technical literature (Pujadas; Oliveira; Neto, 2021). Regarding the degree of risk, anomalies were classified as critical, regular, or minimal, based on the assessment of the potential for damage to safety, habitability, and functionality of the building. This dual classification is fundamental for warranty assessment, as it allows identification, with objective technical basis, of which manifestations constitute construction defects for which the builder is responsible and which result from maintenance failures attributable to the condominium (Medeiros; Helene; Grochoski, 2021).

It is pertinent to note that the adopted methodology is in compliance with ABNT NBR 16747:2020 — Building Inspection: Guidelines, Concepts, Terminology, and Procedure — a standard that, by systematizing building inspection procedures in Brazil, consolidated the state of the art of methodological practices developed and discussed by the national technical-scientific community over the last decade.

3. Results and Discussion

The building inspection conducted in the condominium development that is the object of this study resulted in the identification of an expressive set of pathological manifestations distributed across different construction systems and areas of the building. The anomalies were grouped into four main categories: manifestations in reinforced concrete structures; infiltrations and waterproofing failures; anomalies in anchoring and fastening systems; and manifestations in coatings and sealing systems. This distribution pattern is consistent with the incidence profile reported by recent studies on anomalies in Brazilian residential buildings, in which manifestations related to moisture and structural cracking consistently rank among the most frequent and have the greatest impact on the quality of use and durability of buildings (Carasek; Cascudo; Scartezini, 2019; Silva; Brito; Gaspar, 2020).

The pathological manifestation of greatest recurrence and severity identified in the development was the presence of cracks in ribbed slabs, located predominantly in the basement — parking area — and in the roof slabs. The measured openings ranged between 0.2 mm and 1.8 mm, with numerous occurrences exceeding the control limits established by ABNT NBR 6118:2014 for structures in environmental aggressiveness class II. Cracking in reinforced concrete structures can originate from multiple mechanisms, including plastic and drying shrinkage, excessive loads, differential settlement of foundations, dimensioning errors, and execution failures in reinforcement placement (Medeiros; Helene; Grochoski, 2021).

In the case under analysis, the distribution pattern of cracks, predominantly in regions of rib support and with orientation transverse to the main ribs, is indicative of bending stresses higher than those foreseen in the design or of insufficient reinforcement in the region of negative moments, suggesting possible execution error in the assembly of the reinforcement. This type of anomaly is classified by Bauer, Pavon, and Oliveira (2019) as of endogenous origin, with cause in the execution phase, constituting a construction defect whose diagnosis should be based on the joint analysis of the cracking pattern, the geometric characteristics

of the structure, and the records of technological control of the concrete. In Figure 01, it is possible to visualize the cracks in the ribbed slab.

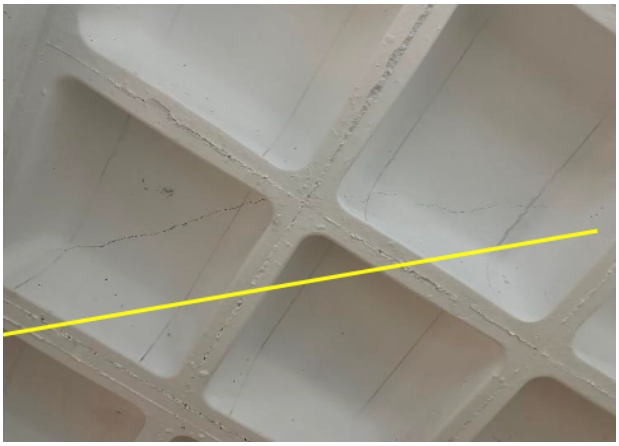

Figure 1 – Authors, 2026

The severity of this manifestation is potentiated by the climatic and environmental context of Fortaleza. Silva, Brito, and Gaspar (2020) demonstrated that the degradation rate of reinforced concrete structures in environments of high relative humidity and temperature is significantly higher than that observed in regions of temperate climate, due to the greater speed of carbonation reactions and the penetration of aggressive agents. On the northeastern coast, the combination of structural cracking with the high concentration of chlorides in the marine atmosphere creates particularly favorable conditions for the depassivation of steel and the development of electrochemical corrosion, compromising the service life of the structure within periods shorter than the design service life (Medeiros; Helene; Grochoski, 2021). This scenario reinforces the classification of these cracks as critical-degree anomalies, with potential for evolution toward compromise of the structural safety of the building.

Monitoring of fissures with fissurometers over thirty days revealed that approximately 60% of the identified cracks exhibited active behavior, with measurable variation in opening throughout the observation period. The distinction between active and passive fissures is methodologically relevant for warranty assessment, as active fissures indicate that the degradation process is ongoing, which, associated with the distribution pattern described, points to a construction defect originating in the execution phase. According to Pujadas, Oliveira, and Neto (2021), the activity of a fissure is one of the central technical criteria for the classification of risk degree and for the definition of responsibilities within the scope of construction warranties, since active fissures in reinforced concrete structures rarely originate exclusively from absence of maintenance, being, in most cases, a symptom of design or execution failure.

Infiltrations constituted the second category of greatest incidence in the development, with occurrences recorded in the basement, in the roof slabs, and in the interfaces between different construction systems. Carasek, Cascudo, and Scartezini (2019) identified, in a survey on pathological manifestations in Brazilian residential buildings, that manifestations related to moisture represent the largest portion of pathological occurrences in buildings, being responsible for significant secondary damage to coatings, electrical installations, and structures, in addition to direct impact on the quality of life of users.

In the basement of the development, infiltrations of groundwater through the retaining walls and floor slab were identified, with formation of efflorescence, moisture stains, and, in some points, emergence of free water. This situation is indicative of failure in the waterproofing system of the buried structures, either due to absence of adequate waterproofing or due to failure in the execution of the system specified in the design. Analysis of the waterproofing designs revealed that the specified system was technically compatible with normative requirements; however, visual inspection indicated failures in execution, particularly at the interfaces between the floor slab and the retaining walls, regions of greatest vulnerability in basement

waterproofing systems (Silva; Brito; Gaspar, 2020). In Figure 2 it is possible to identify points of soiling, caused by the presence of water.

Figure 3 – Authors, 2026

Infiltrations in the basement piping deserve specific analysis, as they presented a distinct pattern from infiltrations due to waterproofing failure. Visual inspection and thermographic analysis revealed moisture concentrated in the regions of connection between piping and structure, suggesting failure in the sealing of pipe passages through the slab and retaining walls, an anomaly of endogenous origin, with cause in the execution phase, which constitutes a construction defect regardless of the time elapsed since the delivery of the development. In Figure 3, it is possible to identify points with failure of watertightness between slab and piping.

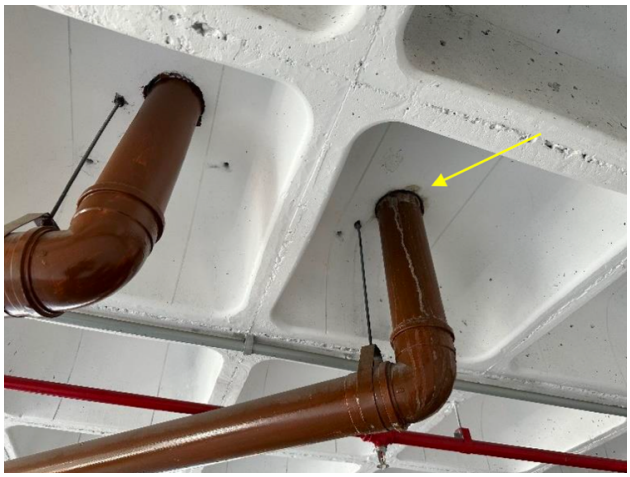

Figure 3 – Authors, 2026

Infiltrations in the roof slabs presented a distinct pattern, with moisture stains on the underside of the slabs and signs of deterioration of the waterproofing coating on the upper surface. The analysis of exposure conditions, flat slab with insufficient slope in some sections, forming ponding, and the condition of the waterproofing coating suggests the concurrence of design failure (inadequate slope) and absence of periodic maintenance of the waterproofing system. This situation exemplifies the complexity of warranty assessment in buildings, in which responsibility may be shared between the builder and the condominium, requiring individualized analysis of each manifestation for the correct attribution of responsibilities (Pujadas; Oliveira; Neto, 2021).

In this sense, it is fundamental to consider that ABNT NBR 5674:2012 establishes minimum periodicities for the maintenance of waterproofing systems, and that the absence of records of preventive maintenance by the condominium may constitute partial loss of warranty. However, as warned by Medeiros, Helene, and Grochoski (2021), the absence of maintenance does not exempt the builder from responsibility when the pathological manifestation has proven origin in execution or design failure, being necessary the analysis of the causal nexus for the correct attribution of responsibilities in each concrete case.

One of the pathological manifestations of greatest technical severity identified in the inspection was the presence of a non-standardized anchoring system in a structural element of the basement, executed with untreated steel rebar, without adequate anchor bolt and without any conformity with design specifications or applicable technical standards. This anomaly represents a serious deviation from good construction practices, constituting potential risk to the structural safety of the building and, consequently, to the physical integrity of the users. In Figure 4, it is possible to visualize the anchoring system executed.

Figure 4 – Authors, 2026

The use of steel rebar as an anchoring element, without structural dimensioning, without corrosion protection, and without conformity with applicable normative prescriptions, is classified as a critical-degree anomaly, in the technical sense of the term, by combining two simultaneous risk factors: the mechanical inadequacy of the element — not dimensioned for the stresses to which it is subjected — and vulnerability to corrosion accelerated by the basement environment, characterized by high humidity and, in the coastal context of Fortaleza, by potential presence of chlorides in groundwater (Carasek; Cascudo; Scartezini, 2019). Bauer, Pavon, and Oliveira (2019) emphasize that anomalies originating from execution failures that compromise the structural safety of the building fall into the category of serious redhibitory defects, for which the builder's responsibility subsists regardless of the user's maintenance conduct, since the defect originates prior to the delivery of the work.

The analysis of pathological manifestations identified in the development evidences the complexity of the technical-legal classification of responsibilities within the scope of construction warranties. The distinction between construction defect — for which the builder is responsible — and deterioration resulting from absence of preventive maintenance — for which the condominium is responsible — is, frequently, the central point of disputes between condominium residents and builders, and its resolution requires the engineer responsible for the inspection to master rigorous investigation methodologies and the ability to technically substantiate their conclusions (Pujadas; Oliveira; Neto, 2021).

ABNT NBR 15575:2013 introduced a significant advance in this debate by establishing, explicitly, that the design service life of construction systems is conditioned to the performance of preventive maintenance according to the minimum periodicities established and by the Manual of Use, Operation, and Maintenance of the building. However, Silva, Brito, and Gaspar (2020) demonstrated that the application of this principle

cannot be done mechanically, being necessary to verify, in each case, whether the pathological manifestation would have occurred even with regular performance of preventive maintenance. When the answer is affirmative — that is, when the anomaly has proven origin in design or execution failure — the builder's responsibility subsists, regardless of the user's conduct.

In the development that is the object of this study, the individualized analysis of each pathological manifestation, based on the causal nexus methodology, allowed the identification of three distinct categories of classification: manifestations of exclusive builder responsibility (active cracks in slabs, non-standardized anchoring system, infiltrations due to execution failure of basement waterproofing); manifestations of shared responsibility (roof infiltrations with concurrence of design failure and absence of maintenance); and manifestations of condominium responsibility (deterioration of coatings due to absence of cleaning and documented periodic maintenance). This tripartite categorization is consistent with the approach proposed by Medeiros, Helene, and Grochoski (2021), who recommend causal nexus analysis as a central methodological instrument in the assessment of responsibilities in building inspections, avoiding both undue imputation of responsibility to the builder and unjust transfer of burden to the condominium.

The climatic context of Fortaleza introduces an additional variable in this debate. Carasek, Cascudo, and Scartezini (2019) demonstrated that the conditions of high temperature, relative humidity, and environmental aggressiveness characteristic of the northeastern coast accelerate the degradation processes of construction systems, effectively reducing the service life of waterproofing systems, coatings, and concrete structures in relation to the reference values established by national technical standards, calibrated for average climatic conditions of Brazilian territory. This finding has direct implications for warranty assessment in Fortaleza, as it suggests that the periodicities of preventive maintenance established by standards and owner's manuals may be insufficient for the local climatic context, which, in turn, may constitute inadequacy of the product delivered to the use environment, responsibility that falls on the builder, not on the user.

4. Conclusion

The inspection identified critical anomalies, such as cracks in ribbed slabs, infiltrations in the basement, and anchoring systems outside normative standards. These failures are classified as construction defects for which the builder is responsible, as they compromise the structural safety and habitability of the condominium. In the case of roof infiltrations, responsibility is shared, requiring individualized expertise to determine the causal nexus of each occurrence.

The climate of Fortaleza, with high salinity and humidity, accelerates degradation, requiring that builders adapt designs and condominiums implement rigorous preventive maintenance plans. The absence of maintenance by the condominium manager does not exempt the builder from responsibility if the origin of the pathology is proven to be endogenous. It is recommended to strengthen quality control during execution and maintain detailed documentary records to substantiate technical decisions and prevent litigation.

Abstract: Ground Penetrating Radar is a non-destructive technique that involves emitting high-frequency electromagnetic waves that travels through a physical medium. Changes in the electromagnetic properties, voids or discontinuities produce reflections that allow the characterization of its internal structure. This technology is widely used for detecting buildings pathologies in both modern and historical built heritage. However, GPR inspection is usually performed manually. This makes the process time-consuming if large areas of a building need to be evaluated. Additionally, manual inspections are restricted to areas accessible by hand, which increase the difficulties in the inspection of the building's upper areas without easy external access.

In this work, a 3d tomographic reconstruction from internal and external GPR inspections of the upper part of the northern facade of the Torre de la Vela is presented. The area analysed is located 20 meters high above the ground and presents visible cracks and deterioration. The wall is made of rammed earth and brick masonry and an external area of 20 m^2 has been studied using a mounted GPR in a self-constructed cable driven robot, while the internal corresponding area has been analysed by manual inspections. Results reveal structural details, cracks depth as well as the level of deterioration that would be difficult to observe without the external inspection.

This case study shows the possibility of conducting complete, quick and efficient inspections in difficult access parts of facades with applications in both historical heritage and modern built structures without the need of installing additional structures such as scaffolding. During the inspection, the inspected façade has remained visible the entire time, allowing the visitors to access areas that might have been restricted using traditional inspection methods. Finally, this application highlights the capability of automated systems in architectural heritage inspection and validation of structural diagnosis.

Keywords: Built heritage; non-destructive testing (NDT); GPR; cable-driven robotic drone; rammed earth.

1. Introduction

The structural diagnosis of architectural heritage has increasingly relied on non-destructive testing (NDT) technologies capable of revealing internal features without compromising the integrity of historic materials. Among these methods, Ground Penetrating Radar (GPR) has emerged as one of the most versatile tools for investigating subsurface conditions due to its ability to detect anomalies such as voids, moisture, cracks,

inhomogeneities, and concealed architectural elements within masonry, stone, and composite historic structures.

GPR involves emitting high-frequency electromagnetic waves into the material being inspected. When these waves travel through the material and encounter material changes, discontinuities, voids, or inclusions, part of the energy is reflected due to changes in electromagnetic properties, allowing the internal structure to be characterized and visualized.

A GPR equipment usually has separate transmitting and receiving antennas operating in pulse-echo mode. The received signal is called a radargram and represents the reflections of the electromagnetic waves as they pass through the material. The radargram is a 2D false-color (B-Scan) representation where the X-axis shows the distance travelled by the antenna and the Y-axis the wave's propagation time through the material or structure. The colors indicate the intensity of the reflections, and any lines, patches, or hyperbolas that appear suggest objects, stratified materials, or anomalies. Generally, strong reflections have bright tones (white, if on a black/gray scale, or very dark); while weak reflections have intermediate tones, and areas without contrast are uniform.

Apart from two-dimensional (B-scan) GPR can provide three-dimensional (C-scan) reconstructions of structural components, allowing a more comprehensive understanding of the physical state of heritage assets. However, despite its proven diagnostic potential, the traditional implementation of GPR remains constrained by practical challenges inherent to build heritage: limited accessibility, fragile surfaces, steep vertical geometries, and safety risks for operators, particularly in elevated or deteriorated areas. [1, 2]

To overcome these limitations, recent research has focused on integrating GPR sensors into robotic and aerial platforms, enabling more systematic, safe, and efficient inspection strategies. Robotic ground systems equipped with GPR, such as omnidirectional platforms combining radar, impact-echo, and vision-based localization, have demonstrated considerable improvements in the speed, accuracy, and spatial consistency of subsurface data acquisition, [3, 4, 5]. These systems also support multimodal data fusion, enabling the correlation of mechanical and electromagnetic indicators of structural health for enhanced decision-making.

A major technological breakthrough has been the integration of GPR into unmanned aerial systems (UAS), enabling airborne, non-contact inspection of vertical and overhead surfaces. Drone-mounted GPR addresses key challenges encountered in heritage environments, notably accessibility and operator safety, by acquiring radar data without physical contact with sensitive surfaces. Although operating GPR in non-contact mode introduces complexities, such as increased signal attenuation and geometric distortion, recent experimental studies employing microwave tomography (MWT) based inverse scattering techniques have demonstrated that contactless UAS-GPR can achieve imaging performance comparable to traditional ground-coupled surveys when properly processed [6].

Hybrid robotic-aerial systems further expand the operational possibilities of GPR in heritage conservation. Platforms such as EASEEbot, which combine free-flight remote sensing with wall-climbing capabilities, allow drones to alternately collect thermal, RGB, and GPR data by transitioning between aerial and contact modes. These systems contribute to the creation of digitally enriched 3D models or digital twins integrating surface and subsurface information to support comprehensive envelope diagnostics. Although originally designed for energy-efficiency assessment, the underlying technology directly translates to the needs of cultural heritage, where multi-sensor integration and precise spatial mapping offer substantial advantages for conservation planning [7].

Advances in electromagnetic modelling and GPR data processing have been crucial to enabling these robotic and drone-based approaches. Developments in linear inverse scattering, clutter mitigation, signal enhancement, and tomographic reconstruction provide the mathematical foundation required to interpret data collected under non-ideal conditions where antenna motion, distance variation, and material heterogeneity introduce significant noise. Such algorithms are essential for analysing complex masonry structures typical of historic buildings, particularly when using mobile platforms that record radar signals

from varying geometries and offsets. Additional refinement through adaptive filtering, edge detection, and thresholding has achieved high accuracy in detecting voids and defects in ancient walls and composite masonry, including large-scale field applications such as the Ming Great Wall [8, 9].

Taken together, these developments illustrate a field undergoing rapid transformation. The integration of GPR into robotic and aerial systems offers a new paradigm for heritage diagnosis, enabling safer, faster, and more comprehensive inspection of culturally significant structures. As research continues to advance in platform design, sensor miniaturization, and inverse modelling, robotic and UAS-based GPR methods are poised to become central tools for preventive conservation, structural monitoring, and long-term documentation of built heritage.

This paper presents a case study inspection carried out using a cable-driven robot, of a section of the Vela tower's external wall located 20 meters high. Section 2 describes the cable-driven robot and the used GPR device. In section 3 the description of the campaign and the experimental setup are presented. Results are shown in section 4 and finally, several conclusions are presented related with this work. This advancement confirms the feasibility of using GPR-equipped robotic to inspect historic walls, façades, and other vertical elements where ground access is restricted

2. The cable-driven robot

For the external façade inspection, a cable-driven robot has been specifically designed and constructed for the automated inspection of large planar structures such as historic masonry facades as is the case of the Torre de la Vela in La Alhambra (Granada). This system allows precise, repetitive and reproducible positioning, an essential requirement for surface GPR inspection.

The Proceq GP8800 equipment, shown in Figure 1, was used in the inspections carried out at the Alhambra. The main advantage of this model is its portability, since its antenna is wireless and the control and processing equipment is located on a tablet (iPad). Furthermore, its weight, including the battery, of less than 800 grams facilitates its integration into robotic applications. This GPR emits an electromagnetic signal in a continuous frequency range between 400 and 6000 MHz, which allows for high-resolution imaging, but has the drawback of a limited penetration depth, approximately 65 cm, depending on the material.

Figure 1 – Proceq GP8800 used in the inspections

The primary objective of the robot is to enable a controlled movement of the frame along the surface of the building. The motion is constrained to a single plane, allowing the system to operate within a two-dimensional workspace. The mechanical part of the robot is composed by a rigid frame suspended by two

cables, and using pulleys as shown in Figure 2 (left). The positioning system is controlled using an Arduino microcontroller, two stepper motors with its transmission components and its control electronics.

Figure 2 – Cable-driven robot deployment in the façade (left) and photograph of the frame carrying the GPR antenna (right).

To maintain stable contact with the façade, the mobile unit employs two propellers mounted parallel to the wall, generating thrust toward the surface. This approach mechanism ensures consistent coupling between the GPR device and the wall while compensating for external disturbances such as wind. Figure 3 shows details of the real-time inspection of the exterior façade.

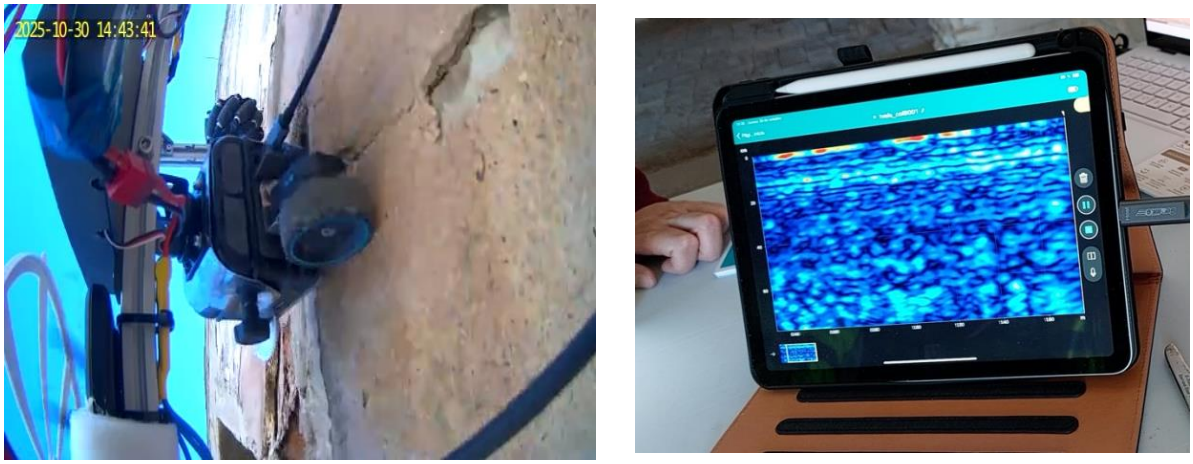

Figure 3 – Real-time inspection of the façade of the Vela tower using the cable-driven robot and the corresponding result shown in a tablet

3. Experimental campaign. Torre de la Vela. La Alhambra (Granada)

The GPR inspections in La Torre de la Vela correspond to the experimental campaign carried out in October 2025. The participating entities are: CSIC (Spanish Research Council) and, UPM (Technical University of Madrid). The central zone of the north façade has been inspected, both the interior and the exterior.

In the Torre de la Vela only the central part, internal and external, has been inspected. The external zone is 20m high from the floor and has been inspected by the cable driven robot. An important aspect for this inspection methodology is that, thanks to the incorporation of the robot, it is not necessary to install external elements as scaffolding. These elements do not allow the complete vision of the monument by the visitors. In this way, the inspections have been carried out to study the state of the monument, while at the same time, the visitor can observe it completely, without any kind of visual obstacle.

3.1 Torre de la Vela. Exterior assessment.

The exterior wall has been assessed using the cable-driven robot. Figure 4 presents the setup used for this inspection. The photograph on the left shows the Torre de la Vela with superimposed elements. Robot, marked in yellow, is suspended by two cables. The two motors that control the movement of the system are located inside the window. Outside, specifically on both sides of the roof, are the set of pulleys, that transmits the tension produced by the motors to the frame, allowing robot's positioning. Inside the tower, near the window, are the operators. It is necessary to both, monitor the robot's positioning, and manage the GPR data received from the inspection in real time.

Finally, since the robot's positioning is not visible to the operator inside, it was necessary to install two cameras, both using WiFi communication, which are essential for the proper operation of the robot. The first is an onboard camera, located in the frame that allows real-time visualization of the GPR, particularly its contact with the inspected wall. The second, located at the base of the tower, allows real-time visualization of the frame position on the facade. This is achieved by using the corrected image to generate an orthophoto overlaid with a mesh that, after initial calibration, indicates the robot's intended position and trajectory, Figure 4.

The inspected exterior area is located at 20 meters high and presents visible cracks and deterioration. The wall is made of rammed earth and, in some areas, brick masonry and the inspected area is 20 m^2.

Figure 4b shows the inspected exterior area, overlaid with a mesh for identifying the vertical lines. For the external measurements, the GPR has been installed on the cable-driven robot described in section 2. In this case, lineal inspections were taken every 25 cm, from vertical references 4 to 10 and from 14 to 21. Vertical lines start at A and ends at H.

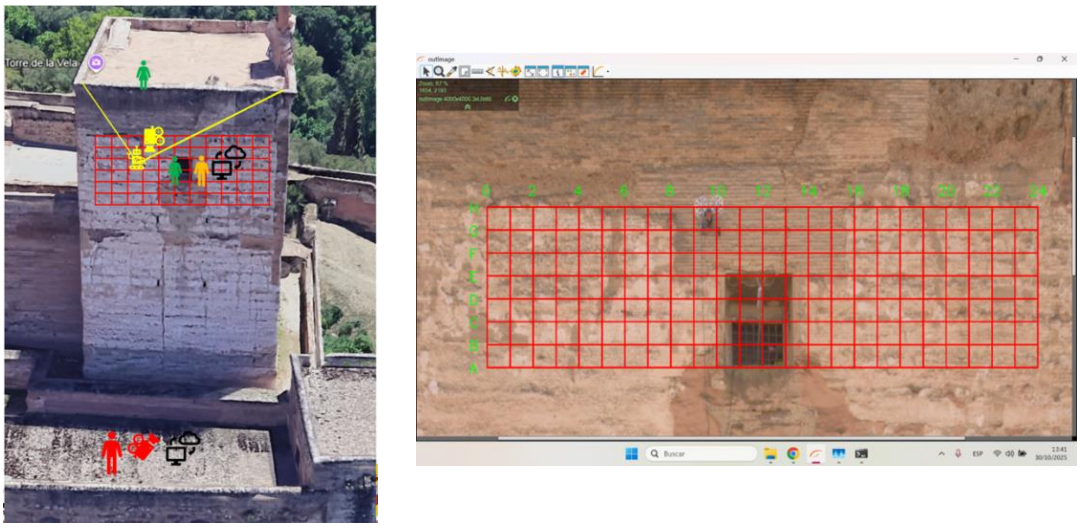

Figure 4 – Vela tower. Inspection setup

3.2 Torre de la Vela. Interior assessment

The interior area, which is accessible, has been manually inspected. The explores areas are located at left and the right of the window. The area at the right of the window is 5x2.8 m, and the area at the left is 2x3.6 m, in both cases an area inspection has been carried out each 10cm, both horizontal and vertical, Figure 5.

Figure 5 – Vela tower. Internal view of the inspected area

4. Experimental results

This section shows some of the most relevant results that were obtained during inspections. Between the selected results are the images that show the different types of material (bricks, rammed earth), cracks or holes and internal elements of high reflectivity.

4.1 External inspection

The exterior area was inspected using a cable-guided robot tracing vertical line. As shown in Figure 4, a grid was defined to reference the position. Each square represents approximately 0.5 meters. Two vertical radargrams were taken per grid in two zones. The first zone is located to the left of the window, between vertical references 6 and 9, while the second zone is located to the right of the window, between vertical references 14 and 21.

Figure 6 shows two vertical radargrams located at references 8.5 and 14. The path of the radargrams has been carried out from bottom to top and are represented by red arrows superimposed on the high-resolution image generated by a point cloud.

The radargram on the left corresponds to the vertical path referenced as 8.5 (left of the window). The most notable feature of this image is the appearance of a high-reflectivity zone at a height of 2 meters, coinciding with the brick wall. These reflections occur at a depth of 50 cm, which likely corresponds to the interface zone between the masonry and the rammed earth wall.

The radargram on the right corresponds to the vertical path referenced as 14 (right of the window). Two aspects stand out in this image: first, the confirmation of the masonry depth on both sides of the window as approximately 50 cm; second, the appearance of reflections at heights of 30 and 90 cm. These reflections correspond to cracks present in the wall, and their depth can be observed to be greater than 70 cm.

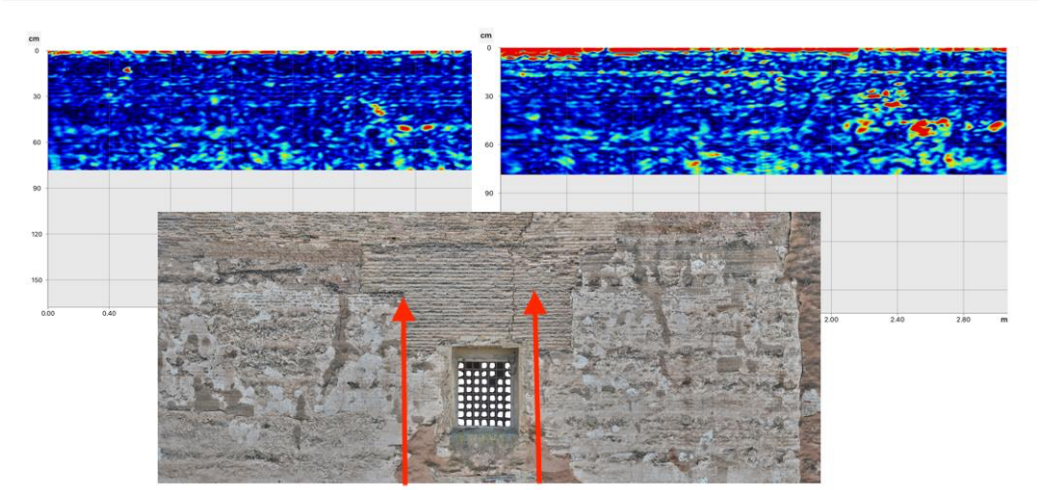

Figure 6 – Vela tower. External radargrams to the left and right of the window. Superimposed to the image are the corresponding red lines of the inspections

4.2 Internal inspection

The inspection of the interior area is a manual area inspection. The inspected portion of the wall is shown in Figure 7. It has been divided into six zones. The three lower zones extend from 20 cm to 1.80 meters in height. The first of these is located to the left of the window, while the remaining two are to the right. The three upper zones extend the inspected area by an additional 1 meter in height, from 1.80 to 2.60 meters. In terms of width, the zones to the left of the window are 2 meters wide, and those to the right are 2.40 and 2 meters wide, respectively.

The most significant results in this inspection were those from the upper zones, with similar results obtained in all three areas. Figure 5 shows, for example, the area near the top right of the window, marked with a red

rectangle. The C-Scan integrates reflectivity between 53 and 67 cm deep. From this, the presence of two materials with different densities and compaction can be deduced. Furthermore, they are separated at a height that coincides with the position of the wooden beam. The same phenomenon can be observed in the inspections of the other zones. The figure also includes two radargrams corresponding to vertical trace 4 and horizontal trace 37.

The vertical trace shows reflections at depths of 20 to 30 cm, indicating the presence of layers of rammed earth from the interior, likely added during a restoration after the original construction. The horizontal trace shows reflections at 1.20, 1.80, and 2.20 meters, originating from cracks that reach depths exceeding 60 cm.

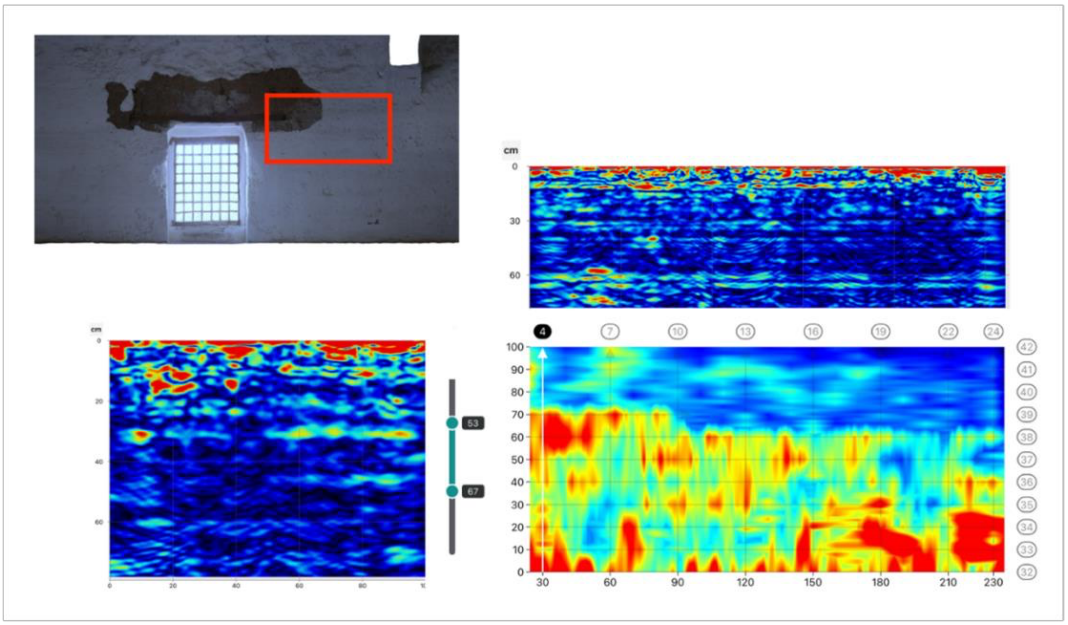

Figure 7 – Vela tower. Internal radargrams and C-Scan of the are marked with a red rectangle

5. Conclusions

This paper presents some of the ground-penetrating radar (GPR) inspections carried out at the Alhambra complex, specifically at the Vela tower. These inspections have analyzed the internal structure of the walls of the building, revealing layers of different materials, cavities, and cracks. A particularly noteworthy aspect of this work is the inspection, using a cable-driven robot, of a section of the Vela tower's external wall located 20 meters high. This inspection did not obstruct the view of the monument, as it did not require the installation of external elements such as scaffolding.

Ground-penetrating radar (GPR) inspections have revealed the internal structure of the walls in the inspected buildings, showing different layers of material, voids, and heterogeneities. Automated inspections using a cabled robot have allowed access to previously uninspected areas and the identification of cracks and their depths within the walls.

[4] University of Brasília, Brasília, Brazil, andressa.jesus@unb.br

Abstract: This paper presents a case study of the collapse of the water tank roof slab at the University of Brasília (UnB) Student Restaurant (RU), an iconic modern architectural building constructed with exposed concrete in the 1970s. The failure was primarily driven by advanced corrosion of the steel reinforcements on the internal face of the slab (tank lid), exacerbated by the tank's high relative humidity and lack of internal waterproofing. The investigation identified the root causes, characterized the degradation state post-collapse, and documented the adopted reconstruction solution, balancing structural safety, durability, and heritage preservation. Preliminary findings revealed permanent saturation from vapor transport via gaseous diffusion and capillary action through the porous concrete matrix, leading to interstitial (within pores) and surface condensations on the internal face — a more aggressive mechanism than the external wet-dry cycle from rainfall. This caused concrete cover spalling, diffuse cracking, deep carbonation exceeding rebar depth, and up to 100% cross-section loss in steel bars, progressively reducing load-bearing capacity under constant humid exposure. Visual inspections, technical surveys, and non-destructive tests confirmed that construction detailing typical of the 1970s, combined with absent waterproofing on both faces, accelerated internal corrosion beyond external influences. Due to irreversible damage, the slab was fully removed and replaced with a lighter steel frame and acoustic steel roofing sheets, minimizing permanent loads on tank walls, enhancing inspectability, and preventing recurrence while preserving the building's volumetric and architectural expression. The study emphasizes continuous monitoring of aging exposed concrete structures, particularly reservoir lids vulnerable to internal vapor/condensation, and contributes to discussions on corrosion mechanisms, risk assessment, intervention strategies, and maintenance for modern Brazilian heritage.

Keywords: Pathological manifestations, exposed concrete, waterproofing, modern heritage, preventive maintenance.

1. Introduction

The degradation of reinforced concrete structures represents one of the main challenges in contemporary civil engineering, particularly when involving buildings of cultural value. The corrosion of steel reinforcements, a complex electrochemical phenomenon, constitutes one of the most frequent causes of structural collapse in aged constructions, compromising the safety, durability, and material integrity of buildings that often hold cultural significance (Tuutti, 1982; Broomfield, 2007; Neville, 2011). In contexts where exposed concrete serves both as a defining element of architectural language and a structural component — as occurs in Brazilian modern architecture — degradation assumes dimensions that transcend purely

technical aspects, posing dilemmas between material preservation and structural adequacy (Prudon, 2008; Jonge and Doolaar, 1998; Kühl, 2008).

The University Restaurant (RU) of the University of Brasília, designed and built in the 1970s, paradigmatically exemplifies this tension. An emblematic edifice of modern architecture, characterized by the expressive use of exposed concrete and innovative structural solutions for its time (Schlee, 2014), the RU recently experienced the rupture of the water tank roof slab, an event that triggered a more in-depth technical investigation into the conservation state of its structure. The collapse, preceded by advanced corrosive processes in the reinforcements, revealed the vulnerability of structural elements exposed to permanent humidity conditions and the absence of adequate protection systems—factors that combined with typical constructive characteristics of the period to accelerate deterioration (Helene, 1992a; Cascudo, 1997; Bolina, Tutikian, and Helene, 2019).

The investigation of this case presents scientific and practical relevance across multiple dimensions. First, the study contributes to understanding corrosion mechanisms in reinforced concrete structures subjected to constant humidity, a common context in water tanks, reservoirs, and roof elements (Macdonald, 2003). Second, the research documents and analyzes pathological manifestations resulting from advanced corrosive processes, providing subsidies for diagnosing similar cases in other buildings (American Concrete Institute, 2016b; Morais et al., 2020). Third, and no less importantly, the investigation records the technical solution adopted for recomposing the element, highlighting the choices and compromises necessary when seeking to reconcile structural safety with patrimonial preservation (Feilden, 2003; Canziani and Quist, 2025).

The preliminary analysis of the case revealed intense moisture penetration, absence of effective waterproofing, detachment of concrete cover, diffuse cracking, and significant loss of cross-section in the steel bars. Mechanisms associated with concrete carbonation and constructive detailing typical of the era resulted in the progressive reduction of the slab's load-bearing capacity until its collapse (Ekolu, 2020; Ribeiro, 2018). Given the high degree of deterioration and the technical and economic unfeasibility of recovering the slab, the decision was made to completely remove the collapsed element and replace it with a lighter roofing structural system, composed of a metal framework and steel tiles—a solution that sought to balance safety, durability, and preservation of architectural volumetry requirements (American Concrete Institute, 2016a).

The present investigation had the following objectives: (i) to identify and characterize the causes of the reinforced concrete roof slab collapse; (ii) to document the degradation state and analyze the failure mode of the element; (iii) to assess the contribution of factors such as carbonation, recurrent infiltrations, and constructive detailing to accelerating the corrosive process; (iv) to document the technical solution adopted for reconstruction; and (v) to contribute to the debate on corrosion mechanisms, risk assessment, intervention strategies, and maintenance in aged reinforced concrete structures, particularly those with patrimonial value (Mehta and Monteiro, 2014; Souza and Ripper, 1998).

The study reinforces the relevance of continuous monitoring of aged structures and highlights the ongoing challenge of reconciling technically adequate solutions with the conservation of formal and material attributes of Brazilian modern architecture's heritage (Croft and Macdonald, 2019; Dyer, 2015). In this sense, the UnB RU case offers significant contributions to the interdisciplinary debate among engineering, architecture, and patrimonial conservation fields. Although these fields often operate with distinct logics, real case studies prove to be opportunities for dialogue and knowledge interaction.

2. Case Contextualization and Building Characterization

The RU/UnB is a landmark of modern architecture on the Darcy Ribeiro Campus. Designed by architect José Galbinski and built in the 1970s, the building reflects Brazilian modernism, characterized by the expressive use of exposed concrete and the integration between structure and form (Prudon, 2008; Jonge and Doolaar,

1998). The edifice is not merely a functional facility supporting academic life, but an exemplar of built heritage that embodies the visual and technical identity of its era (Kühl, 2008).

2.1 The architectural concept and constructive system

The structural conception of the RU is based on the robustness of reinforced concrete, a material that enabled the execution of large spans and cantilevers typical of the period (Neville, 2011). The water tank of the complex was designed as a prominent volume, executed in cast-in-place concrete (Figure 1). The original roof slab, the object of this study, consisted of a solid inclined reinforced concrete slab, whose primary function was the top closure of the reservoir, ensuring the protection of the stored water and the integrity of the architectural volume.

Figure 1 – Aerial photograph of the exposed concrete water tank, highlighting the inclined slab of the tower integrated into the main RU/UnB building. Source: Authors, 2025.

In the 1970s, constructive detailing did not consider cover thickness as a determining parameter for the service life of the reinforcements; mechanical strength was prioritized as the primary factor to ensure the durability of reinforced concrete. At that time, standards were less rigorous regarding watertightness and environmental aggressiveness as factors accelerating the onset of pathological manifestations (Helene, 1992a; Mehta and Monteiro, 2014).

2.2 Exposure conditions

The water tank roof slab, without a waterproofing or protection system, was exposed to climatic variations and rainfall action (Figures 2 and 3):

- Internal Environment: The underside of the slab, lacking a waterproofing or protection system, was subject to moisture from evaporation and condensation of the stored water, maintaining the concrete at high moisture content; and

- External Environment: The upper face was exposed to cyclic variations in temperature, solar radiation, relative humidity, and rain—factors that promote wetting and drying cycles, the opening of microcracks, and the penetration of aggressive agents.

Figure 2 – Illustrative image of the water tank's exposure during a rainy period, showing surface runoff and water penetration through cracks in the roof slab. Source: Authors, 2026.

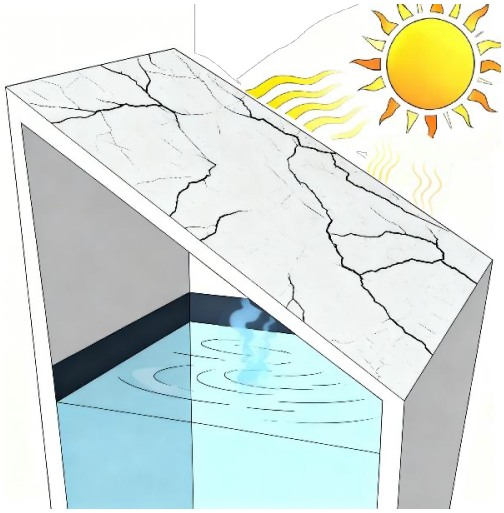

Figure 3 – Illustrative image of the water tank's exposure during a hot and dry period, showing water vapor passage from the internal to the external environment through the roof slab. Source: Authors, 2026.

The presence of an aged waterproofing system at the end of its service life, combined with the absence of periodic maintenance, allowed moisture and carbon dioxide (CO_2) to penetrate the concrete's porous matrix. This scenario is critical for exposed concrete structures, where the aesthetic expression of the exposed material may be compromised by protective coatings that could mitigate the carbonation front and, consequently, corrosion (Broomfield, 2007; Ekolu, 2020).

2.3 The Slab Rupture Event

Throughout its service life, no inspections of the water tank detected excessive deformations or cracks compromising watertightness. Therefore, it cannot be confirmed that the slab collapse occurred suddenly, although the degradation process was progressive over decades. The rupture revealed that the element's load-bearing capacity had been severely compromised by reinforcement cross-section loss, preventing stress redistribution and leading to structural failure (Bolina, Tutikian, and Helene, 2019). The event underscores the need to reconcile preservation of the RU's original volumetry with the adoption of contemporary technological solutions that ensure user safety and heritage longevity (Cascudo, 1997; Croft and Macdonald, 2019).

3. Methodological Procedures for Inspection and Analysis

The investigation of the roof slab collapse in the water tank was conducted through an approach combining visual inspections, technical surveys, and documentation analysis. The objective was to establish a preliminary diagnosis of the rupture causes, document the element's degradation state, and technically substantiate the adopted reconstruction solution (American Concrete Institute, 2016b).

3.1 Visual Inspections and Photographic Documentation

Visual inspections were performed in two stages: the first immediately after the collapse, when the element was still in situ; the second after partial debris removal, allowing access to the underside of the slab and constructive details. During these inspections, visible pathological manifestations were documented, including:

- Cracking: visualization of the distribution, orientation, and width of cracks;
- Spalling: identification of areas with loss of bond between concrete and reinforcement;
- Reinforcement corrosion: visual assessment of the oxidation degree in exposed steel bars;
- Moisture: verification of stains, efflorescences, and signs of recurrent infiltration; and
- Structural integrity: analysis of concrete continuity and identification of weakened zones (Bolina, Tutikian, and Helene, 2019; Morais et al., 2020).

Photographic documentation was carried out using a high-resolution digital camera, capturing details at multiple scales: general views of the element, crack and corrosion details, and close-ups of critical areas. This visual documentation served as the basis for subsequent analysis and communication with project teams involved in the reconstruction (Macdonald, 2003).

3.2 Technical Survey and Geometric Characterization

A metric survey was conducted to characterize the slab's original dimensions, including thickness, spans, and reinforcement detailing. This survey was performed through:

- Direct measurements with tape measure and level, establishing the element's main elevations;
- Consultation of original design documentation for comparison between design and execution; and
- Analysis of concrete cross-sections, allowing estimation of cover thickness and steel bar positions (Neville, 2011).

These data were necessary to determine whether the original constructive detailing complied with executive designs and to assess if design deficiencies contributed to accelerating the corrosion process (Helene, 1992a, 1992b).

3.3 Concrete Degradation Analysis

Characterization of the concrete degradation state was performed through procedures combining visual observation with non-destructive investigation techniques:

- Sclerometry: measurement of surface concrete hardness at multiple points, providing an indication of strength; and
- Carbonation depth: determination of the carbonation front advancement depth through phenolphthalein assays, an indicator that changes color in the presence of alkaline pH (Mehta and Monteiro, 2014; Ekolu, 2020).

These procedures provided quantitative data on the material's deterioration degree and the degradation mechanisms in action.

3.4 Reinforcement Investigation and Corrosion Quantification

Reinforcement corrosion was investigated through procedures that assessed both the extent and severity of the phenomenon:

- Observation of residual diameters: to quantify cross-section loss in bars at multiple points along their length; and
- Adhesion analysis: qualitative assessment of the concrete-steel bond, checking for detachment and anchorage loss (Ribeiro, 2018; Broomfield, 2007).

Quantification of cross-section loss was fundamental to estimate the reduction in the slab's load-bearing capacity and justify the unfeasibility of recovering the original element (Tuutti, 1982).

3.5 Analysis of Exposure Conditions and Moisture

The exposure conditions investigation included:

- Waterproofing system verification: inspection of the presence or absence of protective layers on the upper and lower faces of the slab, highlighting the lack of internal protection that allowed continuous water vapor penetration and surface/interstitial condensations; and
- Drainage assessment: analysis of rainwater runoff capacity on the external face and identification of moisture accumulation or water penetration points.

These data enabled understanding of the element's exposure regime: externally, wet-dry cycles with pluviometric infiltrations accelerating microcracks; internally, high relative humidity (~100%) in the reservoir promoting vapor transport by diffusion and capillarity in porous concrete, with interstitial (in pores) and surface (on the underside) condensations maintaining permanent saturation. This internal mechanism was the main accelerator of underside reinforcement corrosion, surpassing external impact by preventing drying cycles that limit electrochemical corrosion (Ekolu, 2020; Mehta and Monteiro, 2014).

3.6 Consultation of Documentation and Constructive Detailing Analysis

The investigation included consultation of the building's original designs to:

- Verify reinforcement detailing: compare design with actual execution, identifying possible deviations;
- Assess specified cover: compare design requirements with standards in force at the time against current standards and practices;
- Understand constructive solutions: analyze how critical details such as joints, anchorages, and reinforcement protection were resolved; and
- Contextualize the construction era: understand the technological and normative limitations of the 1970s, which may explain design deficiencies (Souza and Ripper, 1998; Associação Brasileira de Normas Técnicas, 2024).

This analysis was important to understand that the collapse resulted not only from maintenance neglect but also from period-typical constructive characteristics that made the element vulnerable to long-term degradation.

3.7 Methodological Framework

The approach enabled constructing a diagnosis by associating data collected from each procedure. Visual inspections provided the general overview; technical surveys established geometry and detailing; concrete and reinforcement analyses quantified degradation; and documentation consultation contextualized findings. This joint and complementary analysis of evidence provided a more comprehensive diagnosis for assessing the situation and decision-making.

4. Diagnosis of the Degradation Mechanisms and Causes of the Slab Rupture

The results obtained from inspections and technical surveys confirmed a critical degradation state of the roof slab, with irreversible damage compromising the structural safety of the element. The collapse of the University of Brasília University Restaurant roof slab indicates a synergy of degradation processes accumulated over five decades. The technical diagnosis indicates that the failure resulted from the combination of the aggressiveness of the reservoir's internal microclimate, the absence of effective protective barriers, and the constructive detailing typical of the 1970s.

4.1 Pathological Manifestations and Conservation State

The investigation revealed that the slab exhibited an advanced deterioration condition, characterized by moisture transport mechanisms of aggressive agents well-recognized in the literature. The collected data pointed to:

- Diffuse cracking: Presence of cracks on both faces of the slab, with openings facilitating direct entry of oxygen and water;
- Spalling: Loss of bond in extensive areas of the underside, exposing reinforcements to the humid reservoir environment;
- Loss of bar cross-section: Drastic reduction in the original diameter of steel reinforcements, reaching levels that made load support unfeasible; and
- Deep carbonation: The carbonation front reached and exceeded the reinforcement depth across nearly the entire slab length, eliminating the steel's natural chemical protection. .

4.2 Determining Factors for the Collapse

The results indicated that the rupture was the outcome of a combination of technical failures. The absence of effective waterproofing was the catalyzing factor, allowing moisture to remain trapped in the concrete matrix for decades.

Inspections confirmed that the 1970s constructive detailing, although common for the era, did not foresee the durability requirements necessary for a high-humidity environment, such as the interior of a water reservoir. The synergy between carbonation and recurrent infiltrations exponentially accelerated the corrosion process in the years leading up to failure.

4.3 Watertightness Failure and Vapor Transport

The primary cause of degradation was intense moisture penetration into the slab, with emphasis on the underside exposed to internal water vapor, exacerbated by the reservoir's high relative humidity microclimate. The absence of waterproofing on the upper and lower faces facilitated vapor transport through diffusion and capillarity in the concrete's porous matrix, generating interstitial condensations (in pores) and surface condensations (on the internal face) that favored steel corrosion reactions (Dyer, 2015; Mehta and Monteiro, 2014).

The internal face of the slab, acting as a reservoir lid, is subjected to a continuous cycle of condensation. According to Cincotto and Helene (1984), the presence of aggressive free CO2 in the condensed water accelerates the leaching of calcium hydroxide (portlandite), increasing the porosity of the cement paste and facilitating the depassivation of the reinforcement. Constant moisture from evaporation and condensation of stored water accelerated underside reinforcement corrosion, surpassing external impact by preventing drying cycles. Externally (Figure 4), pluviometric infiltrations penetrated microcracks, but the wetting-drying cycle made the action less aggressive.

Figure 4 – Original condition of the upper external face of the collapsed slab, highlighting multiple cracks and pronounced wear of the protective mortar layer. Source: Authors, 2025.

4.4 Carbonation and Reinforcement Depassivation

Phenolphthalein tests confirmed the carbonation front advancement not only to the reinforcement level but through the entire slab thickness. The reaction of atmospheric CO_2 with cement hydration products reduced the concrete's pH — originally alkaline (pH > 12.5) — to values below 9.

This phenomenon caused steel depassivation, breaking the protective oxide layer naturally surrounding bars in a basic environment. In 1970s exposed concrete structures, nominal cover was often thin or irregular, advancing the carbonation front's contact with reinforcement and initiating corrosion propagation across its entire area.

4.5 Advanced Corrosion and Cross-Sectional Loss

Once depassivated and in the presence of electrolyte and oxygen, reinforcements initiated accelerated oxidation. The diagnosis identified two critical effects from corrosion:

1. Volumetric expansion: Corrosion products (rust) occupy up to six times the original steel volume. This expansion generated internal tensile stresses in the concrete, resulting in longitudinal cracking and, ultimately, cover detachment (spalling), splitting the slab at half its thickness (Figure 5); and

2. Metallic cross-section reduction: Analysis of bars post-rupture revealed 100% cross-sectional loss at critical points (Figure 5). This drastic reduction compromised tensile stress absorption capacity, essential for the solid slab's equilibrium.

Figure 5 – Internal face of the collapsed slab: exposed corroded reinforcements. Highlighting steel bar cross-section total loss. Source: Authors, 2025.

4.6 Final Rupture Mechanism

The conjunction of the above factors culminated in reducing the slab's load-bearing capacity below service loads (self-weight and occasional overloads). As explained by Souza and Ripper (1998), the era's constructive detailing lacked sufficient safety reserve to withstand such material degradation.

Collapse occurred when the residual steel bar section could no longer support tensile stresses from bending moment. Loss of bond between corroded steel and carbonated concrete also contributed to failure, preventing effective stress transfer and leading to abrupt element rupture.

4.7 Definition of the Intervention

Given the technical unfeasibility of recovering the original solid slab, risk analysis results substantiated complete element removal. The adopted solution consisted of replacement with a lightweight roofing system formed by steel purlins fixed to reservoir walls and closure with thermoacoustic steel tiles.

The main objective of the adopted technological solution for reconstruction was reducing self-weight on reservoir walls and eliminating new corrosion risks in reinforced concrete roofing elements. This intervention restored water tank functionality, ensuring watertightness and safety, without affecting the exposed reinforced concrete tower walls (Figures 6, 7, and 8).

Figure 6 – RU water tank at the start of inspection services. Source: Authors, 2026.

Figure 7 – RU water tank during reconstruction. Source: Authors, 2026.

Figure 8 – RU water tank after roof reconstruction. Source: Authors, 2026.

5. Discussion on the Adopted Solution and Its Structural and Architectural Implications

The adopted solution for the studied case highlights a recurring issue in interventions on modern architecture buildings: the need to reconcile structural safety, durability, and preservation of architectural attributes. In the case of the University of Brasília University Restaurant water tank roof slab, the high degree of degradation of the original element—particularly the advanced corrosion of the reinforcements on the internal face—ruled out a conservative approach based on localized repairs and recovery of the original element. The extent of pathological manifestations, significant loss of reinforcement cross-section, and global compromise of load-bearing capacity indicated that maintaining the original system would pose a risk incompatible with usage and minimum structural performance criteria required for the building, as established by Brazilian standards and the American Concrete Institute (2016b).

From a strictly technical standpoint, the complete removal of the collapsed slab and its replacement with a lighter system—composed of a metal framework and steel tiles—proved to be a solution with lower self-weight, reducing permanent loads transmitted to the reservoir and decreasing demands on existing supports, thereby contributing to overall safety. Additionally, replacing a solid reinforced concrete element with a lighter and more easily inspectable constructive system tends to facilitate future maintenance routines, allowing better control over infiltration points, watertightness failures, and early deterioration processes (Helene, 1992a).

From a durability perspective, by introducing materials and systems more compatible with performance demands in humid environments, the intervention sought not only to recompose the roofing function but also to reduce the likelihood of recurrence of similar pathological mechanisms—such as vapor transport through gaseous diffusion and capillarity in the concrete's porous matrix, with interstitial (in pores) and surface condensations on the internal face. In this sense, the design decision should be understood not merely as an emergency response to the collapse, but as a long-term risk mitigation strategy, aligned with contemporary principles of structural durability management (Dyer, 2015; Mehta and Monteiro, 2014). Thus, the integrity of the exposed concrete walls composing the tower's volumetry was ensured.

In modern buildings constructed with exposed concrete, the original materiality holds intrinsic value. According to the theoretical principles of Kühl (2008) and Prudon (2008), the constructive system often integrates the building's formal language itself, and therefore, the removal of an original element implies a material loss that cannot be considered irrelevant, even if the component is volumetrically recompensed.

In the analyzed case, the technical unfeasibility of reconstituting the original slab—exacerbated by the high internal relative humidity that promoted constant condensations on the underside, accelerating reinforcement corrosion—led to a pragmatic stance, focusing preservation efforts on conserving the volumetry, architectural reading, and integrity of the built ensemble.

The conducted study highlights bottlenecks in conservation practices, where durability required by technical standards proves insufficient after decades of building exposure to the internal vapor

transport/condensation phenomenon without proactive maintenance. The challenge, therefore, is not only to conserve existing matter but to establish criteria for intervening without altering the architectural intent of the asset.

Another important aspect concerns the role of preventive maintenance. The studied case demonstrates that the collapse did not result from a single isolated factor, but from the progressive combination of ineffective waterproofing on internal and external faces, recurrent infiltrations, carbonation, and advanced reinforcement corrosion. In other words, it is a cumulative process that could, at least in part, have been identified and controlled before reaching a critical stage — especially the internal vapor transport that maintained permanent saturation on the underside. This reinforces the need for systematic inspection programs in aged structures, particularly those associated with continuous use and patrimonial value.

6. Conclusion

The investigation into the rupture of the University Restaurant (RU/UnB) water tank roof slab led to the conclusion that the structural collapse was the inevitable outcome of a prolonged degradation process, dominated by advanced corrosion of the reinforcements on the internal face of the reinforced concrete cover. The technical analysis revealed that this phenomenon was accelerated by the absence of waterproofing on the underside, enabling vapor transport through gaseous diffusion and capillarity in the concrete's porous matrix, with constant interstitial (in pores) and surface condensations maintaining permanent saturation due to the high relative humidity in the reservoir—a mechanism that proved more aggressive than the external wetting-drying cycle.

The study demonstrated that the constructive characteristics of the 1970s, although representative of Brazilian modernism, exhibited intrinsic vulnerabilities regarding durability in permanent humid environments. The deep carbonation of the concrete and the loss of steel bar cross-section—up to 100% at nodal points—confirmed the technical and economic unfeasibility of localized repairs, justifying complete replacement with a lightweight metal system. The intervention prioritized structural safety and maintainability, while preserving the building's volumetry, architectural expression, and the reversibility of the adopted technological solution.

Finally, this case underscores the need for preventive maintenance programs and continuous monitoring in aged exposed concrete structures, particularly internal elements exposed to vapor and condensations, such as reservoir covers. The challenge of preserving Brazilian modern heritage lies in the ability to diagnose these internal degradation mechanisms early on, implementing solutions that integrate engineering's technical rigor with the architectural attributes of the patrimonial asset.

Acknowledgments

The authors thank the Brazilian National Council for Scientific and Technological Development (CNPq), the Coordination for the Improvement of Higher Education Personnel (PROAP/CAPES), and the Deanship of Research and Innovation (DPI) of the University of Brasília (UnB) for financial support. They also thank the Infrastructure Secretariat (INFRA/UnB), the Oscar Niemeyer Planning Center (CEPLAN/UnB) for technical support and documentary data, and the Materials Testing Laboratory of the Faculty of Technology at UnB for laboratory analyses.

Resumo: As patologias higrotérmicas constituem um dos principais fatores de degradação do ambiente construído, afetando a integridade física dos materiais, a durabilidade dos elementos construtivos e o desempenho higrotérmico dos edifícios. O seu aparecimento resulta de interações complexas entre a exposição climática, características dos materiais, práticas construtivas, processos de envelhecimento e fenómenos relacionados com a humidade, que assumem um papel central na avaliação da patologia e na definição de estratégias de reabilitação. A diversidade de soluções construtivas e de condições de exposição observadas em edifícios existentes torna particularmente relevante o estudo da manifestação e da evolução destas patologias.

Este trabalho caracteriza as patologias higrotérmicas com base na análise de 103 relatórios técnicos de inspeção do Instituto da Construção Sustentável (ICS) da Universidade do Porto. A análise estatística permitiu identificar a distribuição das patologias por tipologia, elementos construtivos e causas, bem como avaliar a existência de associações significativas entre estas variáveis. Os resultados destacam a infiltração de água como a patologia mais frequente, seguida da degradação de revestimentos e da degradação biológica. Verificaram-se ainda padrões consistentes entre patologias, mecanismos e elementos da envolvente. Identificam-se dois grandes grupos de mecanismos: patologias associadas à entrada de água devido à falta de estanquidade e patologias decorrentes de condições higrotérmicas interiores inadequadas. Os resultados reforçam a necessidade de estratégias de reabilitação integradas e preventivas centradas no controlo das fontes de humidade.

Palavras-chave: Patologias higrotérmicas, edifícios, humidade.

1. Introdução

As patologias da construção representam um desafio significativo para a durabilidade, a funcionalidade e a sustentabilidade do ambiente construído. Entre os diversos processos de degradação que afetam os edifícios, as patologias higrotérmicas assumem particular relevância, uma vez que decorrem de interações complexas entre os fluxos de calor, de ar e de humidade nos elementos construtivos (Bayat Pour et al., 2024; Hajdukiewicz et al., 2015). Estes fenómenos desenvolvem-se frequentemente em camadas ocultas da envolvente do edifício, podendo permanecer indetectáveis até que a deterioração visível se torne evidente,

momento em que danos materiais significativos e problemas na qualidade do ambiente interior já podem ter ocorrido (Dias Pereira et al., 2023; Mattsson et al., 2024; Palani et al., 2023).

Os fenómenos relacionados com a humidade são amplamente reconhecidos como um dos principais motores de degradação dos edifícios. Os seus efeitos vão além dos danos estéticos, afetando a integridade estrutural dos materiais, o desempenho térmico dos sistemas envolventes e a saúde e o conforto dos ocupantes (Heracleous et al., 2025; Schroderus et al., 2025). A exposição prolongada à humidade pode desencadear uma cadeia de mecanismos de degradação, incluindo a degradação de revestimentos, o desenvolvimento biológico, a cristalização de sais e a corrosão de elementos metálicos. Assim, a compreensão dos mecanismos que regem o comportamento higrotérmico é essencial para um diagnóstico fiável e para o desenvolvimento de estratégias eficazes de manutenção e reabilitação.

A relevância destas patologias tem sido amplamente evidenciada em estudos europeus. O sistema SYCODÉS, uma das bases de dados mais completas de relatórios periciais em França, demonstra que as falhas de estanquidade representam mais de 60% dos defeitos registados, o que sublinha o papel dominante dos fenómenos de humidade na degradação dos edifícios (AQC, 2016; CIB, 2013). Tendências semelhantes são observadas em outros contextos europeus, nos quais as patologias da envolvente representam uma parcela significativa dos sinistros reportados (CIB, 2013).

No contexto português, estudos sobre edifícios históricos demonstram igualmente a prevalência de processos de degradação associados à humidade, que afetam uma ampla gama de materiais e sistemas construtivos. Problemas como infiltrações, humidade ascensional, condensação e eflorescência são recorrentes em paredes de alvenaria e em sistemas de revestimento, podendo estender-se a elementos de madeira e de metal (Branco & Torres, 2009).

Apesar do reconhecimento generalizado da importância dos fenómenos higrotérmicos, a investigação existente tende a focar-se em casos específicos ou em análises numéricas, sendo ainda limitada pela disponibilidade de estudos baseados em conjuntos de dados reais provenientes de inspeções técnicas. Estes conjuntos de dados são essenciais para identificar padrões de ocorrência, caracterizar mecanismos subjacentes e compreender a relação entre causas e manifestações.

Neste contexto, o presente estudo analisa uma amostra de relatórios de inspeção técnica do Instituto da Construção Sustentável (ICS) da Universidade do Porto, com o objetivo de caracterizar as patologias higrotérmicas mais frequentes e explorar as suas relações com elementos construtivos específicos por meio de métodos estatísticos. Através da integração de uma tipologia estruturada de patologias com análises descritivas e de associação, o estudo procura identificar padrões consistentes de degradação e apoiar o desenvolvimento de estratégias de diagnóstico e de reabilitação mais eficazes.

Este estudo distingue-se por recorrer a um conjunto alargado de dados empíricos provenientes de relatórios reais de inspeção, permitindo uma abordagem estatística ainda pouco explorada na literatura sobre patologia da construção. A sistematização das patologias, dos elementos construtivos afetados e das suas causas contribui para uma melhor compreensão dos mecanismos de degradação higrotérmica e para o apoio à tomada de decisão em contexto de manutenção e reabilitação de edifícios.

2. Metodologia

2.1 Enquadramento do Estudo

O enquadramento metodológico adotado neste estudo baseia-se na classificação sistemática das patologias higrotérmicas de acordo com os seus mecanismos subjacentes de transporte de humidade e as suas manifestações materiais observáveis. Os processos de degradação higrotérmica são amplamente reconhecidos como decorrentes de interações complexas entre os fluxos de calor, ar e humidade na envolvente dos edifícios, influenciando tanto a durabilidade dos materiais quanto a qualidade do ambiente interior (Bayat Pour et al., 2024; Hajdukiewicz et al., 2015).

Para apoiar a interpretação diagnóstica, as patologias foram organizadas em fenómenos primários, correspondentes aos mecanismos físicos que promovem o transporte e a acumulação de humidade, e em efeitos secundários, que representam os processos de degradação material decorrentes da presença prolongada dessas condições. Esta estrutura de classificação segue abordagens amplamente consolidadas na literatura sobre patologia da construção (Freitas Vasco Peixoto & Almeida, 2012; Palani et al., 2023).

Os fenómenos primários considerados incluem as principais vias de entrada ou mobilização de água nos edifícios: humidade por condensação, quando a temperatura desce abaixo do ponto de orvalho (Freitas Vasco Peixoto & Almeida, 2012; Rohsenow et al., 1998); humidade por infiltração, associada à entrada de água da chuva por meio de fissuras, juntas ou de sistemas de impermeabilização defeituosos (Freitas Vasco Peixoto & Almeida, 2012); humidade ascensional, resultante do transporte capilar a partir do solo (Boinas et al., 2016; Delgado et al., 2015; Guimarães et al., 2016); e fugas em redes técnicas (Freitas Vasco Peixoto & Almeida, 2012). Os efeitos secundários correspondem às manifestações materiais associadas à presença prolongada de humidade, tais como degradação de revestimentos, eflorescências, degradação biológica e corrosão.

Esta organização tipológica permite analisar, de forma estruturada, as relações entre causas e manifestações, fornecendo um quadro consistente para a interpretação dos resultados estatísticos e a compreensão dos padrões observados no parque edificado estudado.

2.2 Aquisição de Dados

A base empírica do estudo consiste numa revisão sistemática de relatórios de inspeção e de diagnóstico produzidos pelo Instituto da Construção Sustentável (ICS) da Universidade do Porto, no âmbito da sua atividade técnico-científica, no período compreendido entre 1995 e a atualidade. Estes relatórios documentam avaliações diagnósticas realizadas em edifícios com diferentes tipos de patologias construtivas.

O processo de seleção da amostra foi desenvolvido em duas etapas sequenciais. Numa primeira fase, foi analisado um conjunto inicial de 384 relatórios técnicos disponíveis na base de dados do ICS. Esta etapa teve como objetivo identificar a totalidade dos casos potencialmente relevantes para fenómenos de natureza higrotérmica.

Numa segunda fase, procedeu-se à aplicação de critérios de inclusão e exclusão previamente definidos, com o objetivo de garantir a consistência da amostra e a sua adequação ao objetivo do estudo. Foram incluídos apenas os relatórios que apresentavam patologias higrotérmicas com manifestação em elementos interiores dos edifícios e informação suficiente para a identificação de causas e mecanismos associados.

Foram excluídos os documentos que não apresentavam patologias higrotérmicas relevantes ou cuja incidência se restringia exclusivamente a outros tipos de problemas, nomeadamente patologias estruturais, questões de acessibilidade ou degradações exteriores sem impacto no ambiente interior.

Após a aplicação destes critérios, obteve-se uma amostra final de 103 relatórios considerados adequados ao âmbito do estudo.

A amostra resultante abrange edifícios habitacionais, de serviços, industriais e de uso misto, representando diferentes períodos construtivos e soluções técnicas.

Para cada caso selecionado, a informação foi sistematizada de forma estruturada em folha de cálculo, tendo sido construída uma grelha de codificação própria para registo consistente das variáveis em análise, nomeadamente: tipologia do edifício, localização, subtipo de patologia, elemento construtivo afetado, causas identificadas e recomendações de intervenção. A codificação foi realizada integralmente pelo autor, com base na leitura sistemática de todos os relatórios e na aplicação de critérios de classificação previamente definidos, garantindo uniformidade na atribuição das categorias.

3. Resultados

3.1 Distribuição de Patologias Higrotérmicas

A análise dos 103 relatórios de inspeção técnica revela uma forte concentração geográfica dos casos: o distrito do Porto é responsável por 73,7% das ocorrências, seguido de Aveiro (17,8%) e de Braga (4,8%). Os restantes distritos representam, em conjunto, 3,7% dos casos (Figura 1). Importa, no entanto, referir que a amostra analisada tem origem predominantemente na área de atuação do ICS, sediado no Porto, o que contribui para a concentração observada nesta região.

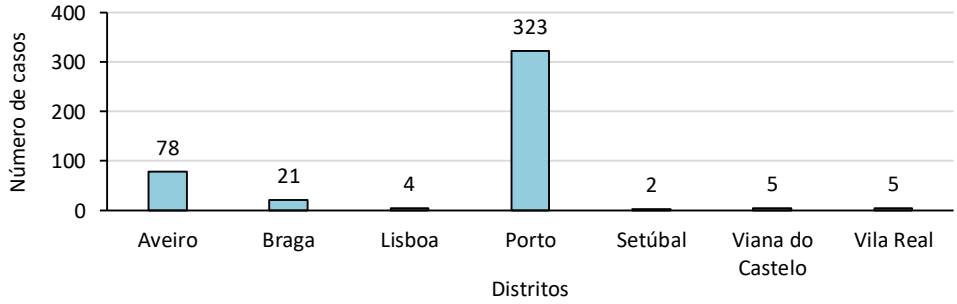

Figura 1 – Distribuição geográfica dos casos (número de ocorrências)

No total, foram identificadas 438 ocorrências patológicas, distribuídas nas oito categorias higrotérmicas definidas na Secção 2.1. A distribuição dos diferentes tipos de patologias encontra-se apresentada na Figura 2.

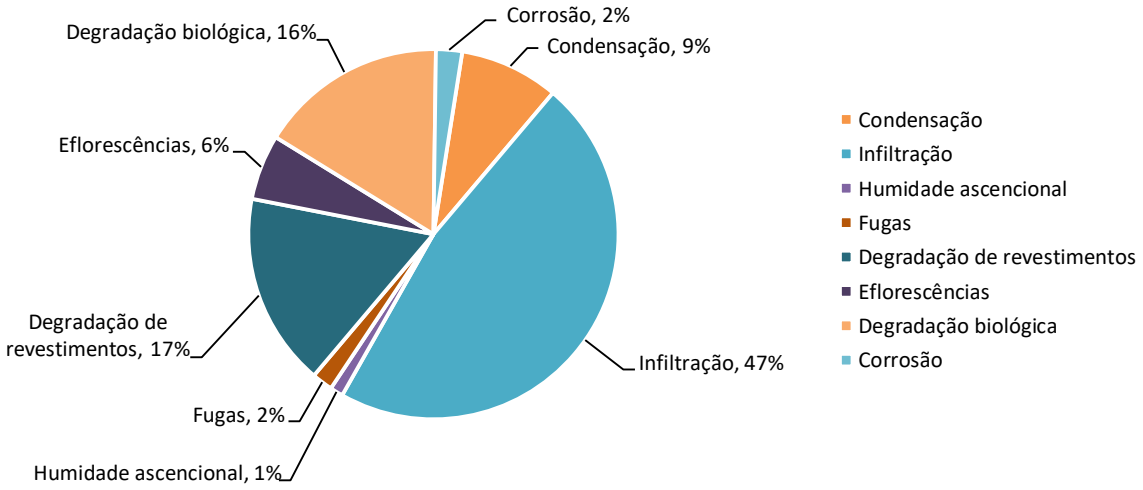

Figura 2 – Distribuição das patologias higrotérmicas (%)

A infiltração de água é a patologia mais prevalente, responsável por 47% das ocorrências totais (206 casos). Este resultado evidencia o papel dominante da infiltração de água na degradação dos elementos da envolvente dos edifícios.

A segunda categoria mais frequente corresponde à degradação de revestimentos, com 74 ocorrências (17%), seguida de perto pela degradação biológica, com 72 ocorrências (16%).

A condensação representa 9% das ocorrências, indicando uma presença moderada, porém relevante, de desequilíbrios de humidade no interior, frequentemente associados à ventilação e aquecimento deficientes. A eflorescência corresponde a 6% dos casos e geralmente está associada à migração de humidade por meio de materiais porosos.

As restantes patologias apresentam frequências comparativamente reduzidas: a humidade ascensional representa 1% das ocorrências, as fugas, 2%, e a corrosão, 2%.

De forma geral, os resultados indicam que a maioria das patologias observadas está diretamente associada a mecanismos de entrada e retenção de humidade, reforçando o papel central dos processos higrotérmicos na degradação dos edifícios.

3.2 Distribuição de Patologias pelos Elementos Construtivos

Foi realizada uma análise estatística, com recurso ao software IBM SPSS Statistics, com o objetivo de avaliar a existência de associações entre: (i) os elementos construtivos e os tipos de patologias; e (ii) as causas e as patologias identificadas. Para o efeito, aplicou-se o teste do qui-quadrado de independência.

A hipótese nula (H_0) pressupõe a inexistência de associação entre as variáveis em análise. Em ambos os casos, os resultados obtidos apresentaram valores de p inferiores a 5% ($p < 0,05$), o que levou à rejeição da hipótese nula. Estes resultados evidenciam associações estatisticamente significativas entre as variáveis analisadas, indicando que a ocorrência das patologias não é aleatória, mas depende tanto das características dos elementos construtivos quanto dos mecanismos causais subjacentes.

3.2.1 Elementos Construtivos vs Tipos de Patologias

A distribuição das patologias entre os diferentes elementos construtivos revela padrões consistentes, como ilustrado na Figura 3.

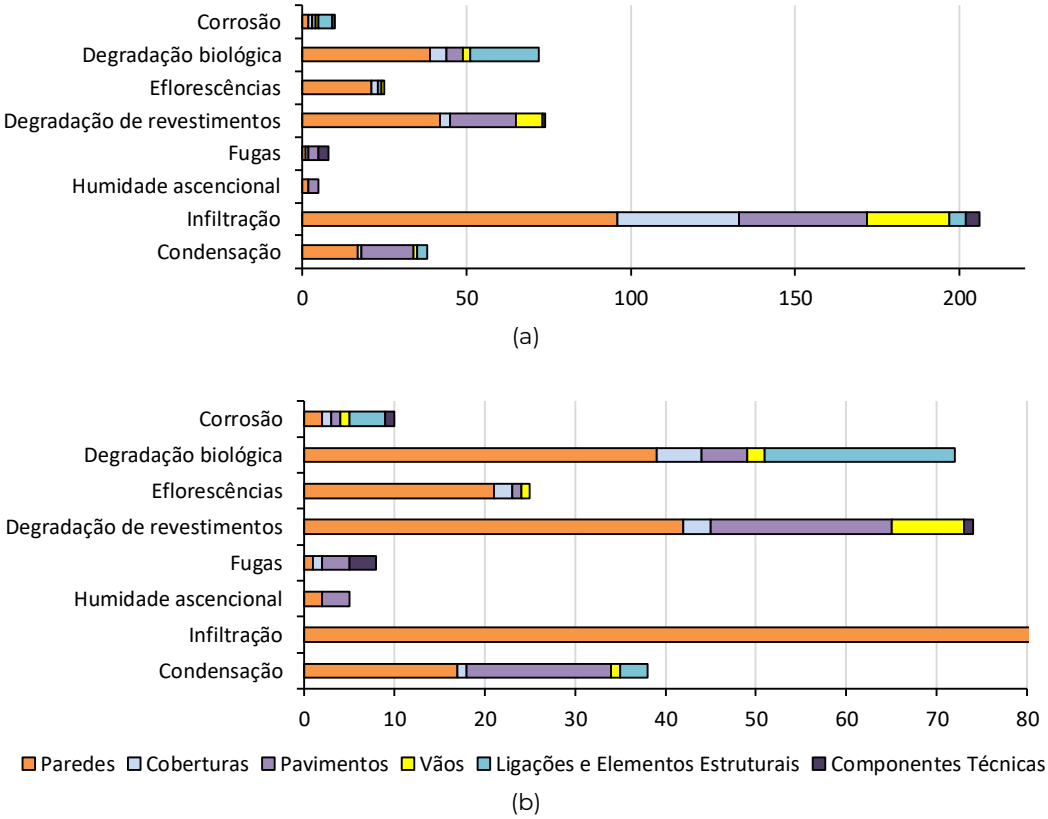

Figura 3 – (a) Distribuição das patologias por elementos construtivos; (b) detalhe ampliado

Verifica-se uma concentração significativa de ocorrências nos elementos da envolvente, com particular destaque para as paredes, que apresentam o maior número de patologias registadas. Este resultado

confirma a elevada exposição destes elementos às ações climáticas, nomeadamente à precipitação e ao vento.

A infiltração de água destaca-se como a patologia mais frequente, ocorrendo predominantemente em paredes, mas também com expressão relevante em coberturas, pavimentos e vãos. A condensação apresenta incidência significativa, sobretudo em paredes e pavimentos, o que reflete problemas associados à ventilação e ao desempenho térmico.

A degradação biológica e a degradação de revestimentos apresentam igualmente um número elevado de ocorrências, distribuídas por diversos elementos. A primeira ocorre predominantemente em paredes, ligações e elementos estruturais, enquanto a segunda se manifesta sobretudo em paredes e pavimentos.

A eflorescência surge principalmente em paredes, associada à migração de humidade por meio de materiais porosos. As fugas apresentam baixa incidência e estão essencialmente associadas a componentes técnicos. A corrosão ocorre de forma pontual, sobretudo em elementos estruturais e em ligações metálicas. Por fim, a humidade ascensional afeta quase exclusivamente paredes, devido ao contacto direto com o solo.

De forma geral, conclui-se que as paredes constituem o elemento mais vulnerável à ocorrência de patologias higrotérmicas, seguidas por pavimentos, coberturas e vãos.

3.2.2 Causas vs Tipos de Patologias

Para a análise das causas associadas às patologias higrotérmicas, adotou-se um sistema de codificação, apresentado na Tabela 1, que identifica e descreve os diferentes mecanismos de origem considerados neste estudo.

Tabela 1 – Codificação das causas das patologias higrotérmicas

Causa	Descrição
1	Ventilação insuficiente ou inexistente; aquecimento insuficiente
2	Ausência ou insuficiência de isolamento térmico
3	Presença de pontes térmicas
4	Falta de estanquidade da envolvente
5	Dimensionamento inadequado da rede de drenagem de águas pluviais
6	Envelhecimento e degradação de materiais
7	Deslocação ou fissuração de telhas
8	Humidade ascensional proveniente do solo
9	Fugas em redes de canalização
10	Utilização de materiais inadequados ou com elevada porosidade
11	Deficiências de conceção construtiva
12	Humidade de construção
13	Migração de sais solúveis
14	Proteção inadequada de elementos metálicos

Com base nesta classificação, foi analisada a relação entre as causas identificadas e os diferentes tipos de patologias, conforme apresentado na Figura 4.

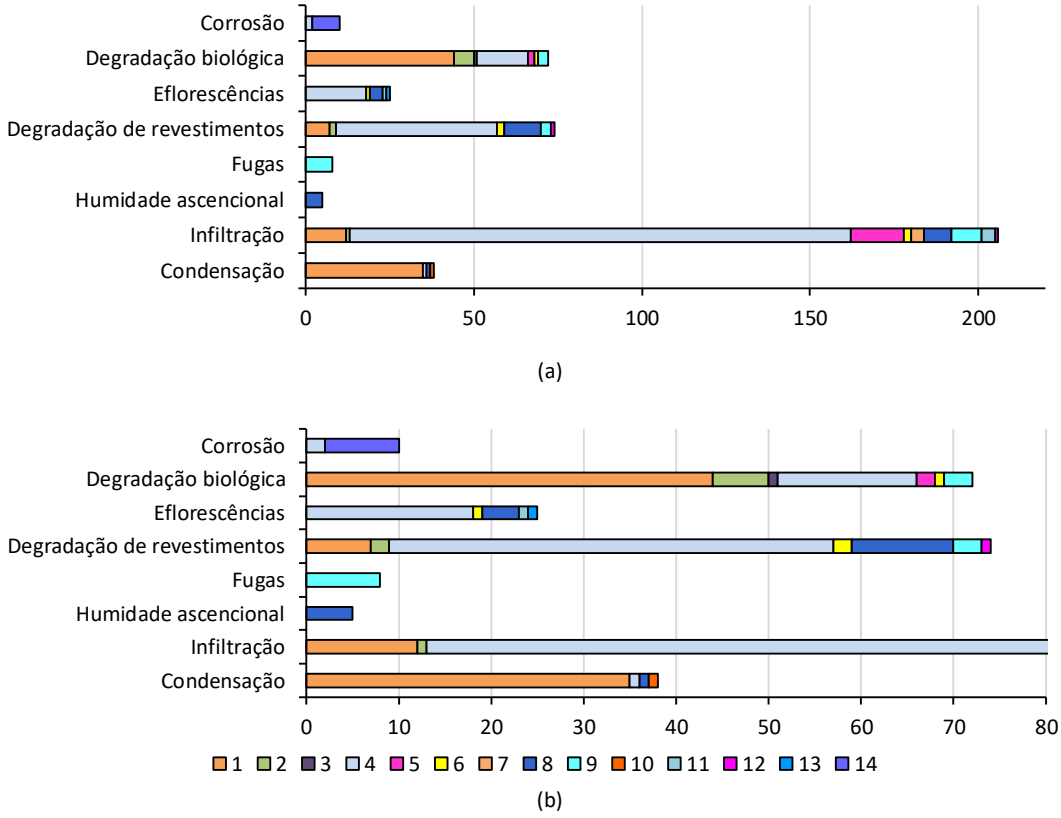

Figura 4 – (a) Distribuição das patologias por causas; (b) detalhe ampliado

A análise evidencia padrões claros de associação entre patologias e mecanismos causais, permitindo identificar as principais origens dos processos de degradação higrotérmica.

A condensação encontra-se quase exclusivamente associada à causa 1, correspondente a condições interiores inadequadas, nomeadamente ventilação insuficiente, renovação de ar fraca, produção elevada de vapor e/ou aquecimento insuficiente. As restantes causas surgem de forma residual, confirmando a forte dependência desta patologia das condições higrotérmicas interiores.

As infiltrações são predominantemente explicadas pela causa 4, relacionada à falta de estanquidade da envolvente e às deficiências de impermeabilização, as quais são responsáveis pela maioria dos casos. Verificam-se ainda contributos secundários associados à drenagem inadequada, à humidade do solo, a fugas e, pontualmente, a condições interiores desfavoráveis.

A humidade ascensional apresenta uma correspondência direta e exclusiva com a causa 8, associada à ascensão de humidade proveniente do solo, não sendo identificadas outras causas relevantes. De forma semelhante, as patologias classificadas como fugas estão exclusivamente associadas à causa 9, correspondente a roturas ou deficiências nas redes de canalização.

A degradação de revestimentos é predominantemente associada à causa 4, evidenciando o impacto da entrada de água na envolvente. Registam-se ainda contributos relevantes da humidade ascensional (causa 8) e das condições interiores (causa 1), bem como ocorrências menos expressivas relacionadas com envelhecimento dos materiais, deficiências de conceção e variações do teor de humidade.

As eflorescências estão sobretudo associadas à causa 4 e também são influenciadas pela humidade ascensional (causa 8). As restantes causas, como a migração de sais ou deficiências de conceção, apresentam expressão residual.

A degradação biológica ocorre predominantemente devido a condições de humidade elevada no interior (causa 1), com contribuição significativa da entrada de água na envolvente (causa 4). Outras causas, como envelhecimento, fugas ou drenagem deficiente, têm impacto reduzido.

Por sua vez, a corrosão está principalmente associada à causa 14, relacionada à proteção inadequada de elementos metálicos, sendo complementada por ocorrências pontuais associadas a deficiências de estanquidade.

De forma geral, identificam-se dois grandes grupos de mecanismos dominantes. Por um lado, as patologias associadas à entrada e circulação de água na envolvente, tais como infiltrações, degradação de revestimentos, eflorescências e parte dos fenómenos de corrosão, estão maioritariamente relacionadas com a causa 4, que se destaca como o principal fator de degradação. Por outro lado, as patologias dependentes das condições higrotérmicas interiores, nomeadamente a condensação e a degradação biológica, encontram-se fortemente associadas à causa 1.

Adicionalmente, verificam-se associações unívocas entre determinados mecanismos físicos e causas específicas, destacando-se a humidade ascensional (causa 8) e as fugas (causa 9). As restantes causas identificadas apresentam contributos residuais, sem impacto significativo no total de ocorrências.

4. Discussão

4.1 Interpretação dos mecanismos de degradação

Os resultados obtidos evidenciam o papel dominante da humidade como principal agente de degradação do desempenho dos edifícios, confirmando tendências amplamente reportadas na literatura europeia (AQC, 2016; CIB, 2013). No entanto, mais do que uma simples prevalência de patologias associadas à água, os dados sugerem a existência de um sistema de degradação estruturalmente dependente de falhas persistentes na gestão da humidade ao longo do ciclo de vida dos edifícios.

A elevada incidência de infiltrações não deve ser interpretada apenas como um problema pontual de estanquidade, mas como um indicador de vulnerabilidades sistémicas associadas ao projeto, execução e envelhecimento da envolvente. A concentração destes casos em elementos como fachadas, coberturas e vãos sugere que os pontos singulares da construção continuam a constituir fragilidades recorrentes, frequentemente subestimadas em fases de projeto e manutenção. Esta tendência é consistente com resultados de outros levantamentos europeus, nos quais as interfaces entre fachadas e vãos são frequentemente identificadas como pontos críticos de entrada de humidade (AQC, 2016).

Adicionalmente, a associação entre infiltração de água, degradação de revestimentos e eflorescências evidencia a natureza progressiva dos processos de degradação. Em vez de fenómenos independentes, estas manifestações representam diferentes estágios de um mesmo mecanismo físico, no qual a entrada de água desencadeia alterações químicas e físicas cumulativas nos materiais. Esta leitura reforça a necessidade de abordagens diagnósticas que considerem cadeias de degradação e não apenas sintomas isolados (Freitas Vasco Peixoto & Almeida, 2012; Palani et al., 2023).

Por outro lado, as patologias associadas a condições higrotérmicas interiores, como condensação e degradação biológica, revelam um segundo regime de comportamento, fortemente dependente das condições de utilização e de ventilação. Este resultado sugere que uma parte significativa das patologias não pode ser explicada apenas por deficiências construtivas, mas também por padrões de ocupação e desempenho dos sistemas de ventilação e aquecimento. Assim, a fronteira entre patologia construtiva e comportamento de utilização torna-se difusa, exigindo abordagens integradas de análise.

A análise das causas permite distinguir dois grandes grupos de mecanismos de degradação. O primeiro está associado à entrada e circulação de água na envolvente e é dominado por falhas de estanquidade e impermeabilização. Este grupo concentra a maioria das patologias mais frequentes, evidenciando que o controlo da água líquida constitui o aspeto mais crítico na prevenção da degradação higrotérmica. O

segundo grupo está relacionado com as condições higrotérmicas interiores, sendo dominado por problemas de ventilação e controlo de vapor, que conduzem a fenómenos de condensação e crescimento biológico.

Adicionalmente, a existência de associações diretas e exclusivas entre determinadas patologias e causas específicas, como a humidade ascensional e o contacto com o solo, ou as fugas e as redes de canalização, demonstra que alguns mecanismos apresentam uma relação física bem definida e previsível. Em contraste, outras patologias resultam da combinação de múltiplos fatores, o que reflete a natureza multifatorial dos processos de degradação em edifícios.

De forma geral, os resultados evidenciam que a degradação higrotérmica resulta da interação entre condições ambientais, características construtivas e fatores de utilização, sendo essencial uma abordagem integrada para sua compreensão e mitigação.

4.2 Implicações e Estratégias de Intervenção

Os padrões estatísticos identificados evidenciam a necessidade de estratégias de intervenção que atuem sobre os mecanismos subjacentes à acumulação de humidade na envolvente dos edifícios. Em particular, a predominância de defeitos associados à infiltração e a sua relação com patologias secundárias indicam que as estratégias de reabilitação devem priorizar o controlo da entrada de água antes da correção das manifestações secundárias.

A elevada incidência de patologias em paredes, coberturas e interfaces com vãos reforça igualmente a necessidade de intervenções direcionadas para os elementos mais expostos às ações climáticas e às falhas de impermeabilização.

4.2.1 Intervenções em fenómenos primários

A infiltração de água, identificada como a patologia mais frequente da amostra, deve ser tratada por meio da correção dos pormenores construtivos em fachadas e vãos, incluindo a aplicação de selantes elásticos, pingadeiras e remates adequados. Em interfaces porosas, podem ser aplicadas barreiras localizadas ou argamassas impermeabilizantes. Em paredes enterradas, deve-se proceder à renovação das membranas impermeáveis e à instalação de sistemas de drenagem eficazes. Em coberturas planas e terraços, é essencial garantir a continuidade das membranas, a correta pendente e o funcionamento adequado dos sistemas de escoamento. Nos pavimentos em contacto com o solo, devem ser adotadas soluções de impermeabilização contínua ou caixas de ar ventiladas.

Os resultados obtidos demonstram igualmente uma associação significativa entre condensação, degradação biológica e condições higrotérmicas interiores inadequadas. Assim, a mitigação destes fenómenos deve passar pela melhoria da ventilação (natural, híbrida ou mecânica), garantindo uma renovação adequada de ar, bem como o reforço do isolamento térmico, assegurando a continuidade nos pontos singulares. A manutenção de temperaturas interiores adequadas e, quando necessário, o recurso à desumidificação são igualmente medidas relevantes.

A humidade ascensional, embora menos frequente, apresentou uma associação direta com o contacto com o solo, justificando intervenções centradas na interrupção da ascensão capilar e na melhoria da drenagem periférica, recorrendo a diferentes técnicas, como, por exemplo, a criação de barreiras químicas ou físicas ou a implementação de soluções de ventilação na base das paredes. Os revestimentos contaminados por sais devem ser removidos e substituídos por soluções compatíveis e permeáveis ao vapor.

As fugas identificadas nos relatórios analisados exigem intervenções localizadas de deteção e reparação das redes de canalização.

4.2.2 Remediação de efeitos secundários

A degradação biológica deve ser tratada com limpeza, desinfeção e aplicação de fungicidas apropriados, seguida da utilização de revestimentos permeáveis ao vapor. As eflorescências podem ser removidas por escovagem ou lavagem controlada, sendo recomendada a aplicação de materiais compatíveis com ambientes sujeitos à migração de sais. A corrosão exige limpeza, passivação e proteção dos elementos metálicos, enquanto a degradação de revestimentos implica a sua substituição após estabilização das condições higrotérmicas.

4.3 Limitações do Estudo

Apesar dos contributos relevantes do conjunto de dados analisado, importa reconhecer algumas limitações do estudo. A análise baseia-se em relatórios de inspeção provenientes de uma única entidade, localizada no Norte de Portugal, o que resulta numa maior concentração de casos nesta região. Consequentemente, a amostra não reflete integralmente a diversidade do parque edificado português, limitando a generalização dos resultados à escala nacional.

A identificação das patologias e respetivas causas depende da interpretação técnica realizada nos relatórios de inspeção, podendo introduzir algum grau de subjetividade. Além disso, a análise das relações entre patologias e causas assenta nessa mesma informação interpretativa, o que pode gerar alguma dependência entre as variáveis consideradas e deve ser tido em conta na interpretação dos resultados.

Embora a base de dados apresente elevada riqueza de informação, variáveis como a idade dos edifícios, o tipo de utilização ou os sistemas construtivos não foram exploradas em profundidade. A inclusão destas dimensões em trabalhos futuros poderá contribuir para uma compreensão mais abrangente da variabilidade das patologias higrotérmicas.

Investigações futuras poderão igualmente alargar o conjunto de dados, integrando informação proveniente de outras instituições ou combinando relatórios de inspeção com a monitorização contínua de parâmetros higrotérmicos, como temperatura e humidade.

De forma global, os resultados obtidos contribuem para uma melhor compreensão das inter-relações entre os mecanismos de transporte de humidade, os processos de degradação dos materiais e os elementos construtivos. Este conhecimento revela-se fundamental para o desenvolvimento de metodologias de diagnóstico mais robustas e de estratégias de manutenção e reabilitação mais eficazes.

5. Conclusões

O presente estudo permitiu analisar, de forma sistemática, a ocorrência de patologias higrotérmicas em edifícios, com base numa amostra de 103 relatórios de inspeção e de diagnóstico, contribuindo para uma melhor compreensão dos mecanismos de degradação associados à humidade.

Os resultados evidenciam que a infiltração de água constitui o principal fator de degradação da envolvente dos edifícios, sendo a patologia mais frequente e associada à maioria dos processos de deterioração observados. Este facto confirma a elevada vulnerabilidade dos elementos construtivos às falhas de estanquidade e à ação da água da chuva, particularmente em fachadas e nas interfaces com vãos.

Verificou-se ainda que as patologias higrotérmicas não ocorrem de forma isolada, mas sim integradas em cadeias de degradação inter-relacionadas. Destaca-se a associação entre infiltração, degradação de revestimentos e eflorescências, bem como entre condensação e degradação biológica, evidenciando a existência de mecanismos físicos distintos associados, respetivamente, à envolvente exterior e às condições higrotérmicas interiores.

A análise por elementos construtivos demonstrou que as paredes constituem o elemento mais vulnerável, devido à sua exposição às ações climáticas e à sua função como principal interface entre o ambiente exterior

e interior. Pavimentos e coberturas apresentam igualmente relevância, sobretudo em situações de contacto com o solo ou exposição direta à precipitação.

Do ponto de vista estatístico, foram identificadas associações significativas entre patologias, elementos construtivos e causas, confirmando a existência de padrões consistentes de ocorrência e reforçando a natureza não aleatória dos processos de degradação higrotérmica. Em particular, distinguem-se dois grandes grupos de mecanismos dominantes: (i) patologias associadas à entrada de água na envolvente, relacionadas sobretudo com deficiências de estanquidade; e (ii) patologias associadas às condições higrotérmicas interiores, resultantes de ventilação insuficiente e desempenho térmico inadequado.

Do ponto de vista aplicado, os resultados evidenciam a necessidade de estratégias de diagnóstico e reabilitação centradas nas causas dos fenómenos e não apenas nas suas manifestações visíveis. A correção de patologias superficiais sem eliminação dos mecanismos subjacentes tende a conduzir à recorrência dos problemas ao longo do tempo.

Em termos gerais, este estudo contribui para o conhecimento dos mecanismos de degradação higrotérmica em edifícios, através da sistematização de um conjunto alargado de dados empíricos provenientes de relatórios técnicos reais. A abordagem estatística adotada permite identificar padrões consistentes entre patologias, elementos construtivos e causas, fornecendo uma base útil para o desenvolvimento de metodologias de diagnóstico mais robustas e estratégias de reabilitação mais eficazes.

Como trabalho futuro, recomenda-se o alargamento da base de dados a outras regiões e instituições, bem como a integração de variáveis contextuais e de monitorização higrotérmica contínua, de forma a aprofundar a compreensão dos mecanismos de degradação e aumentar a capacidade preditiva das análises.

Agradecimentos

Building Inspection As A Technical Tool For Risk Management: A Case Study–Based Methodology For Intervention Prioritization In Residential Buildings

Mariana GOMES SCHAEFER[1], Elisangela SOUZA RIBEIRO SILVA[2]

[1] Instituto Nova Engenharia, Porto Maua, Brasil, marianaschaefer@hotmail.com1

[2]Pindamonhangaba, Brasil, elisaeng.civil@gmail.com2

Abstract: The aging of the existing building stock, combined with the absence of systematic maintenance plans, has increased the occurrence of pathological manifestations and risk situations in multifamily residential buildings. In this context, building inspection plays a strategic role, enabling not only the diagnosis of existing defects but also supporting technical decision-making based on risk criteria. This article aims to present and discuss the application of a structured building inspection methodology using a multifamily residential condominium as a case study and to evaluate its potential as a risk management and intervention prioritization tool. The adopted methodology is based on systematic visual technical inspections, the classification of defects according to building systems, the analysis of their origin and criticality, and the prioritization of interventions according to the associated risk level. The analyzed data were obtained from a technical inspection report, allowing the identification of the most critical systems and the assessment of the impacts resulting from the lack of preventive maintenance. The results indicate that the methodological application of building inspections makes it possible to transform technical information into objective support for decision-making, contributing to risk mitigation, resource optimization, and the extension of the building's service life. It is concluded that building inspection, when guided by technical criteria and risk analysis, constitutes an essential tool for the technical management of residential buildings, with a high potential for replication in different construction contexts.

Keywords: Building inspection; risk management; maintenance management; service life; multifamily residential buildings.

1. Introduction

When dealing with engineering works, they are commonly associated with characteristics such as safety, strength, durability, and versatility. However, constructions cannot be considered permanently durable, as they are subject to deformation and deterioration processes resulting from physical and chemical phenomena inherent to materials over time.

According to IBAPE (2005), pathological manifestations correspond to defects that occur in civil constructions as a result of multiple factors. Building pathology can be understood as the set of manifestations that arise during construction or throughout the service life of a building, compromising the expected performance of the structure and its constituent systems.

The term "pathology" originates from the Greek words *pathos* (disease) and *logos* (study), meaning the study of diseases. In the context of civil engineering, it refers to the analysis of building degradation mechanisms. Pathological analysis also involves fundamental aspects such as the time of occurrence and the exposure conditions of building components, making concepts such as durability, service life, and performance particularly relevant (ALVES and SIMEÃO, 2022).

The safety, performance, and durability of residential buildings are central concerns in contemporary civil engineering. The aging of the building stock, combined with the absence of systematic maintenance practices, has significantly contributed to the emergence of pathological manifestations, premature degradation of building systems, and, in more critical situations, risks to the physical integrity of occupants.

Pathological problems may originate from several factors, including unforeseen overloads, the use of inadequate or low-quality materials, insufficient knowledge of material properties, noncompliance with technical standards, design flaws, construction errors, lack of maintenance, and the natural aging of buildings. Furthermore, environmental conditions exert a direct influence on the degradation processes of building systems (FARIAS and MARINHO, 2021).

For the proper intervention of identified pathologies, a detailed study of their causes and formation mechanisms is indispensable. Knowledge of the different types of pathological manifestations contributes significantly to an accurate diagnosis. Through this process, combined with technical inspection and proper management, it is possible to identify the symptoms, causes, and origins of anomalies (TUTIKIAN and PACHECO, 2013).

Following the stages of inspection, diagnosis, and prognosis, it is the responsibility of the professional in charge to define the interventions necessary to correct the identified problems. The set of actions aimed at the recovery, repair, or strengthening of structures is referred to as therapy. Considering that each type of anomaly presents specific characteristics, the careful selection of the most appropriate techniques and materials for each situation becomes essential (ARAÚJO, 2021).

Traditionally, building maintenance in residential structures is carried out reactively, motivated by the occurrence of visible failures or emergency situations. This approach, besides being economically inefficient, tends to increase risk levels and reduce the service life of the building. In this context, building inspection stands out as a fundamental technical tool, capable of providing structured information regarding the condition of building systems and supporting decision-making based on technical and risk-related criteria (HELENE, BOLINA, and TUTIKIAN, 2019).

For professionals in the field, the correct identification and classification of anomalies present in a building are essential. These manifestations may be associated with both construction defects and performance deficiencies related to the building system, as well as defects that pose risks to the safety and health of occupants. A proper understanding of these occurrences contributes significantly to technical analysis and to the development of effective maintenance and intervention plans.

Given this context, the relevance of studying building pathologies becomes evident, both from preventive and corrective perspectives. Therefore, this article aims to demonstrate how building inspection, when conducted systematically and guided by risk analysis, can be used as a management tool for prioritizing interventions in multifamily residential buildings. To this end, the application of a building inspection methodology in a residential condominium is presented, based on real data obtained from a technical report, with the additional objective of contributing to the development of practical guidelines to assist professionals in decision-making processes.

2. Theoretical Framework

2.1. Building Maintenance

Building maintenance constitutes an essential component of contemporary civil engineering, being directly responsible for preserving the performance, safety, functionality, and durability of buildings throughout their life cycle. According to ABNT NBR 5674:2012, maintenance is defined as the "set of activities to be carried out in order to preserve or restore the functional capacity of a building and its constituent systems."

This definition broadens the traditional concept of maintenance, which is no longer viewed as exclusively corrective but rather as a continuous, preventive, and strategic process. This perspective is aligned with ABNT NBR 15575:2013 (Performance Standard), which introduces the concept of Design Service Life (DSL), conditioning building performance on the proper execution of maintenance activities throughout its lifespan.

ABNT NBR 5674:2012 establishes three main types of maintenance: Corrective maintenance: performed after the occurrence of failures; Preventive maintenance: based on scheduled interventions; Predictive maintenance: based on performance monitoring.

Within the context of the case study, there is a predominance of failures resulting from the absence of preventive maintenance, as evidenced by the presence of pathologies such as water infiltration, cracking, and coating degradation.

Authors such as Helene (2005) emphasize that every building is subject to natural degradation processes resulting from physical, chemical, and biological actions, including concrete carbonation, reinforcement corrosion, thermal variations, and the action of aggressive environmental agents.

Building maintenance should be understood as an organized management system involving the planning, execution, control, and documentation of interventions. Furthermore, the standard highlights the importance of the User, Operation, and Maintenance Manual, as established by ABNT NBR 14037:2011, an essential document for guiding users and facility managers.

According to Sena (2020), the absence of a structured maintenance system is one of the main causes of premature building deterioration, resulting in accelerated degradation, exponential increases in maintenance costs, reduced service life, and safety risks, among numerous other consequences. Studies in the field of building pathology indicate that intervention costs increase exponentially over time and may be up to five times higher when repairs are carried out during advanced stages of deterioration.

In this context, maintenance acts as a fundamental mechanism for controlling deterioration through periodic inspections and planned interventions, contributing to delaying the progression of pathological manifestations and ensuring compliance with performance requirements throughout the building's service life.

2.2. Building Inspection

Building inspection constitutes an important technical tool for the identification, analysis, and classification of anomalies and defects in buildings. However, it is still not widely adopted by condominium managers and facility administrators, which compromises its preventive and predictive role, limiting its application primarily to corrective situations.

Building inspection differs from isolated surveys due to its comprehensive, structured nature and its focus on identifying anomalies, defects, and nonconformities across the various building systems.

According to ABNT NBR 16747 (ABNT, 2020), building inspections must follow specific guidelines, emphasizing the importance of adopting an appropriate methodology, systematically documenting evidence, and conducting a technical analysis of the identified pathological manifestations. When performed rigorously, inspection enables not only the diagnosis of the current condition of a building but also an understanding of the degradation mechanisms that are developing over time.

Deutsch (2016) highlights that the early identification of construction-related problems significantly facilitates their resolution and reduces intervention costs. The analysis and understanding of deterioration symptoms, whether in structural elements or finishing components, help prevent or minimize the progression of damage over time. In this regard, periodic inspections become essential for the continuous monitoring of building conditions.

The absence of inspection and, consequently, adequate maintenance tends to generate progressive problems in buildings, leading to premature obsolescence and the emergence of construction deficiencies. A lack of awareness regarding the importance of building inspection contributes to making necessary interventions more complex and economically burdensome.

Building maintenance is not limited to preserving property assets; it also aims to ensure that performance levels remain within acceptable standards, preventing user discomfort and restrictions on building use. Through appropriate inspection and maintenance practices, it is possible to extend the service life of a building and ensure improved conditions of safety and habitability (Farias and Marinho, 2021).

In this context, building inspection in structures exhibiting pathological manifestations has become an increasingly relevant topic in civil engineering, particularly in response to growing demands for safety and performance in buildings (Sena et al., 2020). Problems resulting from such manifestations may range from minor defects to situations that compromise structural stability and, in extreme cases, may lead to building collapse.

2.3. Risk Management

Risk management applied to buildings involves the systematic identification, analysis, and assessment of events that may compromise the safety, performance, and functionality of building systems. In this context, risk-based maintenance emerges as a strategic approach in which interventions are prioritized according to the probability of failure occurrence and the severity of their consequences throughout the building's life cycle.

Approaches aligned with international standards, such as ISO 31000, reinforce the need for decision-making processes based on technical criteria and structured methodologies, reducing subjectivity in assessments and promoting a more efficient allocation of resources. The integration of building inspection and risk management makes it possible to transform technical data into strategic information, contributing to the development of more effective, performance-oriented maintenance plans.

In the context of residential buildings, risk can be understood as the combination of the probability of failure occurrence and the magnitude of its consequences. Risk management in civil engineering involves stages such as hazard identification, vulnerability analysis of building systems, and the definition of appropriate mitigation measures, considering technical, operational, and economic aspects.

Based on the technical literature and building inspection practices, risks in buildings can be classified into different categories. Structural risk is related to the stability of the building and includes situations such as loss of load-bearing capacity, excessive cracking, and, in extreme cases, partial or total collapse. Functional risk refers to the impairment of building system performance, including failures in installations, water infiltration, and degradation of enclosure components. Health risk is associated with conditions that affect indoor environmental quality, such as the presence of moisture, mold, and biological agents. Economic risk is linked to the progressive increase in intervention costs resulting from the absence of preventive maintenance and the advancement of pathological manifestations (MARTINS and CAVALCANTE, 2022).

In addition to these classifications, risk assessment in buildings should also consider the concept of criticality, which relates the importance of the affected system to the consequences of its failure. Essential systems, such as structural and safety-related systems, require greater rigor in analysis and intervention prioritization. In this regard, the adoption of risk matrices and prioritization tools enables a more objective and transparent approach to defining corrective and preventive actions (Carraro, 2020).

Another relevant aspect concerns the integration of risk management with the principles of durability and service life of buildings. The degradation of materials and building components occurs progressively and, when not monitored, may lead to significant performance loss. The incorporation of risk-based maintenance strategies allows failures to be anticipated, reduces the need for emergency interventions, and increases the overall efficiency of building management, aligning with regulatory requirements and international best practices.

Therefore, it is essential to understand that risk management should be directly integrated into maintenance practices, constituting a continuous and dynamic cycle composed of inspection, diagnosis, intervention, and monitoring stages. This process enables the systematic monitoring of building conditions, supporting more accurate and sustainable decision-making over time.

In summary, the application of risk management in conjunction with building inspection represents a consistent technical approach for improving building performance and safety. By enabling the rational prioritization of interventions and the optimization of available resources, this integration contributes significantly to extending the service life of buildings, reducing long-term costs, and mitigating risks to occupants, thereby establishing itself as an essential practice in contemporary civil engineering (Antunes, 2010).

3. Methodology

This study is characterized as applied research of an exploratory nature, conducted through a case study using both qualitative and quantitative approaches, based on the implementation of a technical building inspection and risk analysis. The adopted methodology consists of the application of a systematic visual building inspection in multifamily residential buildings, aiming to identify and evaluate the performance conditions of building systems.

Initially, a literature review on building inspection and risk management was conducted to provide the theoretical foundation for the study. Sources such as books, scientific articles, technical standards, and specialized publications, both in print and electronic formats, were consulted to ensure the necessary basis and consistency for the research development.

The inspection covered the main building systems of the analyzed properties, including structural systems, façades, roofing systems, electrical installations, plumbing and sanitary systems, and common areas. The identified anomalies were classified according to their origin, nature, and level of criticality, considering criteria related to safety, performance, and potential impact on occupants.

The prioritization of interventions was carried out using a risk-based analysis approach, associating the severity of consequences with the probability of progression of the pathological manifestations. The analyzed data were obtained from a technical building inspection report prepared by a qualified professional, ensuring the reliability of the information used.

As a complementary outcome of the research, a set of technical guidelines was developed and structured in the form of a guidance manual, with the objective of assisting professionals in the identification, analysis, and prioritization of interventions in buildings affected by pathological manifestations.

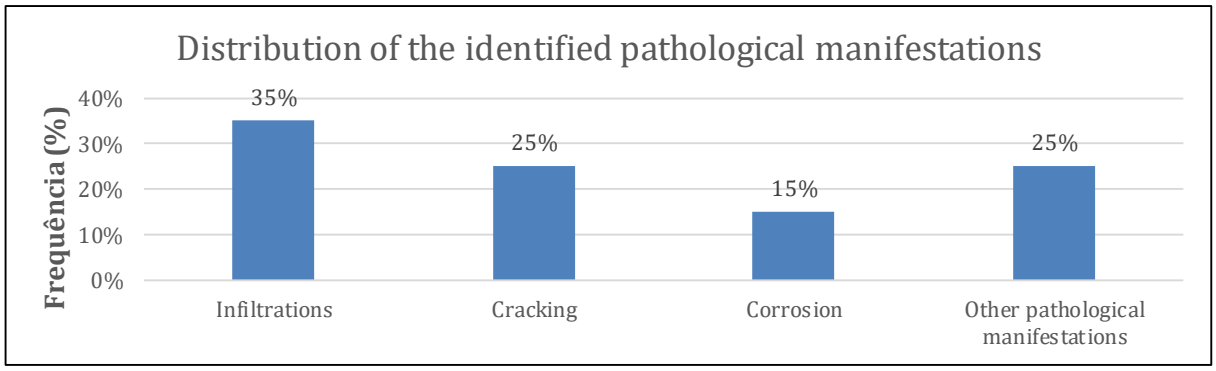
3.1 Description of the Case Study

The case study refers to a medium-sized multifamily residential building, more than a decade old, constructed using a conventional reinforced concrete structural system. The building is in continuous use and lacks a documented history of systematic preventive maintenance. The inspected areas included façades, common areas, exposed structural systems, roofing systems, and accessible building installations. No destructive testing or laboratory evaluations were conducted, characterizing the inspection as predominantly visual in nature.

3.2 Results

The analysis of the pathological manifestations identified during the inspections revealed a predominance of problems related to water infiltration, accounting for 35% of the recorded occurrences. This was followed by cracking, representing 25% of the observed anomalies, corrosion processes, accounting for 15% of the occurrences, and other pathological manifestations, which represented the remaining 25%.

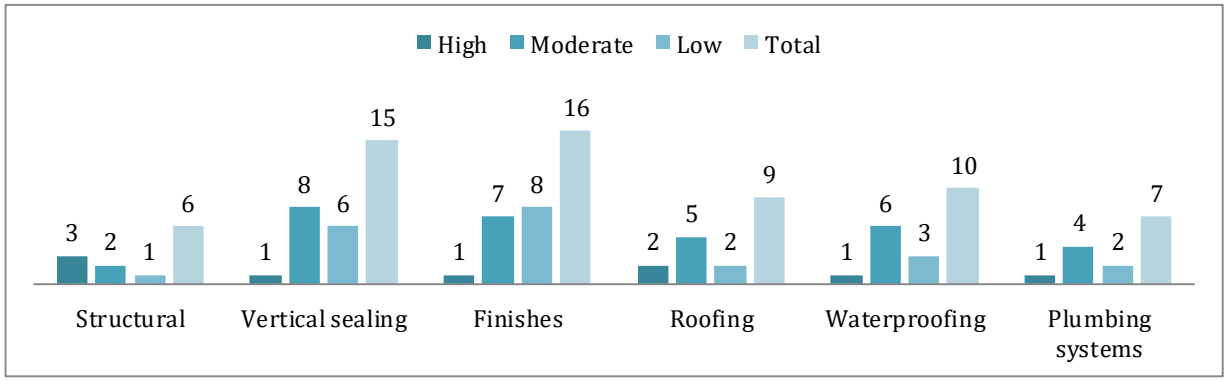
The most affected building systems were the façades, with 12 recorded anomalies classified as having high criticality, followed by roofing systems, with 8 occurrences classified as medium criticality, and structural systems, with 5 occurrences classified as critical.



Based on the pathological manifestations identified during the building inspection, and considering that a significant proportion of buildings lack formal inspection records or systematic maintenance plans, a practical guide was developed for engineering and building inspection professionals. The purpose of this material is to assist in the technical diagnosis of anomalies, risk management, maintenance control, and decision-making support.

The practical building inspection guide was structured based on the analysis of technical reports and the recurrence of pathological manifestations observed in buildings, enabling the systematization of the main occurrences and their implications for the performance of building systems. This approach makes it possible to transform empirical data into technical guidelines applicable to professional practice.

Consequently, the guide contributes to the standardization of inspection and maintenance practices, promoting greater efficiency, safety, and reliability in interventions carried out on buildings.



3.2.1 Analysis of Building Defects Identified in the Residential Building

Figure 1 – Percentage Distribution of Building Defects Identified During the Building Inspection

Water infiltration was identified as the most prevalent defect, accounting for 35% of the recorded occurrences, followed by cracking (25%) and corrosion-related deterioration (15%). The remaining defects collectively represented 25% of the anomalies identified during the inspection process.

Figure 2 – Distribution of Anomalies by Building System and Criticality Level

The analysis of the building inspection results revealed a predominance of pathological manifestations classified as having moderate criticality, accounting for 50.0% of the total recorded anomalies (34 occurrences). Low-criticality anomalies represented 33.8% of the occurrences (23 records), while those classified as high criticality corresponded to 16.2% of the total (11 occurrences).

It was observed that façade cladding and vertical enclosure systems exhibited the highest incidence of pathological manifestations, highlighting the need for both corrective and preventive maintenance actions in these components. On the other hand, although the structural and roofing systems presented a lower number of occurrences, they accounted for the majority of the anomalies classified as highly critical due to their potential risks to occupant safety, building stability, and the performance of building systems.

The results demonstrate that evaluating criticality in conjunction with the frequency of pathological manifestations constitutes a valuable tool for establishing intervention priorities. This approach enables maintenance resources to be directed toward the systems with the greatest potential impact on building safety, functionality, and durability..

3.2.2 Technical Guide for Residential Building Inspection

This manual aims to guide professionals in conducting comprehensive building inspections of existing residential buildings, enabling them to identify construction defects, assess the condition of building components, classify risks, propose technical interventions, and support the development of maintenance plans.

Table 1 – Stage 1: Inspection Planning

Scope definition	
Inspection Type (NBR 16747)	**Description**
Simple Visual Inspection Level (1)	It is a preliminary inspection based on visual observation and photographic records, conducted without the use of diagnostic equipment or destructive and non-destructive testing methods.
Detailed Visual Inspection Level (2)	It involves a more detailed visual inspection and may include the use of basic diagnostic equipment (such as moisture meters, crack gauges, and similar devices), as well as the analysis of technical documentation, including drawings, specifications, and operation and maintenance manuals.
Comprehensive Inspection Level (3)	It is the most comprehensive level of inspection, involving non-destructive testing, laboratory analyses, the use of advanced diagnostic equipment, and, when necessary, consultation with specialized experts.
Inspection Areas	Common Areas; Residential Units; Technical Areas.
Objective	General Diagnosis; Risk Assessment; Support for Rehabilitation Planning..
Documentary Review	
Documents	Design documents (architectural, structural, and building services drawings); Building operation and maintenance manual (ABNT NBR 14037); Maintenance history records (ABNT NBR 5674); Previous inspection reports or technical assessments; Building age.
Logistical Planning	
Description	Schedule access to residential units; Verify personal protective equipment (PPE) requirements (hard hat, gloves, safety boots, safety glasses, etc.); Prepare inspection equipment, including a camera, moisture meter, thermal imaging camera, measuring tape, crack gauge, level, and other necessary tools.

Table 2 – Stage 2: External Building Inspection

Areas	Inspect	Observations
Facade	Cracking (vertical, horizontal, and diagonal); Detachment of cladding or finishing materials; Efflorescence; Presence of vegetation; Condition of expansion joints; Deterioration of stonework elements.	Common Defects: Water infiltration through cracking; Concrete carbonation; Coating system failure.
Roof	Type (flat or pitched); Waterproofing condition; Presence of water ponding; Drains and drainage system; Cracks; Metal elements (corrosion).	Critical Attention: Water infiltration; Drainage system failures; Connections to vertical service risers.
Terraces and Balconies	Cracking; Improper slope (insufficient drainage gradient); Deterioration of flooring surfaces; Water infiltration; Guardrail systems.	
External Structural Elements	Exposed reinforcing steel; Reinforcement corrosion; Concrete spalling/delamination; Structural deformations.	

Table 3 – Stage 3: Internal Inspection of Common Areas

Areas	Inspect	Observations
Stairwell	Walls (moisture and cracking); Ceilings; ventilation and lighting conditions; Condition of surface finishes.	
Basements and Garages	Rising damp; Moisture ingress / water infiltration; Mold growth; Drainage system performance; Ventilation conditions.	
Technical Areas	Mechanical room; Water storage tanks; Electrical distribution boards; Service risers (vertical shafts).	

Table 4 – Stage 4 – Inspection of residential units

Areas	Inspect	Observations
Walls and Ceilings	Cracking; Moisture staining; Mold growth; Paint delamination/peeling..	
Kitchens and Sanitary Installations	Water infiltration; leakage; Ventilation and condensation; Condition of surface finishes.	
Openings (doors and windows)	Sealing performance; Water ingress; Degradation of window/door frames; Thermal bridging.	
Flooring	Detachment (or peeling) Cracking Deformations Moisture / Dampness	

Table 5 – Stage 5 – Inspection of building systems

Areas	Inspect	Observations
Structural system	Structural cracks; Deformations; Reinforcement corrosion	
Waterproofing system	Roof defects (or roofing failures); Infiltrations / Water ingress; Membrane deterioration	
Hydraulic system	Leaks; Inadequate pressure; Infiltrations / Water ingress	
Electrical system	Overloads; Electrical panels (distribution boards); Exposed wiring	

Table 6 – Stage 6 – use of instrumentation

Areas	Inspect	Observations
Thermography	Identify thermal bridges; Detect hidden infiltrations / concealed; water ingress.	
Moisture measurement	Identify rising damp; Assess critical levels.	
Crack gauge	Measure crack progression / crack development over time	
Other equipment	Level; Measuring tape; Lux meter (optional)	

Table 7 – Stage 7 – Identification and classification of pathologies

Type	Origin	Severity classification
Cracking; Infiltration / Water ingress; Corrosion	Design; Execution / Construction; Maintenance	Light; Moderate; Severe

Table 8 – Stage 8 – Analysis of causes

Type	Analysis	Observations
Relate the pathologies	Construction defects; Lack of Maintenance; Environmental factors; Improper use / Inadequate use.	

Table 9 – Stage 9 – Prioritization of interventions

Time for action	Classification and criteria	Priority level	Weight	Action
Immediate	Manifestations with an imminent risk to the physical integrity of users, to the structural stability of the building, or to the continuity of operation of essential systems.	Critical	5	Immediate intervention
Short term	Structural problems, severe infiltrations, detachment of materials, and safety risks.	High	4	Short-term intervention
Medium term	Non-structural cracks, deterioration of finishes, waterproofing failures, and localized infiltrations.	Moderate	3	Monitoring and scheduled corrective action
Long term	Aesthetic manifestations or low-progress defects, with no significant impact on safety or functionality.	Low	1	Preventive maintenance

Table 10 – Stage 10 – Explicit weighting criteria

Criticality Index (CI)	**Rating Scale**	
IC= P x I x U	Note	Description
Where: • P = Probability of progression; • I = Functional/structural impact; • U = Urgency of intervention.	1 2 3	Low Moderate High

Table 11 – Stage 11 – Preparation of the technical report

To be presented in the report	Property identification; Construction description; Methodology; Photographic record; Identified pathologies; Diagnosis; Risk analysis; Recommendations	**Observations**

Table 12 – Stage 12 – Maintenance plan

Proposed Maintenance	Preventive Maintenance; Corrective Maintenance; Schedule; Monitoring.	**Observations**

Table 13 – Stage 13 – Professional best practices

Guidelines	Comply with technical standards; Document all evidence; Use clear technical language; Maintain impartiality; Ensure safety during inspection.	**Observations**

Table 14 – Stage 14 – Practical checklist (operational summary)

CheckList	Planning; Document review; External inspection; Internal inspection; Systems assessment; Use of instruments; Diagnosis; Risk analysis; Prioritization; Report preparation.	**Observations**
Simplified Inspection Flow	Plan → Inspect → Diagnose → Classify risk → Intervene → Monitor	

From a practical perspective, the results contribute to the work of engineers, facility managers, and condominium administrators by providing a technical basis for the development of maintenance plans. The methodology presented can be replicated in other buildings, provided that their specific construction characteristics are taken into consideration. An effective building inspection requires a systematic, technical, and integrated approach that considers all building components and systems. Building pathology professionals should not only identify defects but, more importantly, interpret their underlying causes and implement measures to prevent risks, thereby ensuring safety, durability, and performance throughout the building's life cycle.

4. Conclusion

This study aimed to present and systematize the main stages of building inspection in existing buildings, highlighting its relevance as a technical tool for performance assessment. The objective was to demonstrate to building inspectors, facility managers, and other professionals in the construction industry that building inspection constitutes a fundamental instrument for analyzing risk factors associated with building safety, encompassing activities ranging from data collection and document verification to the technical responsibilities related to building maintenance management.

The results obtained corroborate previous studies that identify water infiltration as one of the most recurrent pathological manifestations in multifamily residential buildings, generally associated with waterproofing failures, sealant degradation, inadequate drainage systems, lack of preventive maintenance, and deficiencies in cladding systems. The high incidence of these occurrences in façades and roofing systems reinforces the need for periodic inspections and preventive maintenance programs focused on building enclosure and protection systems.

Furthermore, although the structural system exhibited a lower number of anomalies, its classification as critical demonstrates that risk assessment should not be based solely on the frequency of occurrences but also on their potential consequences for building safety and durability.

The findings presented are limited to the analysis of a single case study and therefore do not allow for absolute generalizations to other building typologies. Nevertheless, the proposed methodology demonstrates potential for replication in different contexts. The main contribution of this study lies in the development of a simplified methodology for prioritizing interventions based on building inspection and risk analysis.

The analysis clearly demonstrated that building safety is a cross-cutting issue involving all stakeholders in the construction process, from the design phase to maintenance management throughout the building's service life. In this regard, the importance of raising awareness and providing training for managers of multifamily residential buildings regarding the need for periodic inspections and the implementation of structured maintenance plans should be emphasized.

Building conservation represents an essential strategy for ensuring the proper functioning of building systems and minimizing the occurrence of defects. Building safety is directly related to the adoption of appropriate practices in design, construction, operation, and maintenance. Consequently, preventive action proves to be more effective than reactive approaches, making it inadequate to wait for pathological manifestations to appear before taking corrective measures. Therefore, periodic inspections, technical assessments, and continuous monitoring of building conditions are indispensable.

The adoption of a structured maintenance plan, combined with proper document management and systematic monitoring of building conditions, contributes significantly to the prevention of failures, the reduction of corrective intervention costs, and the extension of the service life of building systems.

In conclusion, when conducted through a structured methodology and guided by risk-analysis criteria, building inspection constitutes a strategic tool for the technical management of multifamily residential buildings, promoting greater safety, performance, and durability throughout their life cycle.

Abstract: Sonic testing provides essential information about the internal condition of historical construction systems and materials, such as masonry and rammed earth walls. The method is fully non-destructive and is based on the emission of low frequency acoustic waves that are able to penetrate through thick construction elements. The analysis of the propagation characteristics of the sonic wave through a wall, e.g., sonic velocity, allows differentiating sound areas from deteriorated ones, or identifying inner voids. Nevertheless, sonic inspection is commonly carried out manually, which turns the process highly time consuming if the objective is to evaluate large areas of a building. Moreover, manual inspections are also limited to areas of the buildings that are accessible by hand, preventing the inspection of upper areas of the building with no access from the exterior.

The present paper shows the result of a large-scale sonic inspection of the upper part of the northern façade of the Torre de la Vela, in the Alhambra. The wall is made of rammed earth with visible cracks and alterations done with brick masonry. A Cable-Driven Parallel Robot was fabricated to automate the sonic emission from the exterior part of the tower. The sonic wave was received with accelerometers placed in the interior. An area of 13 m x 4 m, at a height of around 20 m above ground, was inspected. Automating the inspection resulted in a total of 168 emission points and 368 reception points, separated approximately 0.5 m between them, thus obtaining a dense coverage of the inspected area. The results illustrate the large variability in the inner conditions of the earthen wall in different areas of the façade. The presented on-site application and validation shows the potential of using highly automated systems for the inspection and structural diagnosis of the architectural heritage.

Keywords: Built heritage; non-destructive testing (NDT); sonic testing; cable-driven parallel robot; rammed earth.

1. Introduction

Non-Destructive Testing (NDT) is a fundamental tool for the on-site structural diagnosis of construction elements that guarantees their integrity without disrupting their functioning. This is particularly important for historical constructions, as there is a need to avoid any possible harm to the original material during inspection. Among NDT techniques, sonic testing is particularly widespread for historical masonry elements. The propagation of sonic waves through, for example, thick masonry walls, varies according to their internal condition. Thus, the analysis of sonic wave propagation characteristics, e.g., velocity, through a wall, allows detecting deteriorated areas, identifying inner voids or cracks or evaluating their inner morphology (Leucci *et al.* 2011; Valluzzi *et al.* 2018; Luchin *et al.* 2020).

However, most NDT techniques, including sonic testing, usually have an important limitation. They were initially conceived for localized inspections and are carried out manually. As a result, enlarging the scale of inspection to large areas of a building, such as a full façade, becomes impossible in practical terms due to time constraints. More so, if the aim is to evaluate upper areas of the building that are out of reach for manual inspections, unless considering the use of supplementary structures like scaffolding.

This limitation can be addressed through the development of robotic systems. These systems require automating the robot movement, precise positioning and ensuring good quality signal emission. The present paper aims to show the results obtained with a novel Cable-Driven Parallel Robot (CDPR) system developed to carry out sonic testing in large vertical surfaces, such as building façades. Its functioning (movement, repetition, speed, signal emission quality, etc.) was tested at the *Torre de la Vela*, the tallest and most emblematic rammed earth tower in the *Alcazaba* of the *Alhambra*, in Granada (Spain).

The upper part of the northern façade was inspected using the CDPR. The wall is made of rammed earth and shows cracks and alterations done with brick masonry. The automated system allowed inspecting an area of approximately 13 m x 4 m (length x height), at a height of 20 m above the ground. The objective was to collect enough data to carry out the tomographic reconstruction of the portion of the façade inspected, which requires a dense coverage of the inspected area with multiple emission and reception positions.

The present paper first introduces the concept and principles of tomographic reconstruction based on sonic data. Then, the test method and setup are presented, including a brief introduction of the CDPR and its development. Finally, the results obtained are shown and discussed, which include 3D tomographic images and illustrate the high spatial variability in the inner conditions of the earthen wall across the portion of the façade evaluated.

2. Principles of tomographic reconstruction

The procedure used for sonic inspection is based on the transmission method. Sonic waves propagate from one surface of the wall to the opposite one. In practical terms, the test consists of introducing mechanical energy into the solid by means of an impact generated on one of its surfaces. The energy propagates through the solid as elastic waves, and a receiver, e.g., an accelerometer located at another point in the solid, records the signal. For each emitter (impact) and receiver position, i.e., each emitter-receiver pair, the time of flight can be calculated, and, since the distance between them is known, the velocity of propagation can also be estimated. This velocity depends on the physical and mechanical properties of the solid, such as density and modulus of elasticity. However, the velocity estimated by this method also depends on the internal condition of the solid. The existence of cracks or voids within a solid will cause the wave path to deviate from the straight line between the emission and reception coordinates assumed for the calculation, which means that the estimated velocity decreases. Lower velocities are thus generally associated with material deterioration and the presence of cracks or material discontinuities within the structure. That is why sonic tests are particularly useful for evaluating the degree of homogeneity of historic structures, such as the rammed earth walls of the *Torre de la Vela*.

When sonic tests are performed manually, the inspection is usually focused on specific areas. Localized measurements can detect isolated internal defects, but they are not always representative of the highly heterogeneous cross-sections that characterize historic building elements. Sonic tomography can be used to obtain a more detailed graphic representation of the interior, but it requires multiple emitter-receiver pairs to generate a large number of intersecting sonic rays that penetrate the material from different angles.

The results of a tomographic inspection are *N* sonic rays that intersect at different angles, covering a volume defined by the inspection window. There are various tomographic reconstruction methods that allow obtaining images of the interior of masonry elements based on acoustic (sonic or ultrasonic) wave propagation data (Fais and Casula 2010; Zielińska and Rucka 2018; Matías *et al.* 2021). Most methods are based on discretizing the inspected volume into a specific number of voxels. Each voxel is traversed by a

varying number of rays. A value of velocity is assigned to each voxel based on the information from the traversing rays. For example, the Simultaneous Iterative Reconstruction Technique (SIRT) (Kaks and Slaney 2001), estimates the velocity by solving iteratively a system of equations constituted by as many equations as rays resulting from the inspection. Each equation multiplies a slowness value (defined as the inverse of the velocity) in each voxel by the distance traversed by the ray within this voxel. The sum of all the times computed for all voxels traversed by the ray should be equal to the total time of flight of this ray. The iterative process followed to solve such system of equations continues until convergence is reached, i.e., when the calculated times of flight of all rays match the measured times within a predefined margin of error.

In the present paper, the reconstruction method adopted involves assigning to each voxel a value of velocity that is the median of the estimated velocities of all sonic rays passing through that voxel. To minimize the impact of outliers, the median value is used instead of the average. Given the significant variability in the distances between emitters and receivers used for this calculation, the median is weighted, giving greater weight to the velocities calculated for rays traveling shorter distances. The aim is to minimize the greater uncertainty in calculating the velocity for longer rays. It should be noted that, in the present case study, some emitter-receiver distances can exceed 5 m, while the wall thickness is approximately 1.6 m. Finally, to smooth the transition between voxels, the values are adjusted by averaging them with neighbouring voxels.

Obtaining a velocity value for each voxel within the volume, allows reconstructing tomographic images in 3D and obtaining a point cloud of velocity values within the volume, i.e., an inner 3D point cloud. This point cloud can be combined with the 3D point cloud obtained, for example, from a photogrammetric reconstruction, i.e., the exterior 3D point cloud. The integration of both point clouds can help in the interpretation of the results by associating superficial and inner information of the inspected element.

The resolution of the tomographic reconstruction depends on the number of rays. A greater number of rays allows for a smaller voxel size, as there will be more intersecting rays per voxel. Consequently, the resolution of the reconstructed image will be higher. This effect is illustrated by the diagram in Figure 1, representing a 1 x 1 x 1 m inspected volume. Aiming for a tomographic reconstruction, there is a need for intersecting rays that a direct sonic test inspection cannot provide (Figure 1a). Increasing the number of emission and reception points, and, therefore, the number of rays, allows obtaining a denser coverage of the inspected volume, resulting in a higher-resolution tomographic image. For example, if the same voxel size division was used for the two cases displayed in Figure 1b and 1c, the low-resolution case (Figure 1b) could contain voxels with no information (with no rays traversing them).

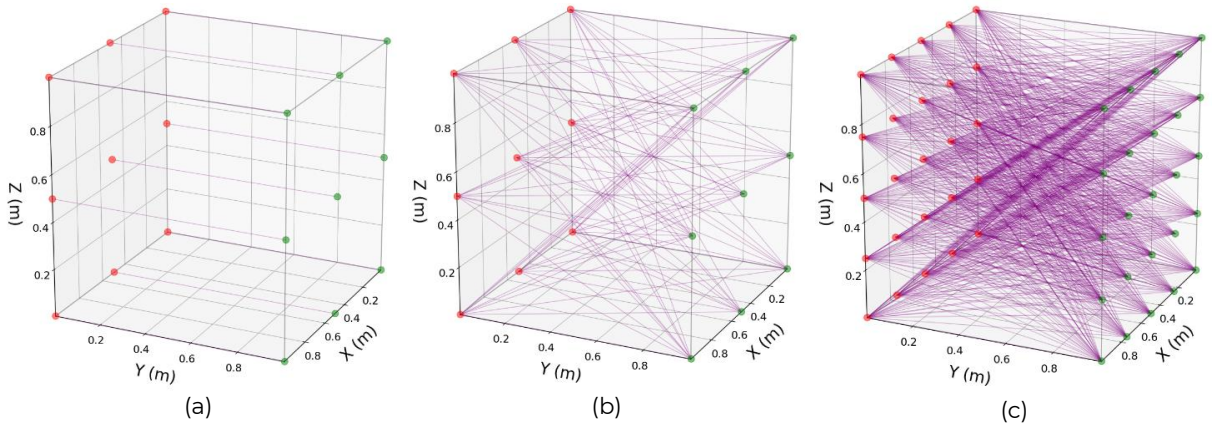

Figure 1 – Tomographic resolution based on the number of rays: (a) only direct transmission rays; (b) low resolution grid (c) high resolution grid

The preceding graphs demonstrate that generating a tomographic image requires a large number of rays to adequately cover a representative volume of the wall. For this reason, sonic inspection for tomographic imaging is difficult to implement in practice if it is done manually, as it becomes highly time-consuming.

For this technique to be viable, automated systems are necessary. Automating sonic tomography inspections allows to increase the resolution in a region of interest simply by increasing the number of sampling points in the area where a relevant structural anomaly or irregularity has been detected. Furthermore, automating the inspection also allows increasing the scale of inspection, moving from local inspections to large areas (e.g., an entire facade).

3. Inspection methodology

The robotic inspection system was tested at the *Torre de la Vela*. Figure 2 shows the inspection area over an orthophoto of the north façade, obtained from a photogrammetric survey. The tower has a square floor plan measuring 16 meters on each side and is 26.8 meters high. The elevation of the north façade shows that it is constructed with two materials: rammed earth as the original material and brick masonry, likely used for repairs. The interior of the wall is whitewashed. The inspection area has a total extent of 12.7 m wide x 3.5 m high (marked in red in Figure 2). Within this area, there are repair patches made with brick masonry, specifically the entire area above the window, and several vertical cracks visible from the exterior.

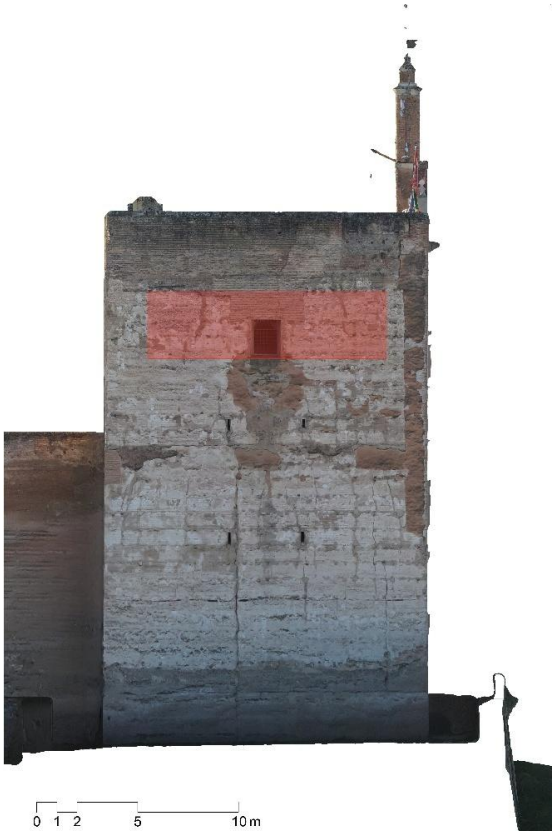

Figure 2 – Orthophoto of the north façade of the *Torre de la Vela* with the inspection area marked in red.

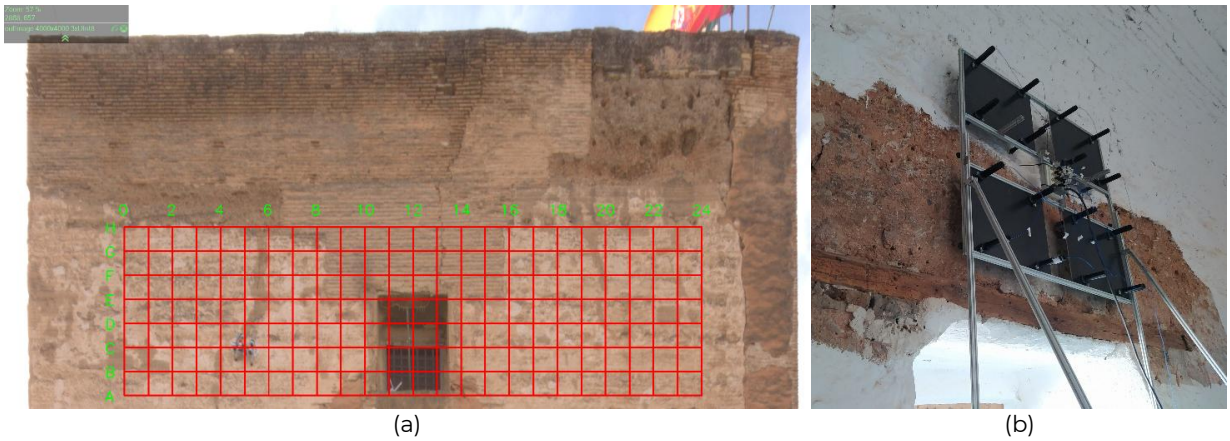
3.1 Robotic system

The system is a CDPR that allows moving an automatic mechanical hitting device, capable of generating controlled acoustic waves, throughout a large area using pulleys, cables and motors. A detailed description of the system can be found in Ramonet *et al.* (2026). In summary, the hitting system is a solenoid with a vibration sensor that records the emission signal (see details in Ortega *et al.* 2024). The system (Figure 3a) is installed on a vertical frame suspended by cables and pulleys that are placed on the top corners of the façade. To ensure contact of the hitting system with the wall during operation, the system incorporates two drone propellers that, when activated, push the frame against the surface (Figure 3b).



(a) (b)

Figure 3 – (a) CDPR suspended at *Torre de la Vela*; and (b) close view of the suspended frame with hitting system

3.2 Test setup

The reception system is a matrix of 16 accelerometers that is placed in the interior of the tower, at the opposite surface of the inspected wall. The testing procedure involved the CDPR going through a predefined inspection grid while the reception system is kept at a fixed position. The reception system is then manually moved to a different position, and the CDPR robot moves through the inspection grid again. This process was repeated as many times as positions are defined for the reception system.

The emission grid is shown in Figure 4a and consists of a uniform reticular grid with a spacing of 0.5 m. The grid has a total of 25 columns and 8 rows. The emission system can move automatically throughout all points defined by the grid. For remote control and monitoring, a camera was installed outside the tower that transmitted video via videoconference. A code was developed for real-time correction of the image perspective, eliminating distortion, creating parallel lines, and enabling measurements by superimposing the reference grid shown in Figure 4a to the video. The code was developed using Adaptive Vision Studio 5.1 software, based on OpenCV. This system allowed for real-time visualization of the robot's movement and the recording of its exact position during each phase of the inspection and at the exact moment of impact, which is essential for CDPR control and subsequent tomographic reconstruction. This system guaranteed a full control of all emission and reception coordinates at all times during the inspection.

(a) (b)

Figure 4 – (a) Emission grid with CDPR placed on point 5C; and (b) example of positioning of reception system

The reception system was placed in 23 different positions to cover a similar area on the opposite wall surface. Figure 4b shows an example of the reception system, positioned in the area above the façade window. The 16 accelerometers can measure simultaneously. Thus, the total number of reception points is 368 (23 x 16). It is noted that, for each position of the reception system, the emission system did not go through all columns defined in the grid of Figure 4a. Depending on the position of the reception system, only a number of columns on either side of that position were inspected, with the aim of ensuring that no distance between the emitter and the receiver exceeded 5 m. For example, for the receiving positions closest to column 24, only columns 16-24 were inspected.

The total number of transmitter-receiver pairs resulting from this inspection setup was 22,384. For each pair, 10 sonic signals were emitted (10 hits per emission point), so the number of measurements taken was 223,840. These numbers again demonstrate the impossibility of carrying out this inspection without automated systems. The inspection took approximately 12.5 hours, spread over three mornings. System setup and testing took another morning (approximately 5 hours), while the removal of the system, clean up and pick up of all devices took approximately 2 hours on the last day of the inspection. The large amount of data generated also highlights the importance of automating signal processing to obtain the results that will be shown in the next section. It is also important to note that not all transmitter-receiver pairs resulted in signals of sufficient quality. Occasionally, due to possible decoupling between the accelerometers and the wall surface, impact failure, or lack of transmission between the emitter and receiver points, some sonic waves were not received or the noise was greater than the signals. After eliminating those signals that could not be processed, the total number of valid emitter-receiver pairs for processing was 16,076. Figure 5 shows the rays coverage of the inspected area (the figure shows only 5,000 of the 16,076 total rays for readability). The reception points are marked in green and correspond to the 23 positions of the system. The emission points are marked in red. These points varied slightly with respect to the position of the grid. The use of the camera, capable of recording the exact position of the system in real time, allowed for obtaining the exact coordinates of each emitter point.

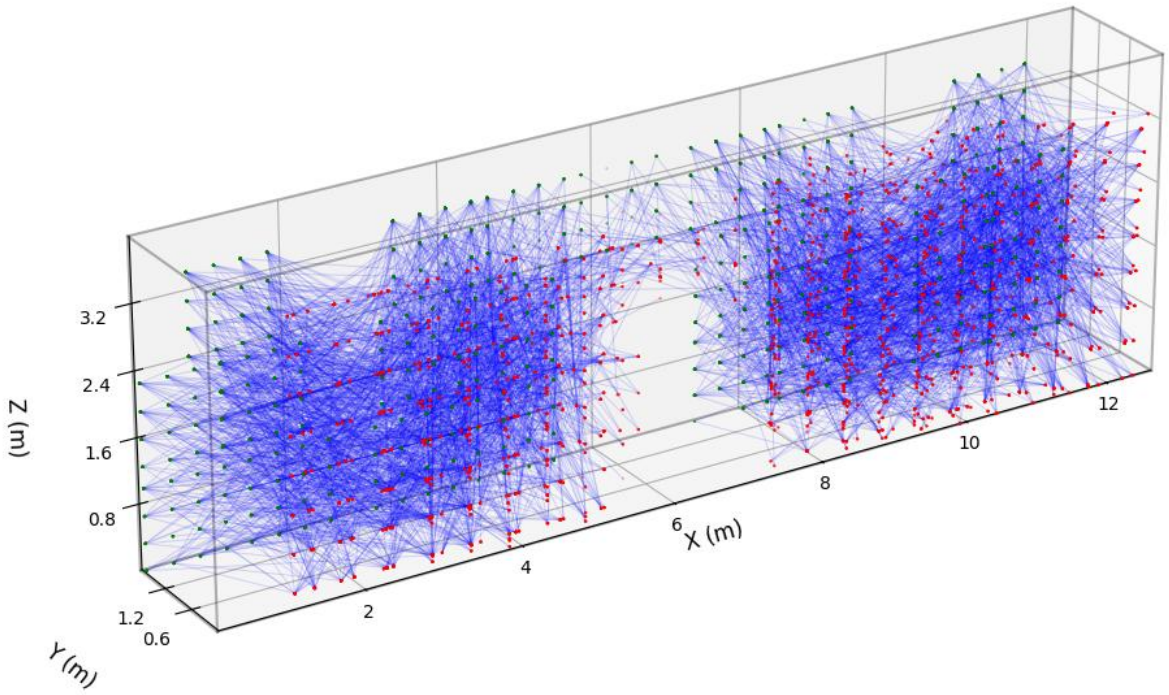


Figure 5 – Sonic rays (selection of 5,000 out of the total of 16,076) generated during the inspection at *Torre de la Vela*. Emission points at the exterior are marked in red while reception points in the interior are marked in green

As previously mentioned, the resolution of a tomographic image depends largely on the number of rays passing through each voxel. Figure 6 shows a 3D representation of the ray coverage density per voxel, for a voxel size of 0.2 m. Each voxel is marked with a sphere at its centroid, and the colour indicates the number of rays passing through it. There is a high number of rays per voxel in the two central areas at both sides of the window, consistently above 10, and in some cases exceeding 20 rays per voxel. In those areas near the perimeter of the inspection area, the density decreases. Nevertheless, most voxels are traversed by a minimum of 5 rays.

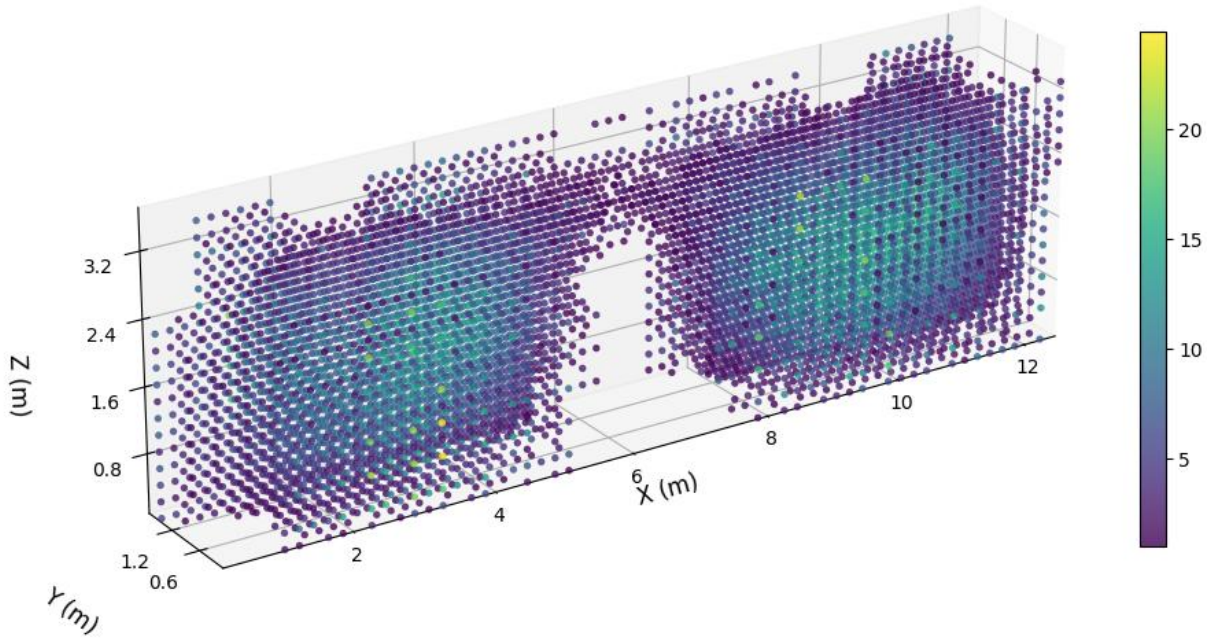

Figure 6 – Ray coverage density per voxel (scale indicates the number or rays per voxel)

4. Results and discussion

Using the tomographic reconstruction procedures described previously, 3D images of the inspected area in the tower were generated. The reconstructions provide a smeared (and smoothed) spatial distribution of velocities across the inspected volume. Voxels with constant velocity values can be joined in the visualization to form iso-surfaces, delimiting homogeneous areas. The iso-surfaces represent velocity variations throughout the volume, offering valuable information about the interior of the structure by dividing the volume into areas with poor or good sound transmission.

The tomographic reconstruction of the inspected volume in the Torre de la Vela is shown in Figure 7, using a velocity range between 500 (red) and 1,400 m/s (blue). The reconstructed volume shows areas of significant variability in terms of velocity. The lowest recorded velocities (< 500 m/s) are found in the upper central section (above the window). This area coincides with the brick masonry patch visible from the exterior. In the interior of the tower, this area is constructed of rammed earth, thus indicating that the repair must have an unknown thickness within the wall. The inner interface between rammed earth and brick masonry is likely the reason for the poor sonic transmission in this area.

On both sides of the window, greater homogeneity is observed, with less extreme variations. The highest velocities are recorded in the lower half of both areas, reaching up to 1,700 m/s in some localized zones. Velocities decrease in the upper half. In particular, there is a vertical band in the middle of the left panel where velocities drop below 1,000 m/s. Similarly, almost symmetrically, in the middle part of the right panel, estimated velocities decrease in the upper half.

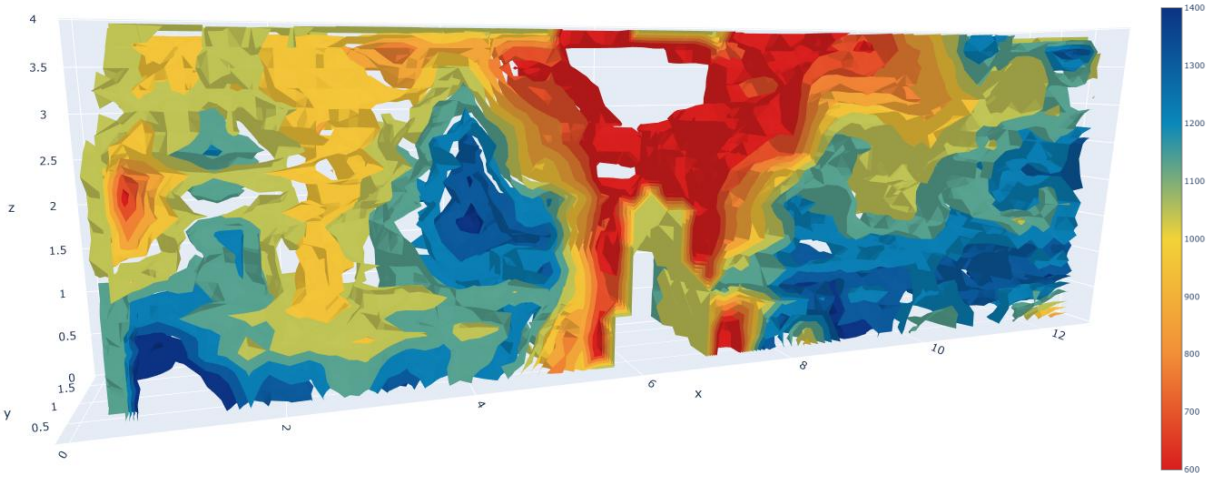

Figure 7 – 3D tomographic reconstruction of the interior of the inspected area at *Torre de la Vela*, based on iso-surfaces (dimensions in m and values of velocity in m/s)

Overlaying the tomographic reconstruction with the photogrammetric 3D point cloud of the Torre de la Vela helps to validate the observations made. Figure 8 shows the combination of the tower's exterior point cloud, the interior point cloud (both obtained by photogrammetry), and the inner point cloud of the inspected wall, resulting from the sonic tomography.

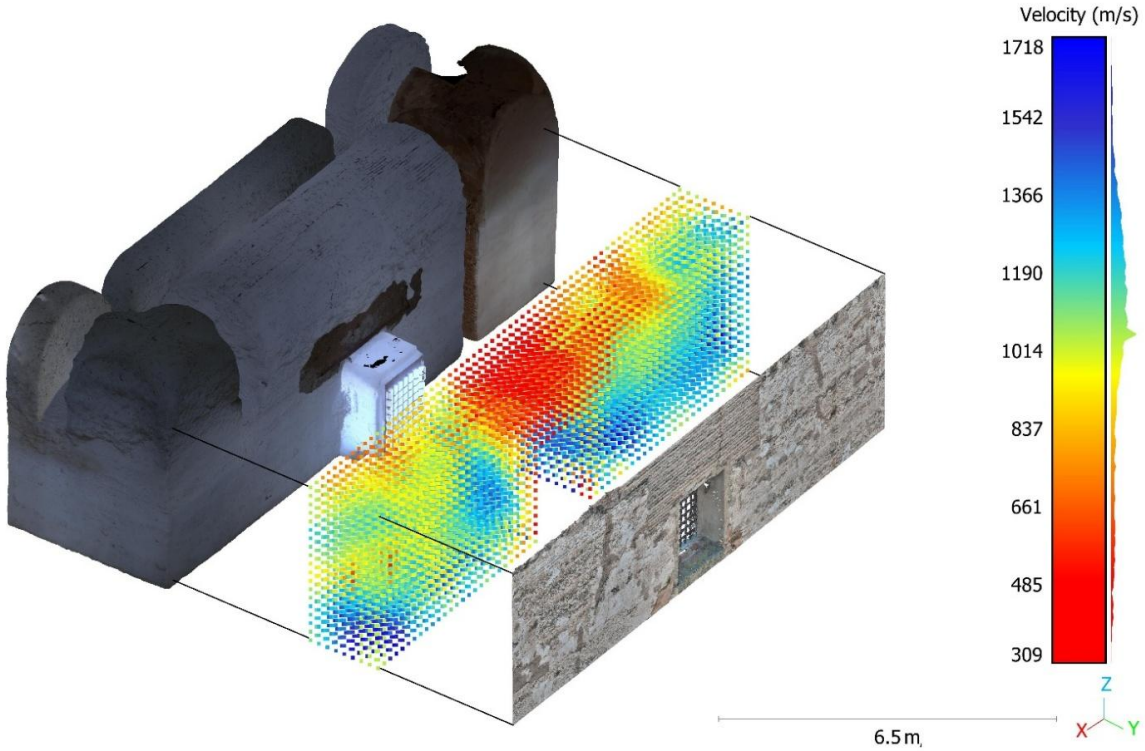

Figure 8 – Combination of the 3D point cloud obtained from the photogrammetric survey and the inner point cloud obtained from the tomographic reconstruction of the inspected area at the *Torre de la Vela*

Regarding the velocities obtained, the average velocity within the inspected area was 970 m/s, the median was 925 m/s, and the standard deviation was 350 m/s (coefficient of variation of 36%). Results show high heterogeneity, revealing variations in terms of material, but also in terms of internal conditions, such as the presence of cracks running through the wall.

Figure 9 shows a detail of the 3D point cloud, with a perspective view of the tower's north elevation from the outside. The first image shows the photogrammetric point cloud. The second image shows also the inner point cloud obtained from the tomographic reconstruction, but only displaying (in red) those points with a velocity lower than the median velocity (970 m/s). These points correspond to areas with poor sound transmission and may correspond to deteriorated areas or highlight the presence of structural discontinuities (e.g., cracks). The images show good correlation between both point clouds, between the areas with lower velocities and the damage (or alterations) visible from the outside. As previously mentioned, a high density of low-velocity points is observed above the window, which is made of a different material and exhibits vertical cracks. On both sides of the window, at x = 3 m and x = 10 m (according to the coordinate system used in Figure 7), there are two vertical cracks in the rammed earth wall that correspond well to the decrease in velocities observed in those areas. The 3D reconstruction indicates that these cracks are not superficial and extend through the wall. These results aim to demonstrate the potential of combining both techniques to aid in the interpretation of the findings.

Figure 9 – Perspective view of a detail of the façade comparing the point cloud obtained from the photogrammetry (left) and adding the point cloud from the tomographic reconstruction, showing (in red) only those points with velocities lower than the median (v < 970 m/s) (right)

5. Conclusions

The results of the sonic inspection carried out at the *Torre de la Vela* of the *Alhambra* demonstrate the potential of automating inspection systems for the characterization of historical buildings. The large amount of data that can be collected using these systems allows for the creation of 3D tomographic images of the interior of the rammed earth walls. These images provide qualitative information about large structural elements, locating and delimiting deteriorated areas, identifying potential cracks and their extent, and distinguishing between different building materials.

The inspections carried out covered an area of approximately 13 x 4 meters. The results showed that, for this type of historical constructions, variations in the internal condition of the wall can be significant. Assuming that the material properties are uniform throughout the wall can lead to a conservative analysis (if material properties are based on the results obtained in the most deteriorated areas, for example), which may result in a more invasive intervention on the heritage site than necessary. Conversely, assuming average or upper-range properties could lead to overlooking potentially more deteriorated areas and overestimating the structural capacity of the building. Scaling up the inspection to the entire building or large elements, such as the façade, allows for more detailed structural analyses that can inform localized interventions targeted at specific areas.

Overlaying tomographic images with point clouds obtained from photogrammetry aids in the interpretation of the results. Combining both techniques allow for the precise location and delimitation of the most deteriorated areas, as well as the correlation of internal information with surface data visible from the outside.

Abstracto: Las estructuras prefabricadas de concreto han experimentado un crecimiento significativo a nivel mundial debido a sus ventajas constructivas y económicas, especialmente en edificaciones industriales, comerciales y residenciales; sin embargo, su desempeño sísmico ha mostrado una respuesta variable a lo largo de la historia. Eventos como el terremoto de Tangshan, China (1976), evidenciaron colapsos masivos del orden del 85% en zonas de máxima intensidad, lo que reveló la alta vulnerabilidad de sistemas con detalles sísmicos deficientes. Posteriormente, sismos como Armenia (1988), Northridge (1994), Wenchuan (2008), L'Aquila (2009), Turquía (2011), Emilia (2012) y Kaikoura (2016) confirmaron que las principales fallas en edificios prefabricados existentes se concentran en las conexiones entre los elementos. Entre las deficiencias más recurrentes se identifican las losas alveolares simplemente apoyadas sin anclaje adecuado, la ausencia de capa de compresión colada en sitio, la falta de continuidad del refuerzo y las conexiones incapaces de transmitir momento o fuerzas cíclicas significativas. Estas condiciones han provocado comportamientos frágiles, pérdida del apoyo de los elementos horizontales y, en algunos casos, colapsos progresivos. Por otro lado, la evidencia también muestra casos de desempeño satisfactorio cuando existen detalles estructurales adecuados. Durante la secuencia sísmica de Canterbury (2010–2011), varios edificios prefabricados presentaron un comportamiento satisfactorio; de igual manera, las estructuras prefabricadas presforzadas mostraron un desempeño sobresaliente durante el sismo de Kobe (1995). Estos antecedentes sugieren que el comportamiento sísmico no depende del sistema prefabricado, sino del diseño adecuado de las conexiones y de la continuidad estructural. El presente trabajo investiga y analiza la evidencia documentada del comportamiento sísmico de estructuras prefabricadas existentes. Las conclusiones explican con claridad las principales vulnerabilidades de las estructuras prefabricadas y los factores que han tenido mayor influencia en su respuesta sísmica, con un enfoque especial en el desempeño sísmico de las conexiones empleadas en los casos analizados.

Keywords: Concreto prefabricado, comportamiento sísmico, conexiones prefabricadas, estructuras existentes.

1. Introducción

Las estructuras prefabricadas de concreto han sido ampliamente utilizadas desde mediados del siglo XX debido a sus ventajas en rapidez constructiva, control de calidad y eficiencia económica, Fib (2003). No obstante, su desempeño sísmico ha sido objeto de debate, en particular en edificaciones existentes diseñadas sin criterios específicos para acciones sísmicas.

Diversos terremotos han evidenciado que las fallas en estas estructuras se concentran principalmente en las conexiones entre elementos, más que en los propios elementos prefabricados, Karuma *et al.* (2018). En

este contexto, estudios posteriores han señalado que la falta de continuidad estructural y la incapacidad de las conexiones para transmitir fuerzas cíclicas constituyen las principales fuentes de vulnerabilidad, *Wood et al. (1993).*

El objetivo del presente trabajo es realizar un análisis crítico del comportamiento sísmico de estructuras prefabricadas existentes, identificando patrones comunes de falla y los factores estructurales que rigen su respuesta.

2. Evidencia sísmica y evolución del comportamiento estructural

Las estructuras prefabricadas de concreto han sido ampliamente utilizadas desde mediados del siglo XX en países como Japón, China, Nueva Zelanda, Italia y Estados Unidos, debido a sus ventajas constructivas y de control de calidad. Sin embargo, su desempeño sísmico ha sido históricamente cuestionado, principalmente por deficiencias en el diseño y la ejecución de las conexiones (Fib 2003).

En los primeros eventos sísmicos relevantes, como el terremoto de Tangshan (Ms 7.8, 1976), se registraron colapsos generalizados en edificaciones que incorporaban elementos prefabricados, en particular sistemas de losas de concreto apoyadas sobre muros con escasa o nula conexión entre los elementos. La ciudad se ubicaba en una zona donde no se requería diseño sísmico, por lo que estas estructuras fueron concebidas únicamente para resistir cargas gravitacionales (Housner *et al.* 2002).

En consecuencia, los elementos horizontales dependían del apoyo por contacto, sin garantizar la transferencia de fuerzas laterales ni la continuidad estructural. Durante el sismo, la ausencia de conexión entre diafragmas y elementos verticales provocó la pérdida de soporte de las losas y fallas frágiles en los muros, lo que activó mecanismos de colapso progresivos. Este evento marcó un punto de partida al impulsar la investigación sobre las conexiones en sistemas prefabricados.

Posteriormente, el sismo de Armenia (1988) mostró colapsos en edificaciones prefabricadas de mediana altura, conformadas por muros prefabricados que actuaban como elementos principales tanto para cargas verticales como para cargas laterales, junto con losas prefabricadas que formaban los diafragmas de piso. A pesar de esta configuración, el sistema no logró adoptar un comportamiento monolítico debido a la deficiente capacidad de sus conexiones. Las uniones entre muros presentaban baja resistencia y escasa ductilidad, lo que impedía la adecuada transmisión de las fuerzas sísmicas (Wood *et al.* 1993).

En Northridge (Mw 6.8, 1994), a pesar de existir normativa sísmica avanzada, se observaron fallas importantes en estacionamientos prefabricados. Estas fallas no se debieron a la resistencia de los elementos, sino a la incompatibilidad entre el sistema de gravedad y el sistema lateral, así como a la falta de continuidad en el diafragma, como se muestra en la Figura 1. Estas fallas se manifestaron en colapsos parciales de estructuras de estacionamiento (Iverson *et al.* 1994; Mitchell *et al.* 1995).

Figura 1 – Daños en el estacionamiento de la Universidad Estatal de California en Northridge tras el sismo de 1994: (a) separación entre elementos prefabricados y pérdida de continuidad del sistema de piso; (b) falla de columnas del sistema de gravedad y pérdida de soporte en vigas y losas. Fuente: Iverson *et al.* (1994).

En contraste, en Japón, tras la actualización de la normativa de 1981, las estructuras prefabricadas presforzadas mostraron un desempeño sobresaliente durante el sismo de Kobe (Mw 7.2, 1995), las estructuras prefabricadas presforzadas correspondían principalmente a edificaciones con comportamiento tipo marco, en las que vigas presforzadas y columnas de concreto reforzado conformaban sistemas estructurales continuos capaces de transmitir fuerzas laterales y momentos. A diferencia de sistemas prefabricados basados en apoyos simples, la evidencia de formación de articulaciones plásticas, de interacción viga-columna y de ocurrencia de fallas en columnas antes que en vigas sugiere que las conexiones proporcionaban continuidad estructural, probablemente mediante detalles de tipo monolítico o conexiones húmedas coladas en sitio. Esta configuración favoreció un comportamiento dúctil y estable, lo que permitió el desarrollo de mecanismos resistentes y controlados. El buen desempeño observado se atribuye, además, al uso de criterios de diseño sísmico más conservadores, a la regularidad estructural en planta y en elevación, al empleo de materiales de alta calidad y a la supervisión de los procesos constructivos de las edificaciones (Muguruma *et al.* 1995).

Asimismo, en Nueva Zelanda, la evolución normativa y el desarrollo de tecnologías como PRESSS (Precast Seismic Structural Systems) permitieron mejorar significativamente el desempeño sísmico de estructuras prefabricadas, como se evidenció en la secuencia sísmica de Canterbury (2010–2011) (Fleischman *et al.,* 2014). Este avance fue el resultado de una transición en el diseño sísmico, que incorporó criterios de diseño por capacidad y de diseño detallado dúctil.

A partir de la actualización de la norma NZS 3101, se introdujeron requisitos específicos para sistemas de piso prefabricados, reconociendo dos problemas fundamentales antes ignorados: 1) el alargamiento de vigas asociado a la formación de articulaciones plásticas, que induce pérdidas de apoyo en elementos prefabricados, y 2) la incompatibilidad de deformaciones entre sistemas de piso y sistemas laterales (marcos o muros), lo que compromete la transferencia de cargas (Fleischman *et al.* 2014).

La evidencia observada en los edificios de Christchurch confirma la efectividad de estos enfoques. En estructuras con marcos prefabricados emulativos que empleaban conexiones coladas en sitio (Figura 2), se observó la formación controlada de articulaciones plásticas en las vigas, mientras que las columnas permanecieron esencialmente en el rango elástico, en concordancia con los principios de diseño por capacidad. Sin embargo, aun en estos sistemas se identificaron vulnerabilidades en los sistemas de piso prefabricados. Se registraron agrietamientos longitudinales, fractura de la malla electrosoldada y una reducción de la capacidad de transferencia de fuerzas, asociados principalmente a la incompatibilidad de deformaciones y al alargamiento de las vigas.

Aunque no se produjo el colapso del sistema de piso, estas requirieron apuntalamiento temporal y fueron evaluadas como cercanas al estado límite de colapso, evidenciando que los efectos acumulados de la deformación del sistema estructural pueden comprometer el desempeño de los elementos prefabricados aun cuando el sistema principal mantiene su estabilidad.

Figura 2 – a) Conexión de esquina en marco prefabricado; b) Colado de cierre (stitch joint) entre vigas prefabricadas. Fuente: Fleischman *et al.* (2014).

En contraste, estructuras que incorporaron tecnologías avanzadas como aislamiento sísmico en la base o sistemas desarrollados bajo el programa PRESSS tales como marcos postensados no adheridos (PT) con comportamiento auto-centrante y sistemas de muros acoplados tipo “rocking” con disipadores de energía UFPs, mostraron un desempeño sísmico sobresaliente, con daño estructural prácticamente nulo y rápida recuperación funcional (Fleischman *et al.* 2014).

En el caso del edificio Southern Cross Medical Building, su sistema estructural consistía en el uso combinado de marcos postensados en una dirección y muros “rocking” en la otra, lo que permitía controlar la respuesta sísmica mediante mecanismos de recentrado y de disipación de energía localizados. Asimismo, el detalle de la conexión viga–columna de la Figura 3 confirma la efectividad del sistema postensado no adherido (PT), donde la ausencia de daños y fisuraciones en la zona de conexión refleja la capacidad del sistema para acomodar deformaciones sin provocar daños permanentes.

Figura 3 – Detalle de la conexión viga–columna en un marco postensado no adherido (PT). Fuente: Pampanin *et al.* (2011) y Fleischman *et al.* (2014).

Por otro lado, en el edificio con aislamiento sísmico en la base, mostrado en la Figura 4, el excelente desempeño observado se atribuye a la reducción significativa de las demandas sísmicas transmitidas a la superestructura, lo que permite desplazamientos controlados y una respuesta esencialmente elástica.

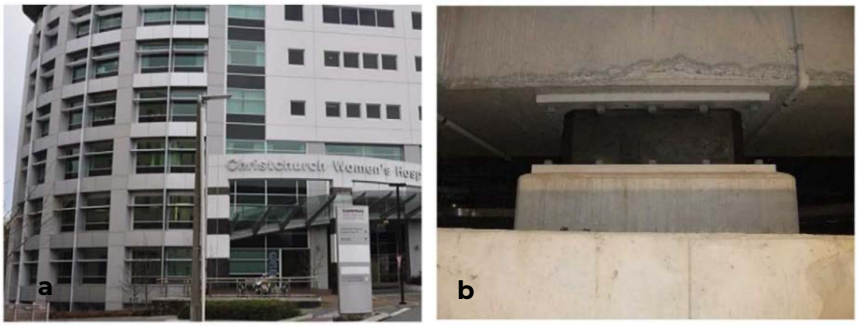

Figura 4 – a) Fachada principal del Christchurch Women’s Hospital (Christchurch, Nueva Zelanda); b) disposición del aislamiento sísmico tipo LRB en la losa de cimentación. Fuente: Kam *et al.* (2011).

Estos sistemas logran controlar la respuesta sísmica mediante dos estrategias distintas pero complementarias: 1) reducción de la demanda sísmica mediante el aislamiento en la base, y 2) control de la no linealidad estructural mediante mecanismos de recentrado y disipación de energía en las conexiones PRESSS. Este enfoque representa un cambio fundamental respecto a los sistemas tradicionales, en los que el daño se distribuye de manera no controlada entre los elementos estructurales.

A diferencia de lo observado en Tangshan (1976), en China el terremoto de Wenchuan (Mw 7.9, 2008) evidenció un comportamiento significativamente más favorable en edificaciones industriales prefabricadas, donde las conexiones tipo ménsula no presentaron fallas, y solo mostraron agrietamientos locales, sin

pérdida de soporte. Este comportamiento sugiere la existencia de mecanismos de conexión mecánica capaces de garantizar la continuidad estructural (Zhao *et al.* 2009).

En el terremoto de L'Aquila (Mw 6.3, 2009), se evidenciaron nuevamente deficiencias críticas en estructuras prefabricadas industriales. La mayoría de las estructuras afectadas correspondían a naves industriales de un solo nivel y edificios comerciales de hasta tres niveles, diseñados conforme a normativas que, en muchos casos, carecían de disposiciones específicas para el diseño sísmico de conexiones prefabricadas. Las conexiones viga–columna, diseñadas principalmente para cargas gravitacionales, fallaron por pérdida de apoyo debido a su dependencia de la fricción. Las altas aceleraciones verticales registradas redujeron la fuerza normal en los apoyos, lo que disminuyó la capacidad de fricción y provocó el deslizamiento de las vigas (Toniolo y Colombo 2012). Este mecanismo se ilustra en la Figura 5, donde se observa la pérdida de apoyo de una viga prefabricada.

Figura 5 – Falla por pérdida de apoyo en la conexión viga-columna de la estructura prefabricada. Fuente: Toniolo y Colombo (2012).

Asimismo, se documentó la falla de los conectores metálicos utilizados para la fijación de muros prefabricados, que presentaron deformaciones plásticas y desgarramiento bajo la acción de fuerzas laterales inducidas por el sismo, como se observa en la Figura 6. Estas fuerzas no fueron consideradas en el diseño original, ya que los muros fueron idealizados como elementos no estructurales. Sin embargo, durante el evento sísmico, los muros interactuaron con el sistema estructural principal, lo que modificó la distribución de fuerzas e indujo demandas no previstas en las conexiones.

Figura 6 – Falla de conectores metálicos en muros prefabricados sometidos a fuerzas laterales en su plano. Fuente: Toniolo y Colombo (2012).

En el terremoto de Van, Turquía (Mw 7.2, 2011), se observaron comportamientos contrastantes en estructuras prefabricadas. Ozden *et al.* (2014) realizaron investigaciones de campo en doce estructuras prefabricadas, incluyendo edificios residenciales de varios niveles, edificaciones públicas y naves industriales de un nivel,

con el objetivo de identificar mecanismos de daño, niveles de desempeño y deficiencias asociadas al diseño, al detallado y a la construcción.

Una de las estructuras evaluadas fue un edificio residencial prefabricado de siete niveles con conexiones viga–columna postensadas resistentes a momento, que mostró un comportamiento sísmico sobresaliente.

No se observaron daños estructurales en los elementos prefabricados ni en las conexiones (Figura 3(a–c)), y el sistema permaneció esencialmente en el rango elástico. Únicamente se registraron grietas diagonales en muros divisorios no estructurales (Figura 3(d)), atribuibles a incompatibilidad de deformaciones.

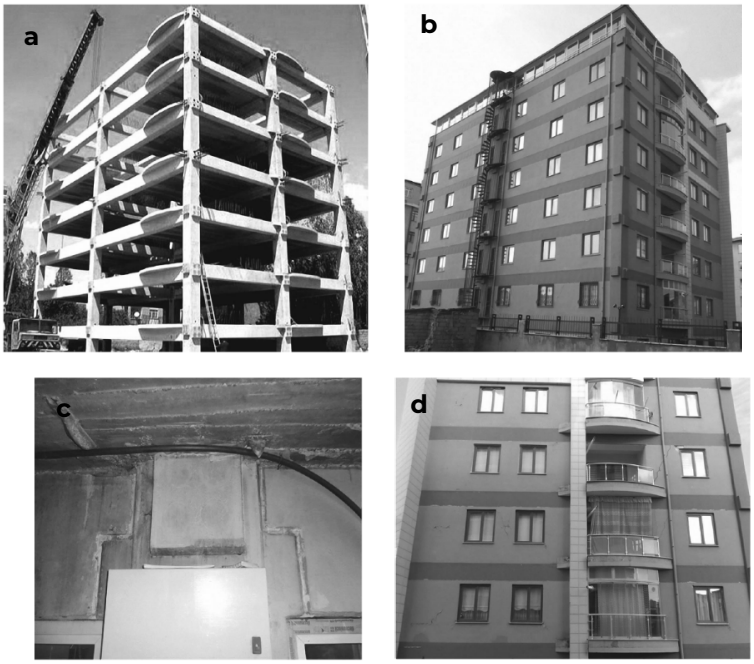

Figura 7 – Edificio residencial prefabricado de siete niveles con conexiones viga-columna postensadas resistentes a momento. (a) Etapa de construcción previa al sismo (b); vista del edificio después del sismo; (c) vista de la conexión postensada sin daños y (d) grietas diagonales en muros divisorios no estructurales. Fuente: Ozden *et al.* (2014).

Asimismo, un gimnasio prefabricado de dos niveles, que incorporaba muros de cortante de concreto colado en sitio como sistema resistente a cargas laterales, presentó daños insignificantes (Figuras 4(b) y 4(c)), a pesar de que estructuras cercanas sufrieron daños considerables. Este comportamiento favorable se atribuyó a la rigidez lateral adecuada proporcionada por los muros de cortante y al efecto de diafragma del sistema de entrepiso.

Figura 8 – Vista exterior del gimnasio prefabricado de dos niveles que incorpora muros de cortante de concreto colado en sitio como sistema principal de resistencia lateral. a) Vista de la primera planta; b) Vista de la segunda planta. Fuente: Ozden *et al*. (2014).

En contraste, se observaron daños severos y colapsos parciales en estructuras en procesos de construcción que carecían de muros perimetrales y sistemas de cubierta. En estos casos, la falla se asoció principalmente a la pérdida de soporte de las vigas debido a deficiencias en las conexiones, como la ausencia o mala calidad del grout y la falta de elementos de fijación Figura 7(a–b).

La caída de las vigas generó demandas adicionales no consideradas en el diseño, provocando la formación de articulaciones plásticas en la base de las columnas, la fluencia y ruptura del refuerzo longitudinal y, finalmente, el colapso estructural Figura 7(c–f).

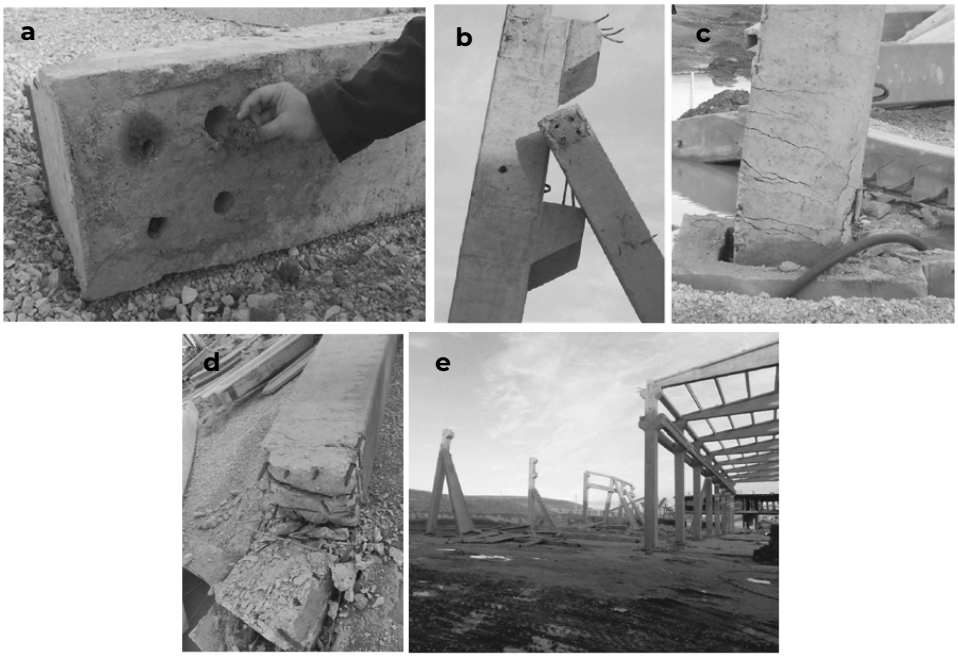

Figura 9 – Falla en la conexión viga-columna y pérdida de apoyo de las vigas de cubierta en la estructura industrial. a) Mala calidad del grout; b) desplazamiento y pérdida parcial del apoyo de la viga; c) formación de una articulación plástica en la columna; d) fluencia y ruptura del acero longitudinal de la columna; y e) colapso de la estructura. Fuente: Ozden *et al.* (2014).

Adicionalmente, se identificaron deficiencias en la calidad de los materiales y en la ejecución constructiva, incluyendo cuantías de refuerzo insuficientes, dimensiones menores a las de diseño y propiedades mecánicas del acero fuera de especificación.

El sismo de Emilia (Mw 6.1**,** 2012) constituye uno de los casos más representativos del comportamiento sísmico deficiente de estructuras prefabricadas existentes, en el que más del 60% de los edificios prefabricados industriales colapsaron o sufrieron daños severos. El mecanismo dominante fue la pérdida de apoyo de las vigas y los elementos de cubierta, debido al uso de conexiones basadas únicamente en fricción y a la ausencia de anclajes mecánicos (Magliulo *et al.* 2013).

Desde un punto de vista mecánico, la resistencia por fricción ($\mu \approx 0.09–0.13$), resultó insuficiente frente a las demandas sísmicas, provocando el deslizamiento de las vigas sobre las columnas y la consecuente pérdida de soporte (Magliulo *et al.* 2013). Este mecanismo se casos, lo que facilitó la caída de los elementos de cubierta y desencadenó colapsos progresivos. Como se observa en la Figura 10, el deslizamiento de las vigas sobre las columnas provocó el colapso de los sistemas de cubierta.

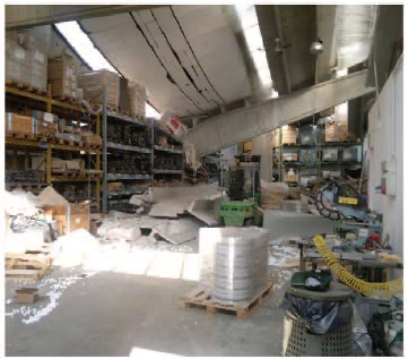

Figura 10 – Pérdida de apoyo de vigas sobre columnas en estructuras prefabricadas, lo que provoca el colapso de los elementos de cubierta. Fuente: Magliulo *et al*. (2013).

Cabe destacar que una gran proporción de las edificaciones afectadas fue diseñada antes de que la región de Emilia fuese clasificada como zona sísmica. Aunque el mapa de peligro sísmico se actualizó en 2003, su aplicación obligatoria en el diseño estructural no se implementó hasta 2008, por lo que muchas estructuras existentes no incorporaban criterios sismorresistentes (Savoia *et al*., 2017). Sin embargo, la evidencia observada en este evento, junto con estudios posteriores, ha llevado a modificaciones normativas significativas. En particular, la normativa italiana DM 14/01/2008 y el Eurocódigo 8 establecen que la resistencia por fricción no debe considerarse como mecanismo principal para resistir acciones sísmicas, y requieren, en su lugar, conexiones capaces de transmitir fuerzas laterales y resistir cargas cíclicas.

En Nueva Zelanda, más recientemente, el sismo de Kaikoura (Mw 7.8, 2016) permitió reevaluar el comportamiento sísmico de estructuras prefabricadas, evidenciando mecanismos de daño asociados a la compatibilidad de deformaciones que no habían sido plenamente identificados en la secuencia sísmica de Canterbury (2010–2011), de acuerdo con Henry *et al*. (2017).

Se registraron demandas sísmicas que excedieron los niveles de diseño en edificaciones con periodos del orden de 1 a 2 segundos, correspondientes principalmente a edificios de marcos de concreto reforzado de entre 5 y 15 niveles, muchos de ellos construidos a partir de la década de 1980 e incorporando sistemas de piso prefabricados, particularmente losas alveolares y unidades tipo doble “tee”. A pesar de que no se observaron colapsos generalizados, aproximadamente el 52% de los edificios evaluados presentaron algún nivel de daño estructural, destacándose las afectaciones en los sistemas de piso. Un fenómeno particularmente significativo fue la elongación residual de las vigas, producto de la acumulación de deformaciones inelásticas en las regiones de articulación plástica, lo que generó rotaciones en las vigas de apoyo y una reducción del apoyo efectivo de las unidades prefabricadas.

Este mecanismo evidenció la vulnerabilidad de conexiones típicamente diseñadas como apoyos simples, lo que provocó daños por desprendimiento del concreto, pérdida de longitud de apoyo y, en otros casos, pérdida de soporte en unidades tipo doble “tee”. Adicionalmente, se identificaron daños significativos en diafragmas de piso, especialmente en sistemas con losas alveolares, donde se observaron agrietamientos concentrados en las esquinas debido a incompatibilidades de deformación, así como grietas transversales cercanas a los apoyos, asociadas a posibles fallas a cortante.

3. Análisis comparativo

El análisis comparativo de los eventos sísmicos estudiados permite establecer que el comportamiento de las estructuras prefabricadas ha estado históricamente dominado por el desempeño de sus conexiones, más que por las propiedades de los elementos estructurales en sí.

En los sistemas prefabricados tradicionales, como los observados en Tangshan (1976), Armenia (1988), L'Aquila (2009) y Emilia (2012), el daño estuvo dominado por la falta de continuidad estructural y por el uso de conexiones incapaces de transmitir fuerzas laterales. En estos casos, las conexiones basadas en fricción o apoyos simples mostraron un comportamiento altamente vulnerable, caracterizado por la pérdida del soporte de los elementos horizontales y el desarrollo de mecanismos de colapso progresivo. Este patrón se repite independientemente de la ubicación geográfica, lo que evidencia una deficiencia conceptual en el diseño estructural.

En contraste, en sistemas cuyas conexiones fueron diseñadas para proporcionar continuidad estructural, como en Kobe (1995), Wenchuan (2008), Canterbury (2010–2011) y en algunas edificaciones evaluadas en Van (2011), se observó un comportamiento sísmico significativamente más favorable. En estos casos, el uso de conexiones húmedas, conexiones postensadas no adheridas, desarrolladas bajo el enfoque PRESSS o mediante dispositivos mecánicos permitió desarrollar mecanismos dúctiles y evitar la pérdida de estabilidad global. Estos resultados indican que el buen desempeño no depende únicamente del tipo de sistema prefabricado, sino también de la existencia de mecanismos de conexión capaces de proporcionar resistencia, ductilidad y capacidad de transmisión de esfuerzos.

El sismo de Kaikoura (2016) introduce un cambio significativo en la interpretación del comportamiento sísmico de las estructuras prefabricadas. A diferencia de eventos como L'Aquila (2009) y Emilia (2012), donde el daño estuvo asociado a la incapacidad de las conexiones para transmitir fuerzas laterales y garantizar la estabilidad del sistema, en Kaikoura se observó que, aun con normativas detalladas, los sistemas de piso prefabricados no estuvieron exentos de daño.

Si bien las normas vigentes hasta ese momento contribuyeron a prevenir el colapso de los sistemas de piso, se registraron daños importantes, incluyendo la reducción del apoyo, el agrietamiento longitudinal y transversal en las losas alveolares, así como afectaciones en la capacidad de transferencia de fuerzas del diafragma. Estos resultados indican que, aunque el nivel de seguridad estructural ha mejorado, el desempeño funcional y la integridad de los sistemas siguen siendo vulnerables ante demandas sísmicas elevadas.

4. Conclusiones

El análisis de la evidencia sísmica documentada permite establecer que el comportamiento sísmico de las estructuras prefabricadas existentes no depende del sistema constructivo en sí, sino del diseño, del detallado y del desempeño de sus conexiones. Los casos estudiados muestran que las fallas más severas se presentan en sistemas en los que las conexiones no garantizan la transmisión de fuerzas laterales ni la continuidad estructural, particularmente en configuraciones basadas en apoyos simples o en mecanismos de fricción.

Asimismo, la evidencia recopilada documenta casos de desempeño satisfactorio. En particular, los sistemas prefabricados que emplean conexiones postensadas desadheridas y conexiones húmedas coladas en sitio han mostrado un comportamiento sísmico favorable, al permitir la transmisión efectiva de las fuerzas, la continuidad estructural y una respuesta más dúctil. Estos sistemas destacan por su capacidad para acomodar deformaciones inelásticas y limitar mecanismos de falla frágil, lo que respalda su implementación como estrategia para mejorar el desempeño sísmico de estructuras prefabricadas.

En este sentido, en los últimos años se han propuesto diversas soluciones de conexión para sistemas prefabricados, particularmente en uniones viga–columna, muros y sistemas de piso orientadas a mejorar su desempeño sísmico. Sin embargo, más allá del desarrollo tecnológico, el desafío actual radica en incrementar la confiabilidad y adopción en zonas sísmicas, lo cual requiere no solo validar su comportamiento mediante evidencia experimental, sino también desarrollar herramientas de análisis y diseño que permitan su aplicación consistente en la práctica profesional.

Abstract: The main requirements of a building are structural safety, watertightness, thermal and acoustic comfort, as well as durability, which can be compromised by pathological manifestations. After anomalies occur, repairs must be carried out promptly to avoid further deterioration. To provide effective solutions, it is essential to properly identify the causes of the anomalies. This study aims to survey pathological manifestations in a public school in the municipality of Juazeiro do Norte-CE. The data were obtained through an on-site visual inspection. The inspection covered both internal and external areas, with photographic records taken in panoramic and detailed form. To determine the dimensions of the openings, a crack gauge was used. Horizontal cracks and fissures were identified in the wall coatings of the classrooms, as well as cracks in different directions and inclined gaps. In addition, cracks were found at the junctions between columns, beams, and slabs. Cracks and detachment in the ceramic flooring were observed, along with diagonal gaps in coatings of wet areas. Furthermore, disintegration of coatings, detachment of PVC ceiling panels, and water/moisture infiltration associated with mold growth were noted. Horizontal and diagonal cracks near window frames, peeling paint on the wall, as well as vertical cracks and detachment in the external masonry were also identified. Finally, dark stains, fissures, and mapped cracks were found on the floor. Thus, the existence of pathological manifestations may be related to failures in some construction phase, lack of maintenance, or design flaws. Correct construction practices, use of quality materials, and preventive maintenance, along with proper care in the use of the building as outlined in the Building Use, Operation, and Maintenance Manual, constitute effective measures not only to mitigate the emergence of pathological manifestations but also to resolve them when already present.

Keywords: Pathological Manifestations. Structural Damage. Maintenance.

1. Introduction

In many countries, the construction sector strongly contributes to economic growth (Chellappa et al., 2020). Globally, with an annual budget of US$ 10 trillion, the sector accounts for 13% of the Gross Domestic Product (GDP) (Barbosa et al., 2017). The sector provides employment to many people and solutions for the growing needs of the world's population (Chellappa; Srivastava, 2024).

However, despite the growth of the construction industry and investments in technologies to improve materials, techniques, and construction systems, a portion of buildings continues to show unsatisfactory performance over time. These construction anomalies, ranging from design flaws and material defects to poor execution, often compromise the longevity and structural integrity of buildings (Lima Júnior et al., 2025).

Among these anomalies are endogenous factors originating from design, materials, or execution, as well as exogenous factors resulting from external influences, natural phenomena, or functional issues that arise after the expected service life of a building. These deficiencies can be attributed to several factors, such as design flaws, execution problems, or the quality of materials used.

Sena et al. (2020) state that pathological manifestations are degradations identified in the building, which may be generated during the construction period (whether using inappropriate construction methods or materials), in the project design itself, or may arise over time due to misuse or inadequate use of the building.

Construction failures are a serious problem by all project stakeholders. This occurs because they can happen at any point in the project life cycle and have a significant effect on project cost and time due to rework, potentially compromising trust among stakeholders (Awasho; Alemu, 2023). Supporting this understanding, Alomari (2022) states that repairing construction failures costs between 2.4% and 3.15% of the total building cost.

Problems arising from pathological manifestations range from minor damage to compromising the safety of buildings, which may culminate in structural collapse (Marinho, Mesquita; 2022). In this regard, Aguiar et al. (2022) argue that knowledge and treatment of building failures contribute to increasing its service life, while also providing notable safety to users. Supporting this understanding, Resende et al. (2022) affirm that by investigating and understanding these manifestations, it is possible to identify the causes of deterioration and take measures to prevent further damage to the building and financial losses to owners.

In this context, pathological manifestations may be related to inadequate use of the building, lack of maintenance, natural wear of materials, exposure to adverse weather conditions, or even design or execution errors (Santos Júnior; Santos; Santos, 2023).

Furthermore, the lack of preventive maintenance and improper use of the building may also compromise its service life. It is important to emphasize that the service life of a building is an important aspect to be considered in civil construction, as it is related to its sustainability and the environmental and economic impact that its premature replacement or repair may generate (Santos Júnior; Santos; Santos, 2023).

In this sense, the main objective of this study is to survey the pathological manifestations in a public school located in the municipality of Juazeiro do Norte-CE.

2. Material and Methods

2.1 Choice of the Study Object

The research carried out was a case study, and for this purpose, the educational institution of interest in this article was the João Alencar de Figueiredo Public Elementary School, one of the largest in the municipal public-school network in Juazeiro do Norte-CE, located on Avenue President Castelo Branco, Romeirão neighborhood, with the following geographic coordinates: 7°13'25.60" S Latitude and 39°18'56.99" W Longitude. It is situated in an urban area, on one of the main avenues of the neighborhood, approximately 80m from Arena Romeirão and 1km from Cariri Shopping, among other high-standard developments nearby. Figure 1 shows the front view of the school, which is surrounded by railings.

Figure 1 – Escola de Ensino Fundamental João Alencar de Figueiredo in Juazeiro do Norte – CE

Currently, the school is closed due to its critical structural condition, with risk of collapse in certain areas. The main justification for choosing the school was the compromised state of its structure, which shows advanced levels of pathological manifestations. In addition, the ease of access for inspection was a determining factor.

It is a building from the 1970s and currently belongs to the State of Ceará. The building has a single floor and about 29 rooms, including classrooms, library, covered sports court, reading room, bathrooms, auditorium, kitchen, and storage room.

Its structure consists of reinforced concrete columns, beams, and slab, with internal and external masonry made of ceramic brick. The facades are coated with mortar and finished with paint. The finishing standard is considered normal/low, with industrial flooring in circulation areas, while other rooms have commercial ceramic flooring. Wet areas also have internal walls coated with commercial ceramic. Most rooms have a slab ceiling, while others are finished with PVC panels, and the roof is covered with ceramic tiles. The internal environments have wood/glass windows, while the doors no longer exist, as they were removed by vandals. The building occupies an entire block, with approximately 60% of the total area built. The dimensions/area of the property were estimated using Google Earth: front – 63.00m, left side – 90.00m, right side – 65.00m, back – 57.00m. The total land area is estimated at 4,569m^2.

The inspection covered the internal and external areas of the school and was carried out on February 15, 2025, using the non-destructive technique of visual inspection of the surface of the structures, aiming to identify signs of failures or damage to confirm the presence of pathological manifestations in the building.

In addition, each photographic record was properly documented with the inclusion of date, time, and geographic coordinates.

To determine the classification of cracks (fissures, cracks, fractures, gaps, and breaches), the methodology of Oliveira (2012) was used, as shown in Table 1, determined through visual inspection using a crack gauge to measure the openings.

Table 1 – Classification of Cracks

Anomalies	Openings (mm)
Fissure	Up to 0,5
Crack	0,5 to 1,5
Fracture	1,5 to 5,0
Gap	5,0 to 10,0
Breach	Above 10,0

According to Table 1, the classification of anomaly openings serves to assess the degree of severity of this type of pathological manifestation and to evaluate the type of maintenance to be applied for the solution of each case.

3. Results and Discussion

During the inspection carried out at the school to assess conditions and identify pathological manifestations, some internal classrooms were selected for photographic records, since most of them presented identical manifestations with the same degree of deterioration. Despite the school's critical structural condition, some environments were in good conservation state, requiring only minor repairs. Below, the pathological problems found only in the internal classrooms of the school are presented (Figures 2 to 14). Subsequently, the pathological manifestations found only in the external areas and internal circulation of the school are presented (Figures 15 to 23).

Figure 2 – Access wall to the classroom

(a) Horizontal fissure (opening of 0,25mm)

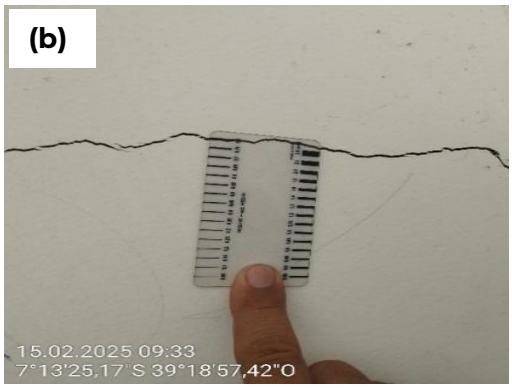

Figure 3 – Corner of the classroom wall

(b) Horizontal crack (opening of 0,8mm)

Regarding the fissures and cracks, these were found in most areas of the school, considering that their presence progressively turned into fractures, as this evolution becomes noticeable throughout the development of this work. From the analysis of Figures 02 and 03, it is possible to identify the potential causes of the anomaly, since according to Caporrino (2018), the main possible causes of horizontal fissures are the expansion of the bedding mortar due to delayed hydration of the magnesium oxide in lime. In addition, another factor would be the expansion of the bedding mortar caused by the cement-sulfate reaction or by the presence of expansive clay minerals in the aggregate. Caporrino (2018) further states that any expansion of the mortar results in horizontal fissures. When expansion occurs and there is no space, the bedding mortar ruptures.

Supporting this understanding, Carneiro, D'Ávila, and Luís (2018) emphasize that fissures, in many situations, are not easily identified, thus requiring extensive knowledge in the field for the application of appropriate correction procedures.

Figure 4 - Fracture located in the central part of the classroom wall

Opening of 1,6mm

As presented in Figure 4, it is possible to identify the potential causes of the pathological manifestation, with the occurrence of the crack located in the central part of the classroom wall being attributed to the lack of proper bonding between the existing masonry and the area where a window had previously been located, later removed during renovations. The absence of bonding mesh during the execution of the masonry contributed to the emergence of this pathological manifestation, since there was no effective connection between the structural elements, leading to the appearance of straight cracks in the region.

In line with this reasoning, Sena et al. (2020) argues that in interface regions between masonry walls and concrete columns, it is also recommended to execute bonding with mesh. These bonds should be applied in the marking masonry (first course) and every two courses along the masonry/column interface. For fixing the mesh, the use of a pin gun is recommended, and a special precaution to be taken is that the pin must be fixed exactly at the mesh fold to prevent possible movements. One way to facilitate this is by employing a metal angle that helps fold the mesh in the correct place and fix the pin. If the pin is not fixed at the fold, interface fissures may occur even with the use of this solution (Sena et al., 2020).

Figure 5 - Inclined fracture near the classroom blackboard

Opening of 2,0mm

As observed in Figure 5, the probable factors contributing to the crack include low soil compaction, which made the building susceptible to structural movements that ultimately compromised it. The likely causes are differential settlements of the foundation, with Caporrino (2018) stating that cracks in structural masonry predominantly develop diagonally from the corners of openings, where stress concentrations are greatest. The author also notes that the main possible causes include aquifer drawdown, settlements caused by neighboring buildings, excavations, vibrations, inadequately designed foundations, and soil alterations.

When, for any reason, foundations undergo differential settlements, the superstructure becomes subject to loads not anticipated in the design. These loads can generate tensile and shear stresses that, consequently, may cause cracks in structural masonry that was not calculated to withstand such forces (Caporrino, 2018).

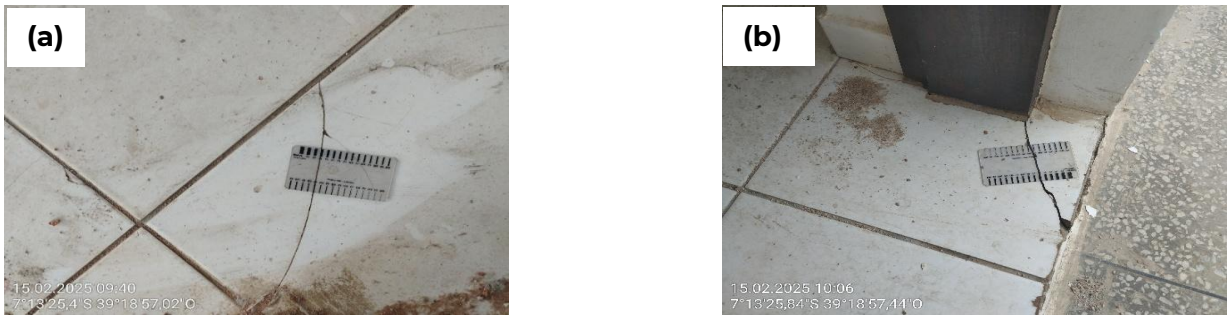

Figure 6 - Crack in ceramic flooring at classroom entrance

(a) Opening of 0,6mm (b) Opening of 1,4mm

Cracks measuring approximately 0.6 mm and 1.4 mm in width were found at the entrance of the school's classrooms (Figure 6). As observed, the probable causes are the lack of adequate negative reinforcement to connect two slab compartments. In this context, Accetti (1998) states that negative reinforcements act in the load flow to prevent stress concentrations, with the purpose of avoiding the possible appearance of cracks over the supports. Since the characteristics of the cracks are not "active," Morais et al. (2020) argue that no major precautions are necessary, as this is a pathological manifestation with only aesthetic effects.

Supporting this understanding, Thomaz (2020) points out that regarding coatings, another pathology resulting from the deformability of structures is the cracking or detachment of ceramic floors or even rigid flooring, because of excessive deformation of the slabs on which they are laid. The author reinforces that when significant slab deflection occurs, the flooring begins to act as its compression layer, producing cracks, chipping, and detachment in the coating. This mainly occurs in cases of "zero slabs" (without screed, with the coating directly bonded to the upper surface).

Figure 7 – Ceramic detachment

Figure 7 shows the detachment of the ceramic coating tile. Detachments are considered when the ceramic tile or the final layer has already fallen off. Sena et al. (2020) state that the main causes of detachments are execution problems that lead to adhesion failure, the lack of an adequate design that considers the variables and materials to be used, as well as the climatic variations to which the coating is subjected, which cause daily temperature differences. The authors further emphasize that another quite common practice that causes detachment is the lack of proper filling and spreading of the adhesive mortar during application.

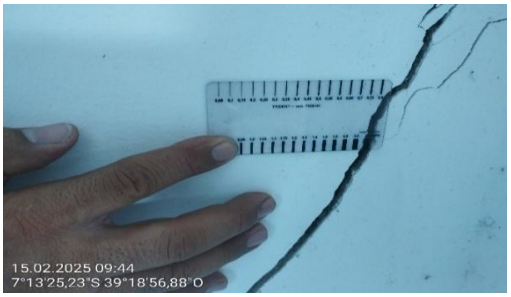

Figure 8 – Inclined gap near classroom entrance
Opening of approximately 6,0mm

Figure 09 – Crack below the classroom blackboard

(a) Opening of approximately 5,0mm

Figure 10 – Crack at the junction of the living room wall

(b) Opening of approximately 3,0mm

As shown in Figures 08, 09, and 10, the probable causes are differential foundation settlement, as previously described in Figure 05 and later in Figure 14.

Figure 11 - Disintegration of wall coating

The presence of disaggregating coating (Figure 11), according to Caporrino (2018), may occur due to the presence of uncarbonated lime and may also be caused by moisture. Possible repairs include eliminating moisture infiltration, drying the coating, brushing the surface, repairing the coating when it becomes powdery, and washing with a hypochlorite solution. All loose material must be removed through brushing and washing, and the coating must be completely dried (Caporrino, 2018).

It is worth noting that the presence of clayey nuclei, with excess fines in the sand or a considerable amount of mica, can lead to coating disaggregation. Mica may also reduce the adhesion of the coating, both to the substrate and between two layers (Cincotto, 1988).

Figure 12 - PVC ceiling panels detaching

As observed in Figure 12, the finishes with functions of waterproofing, weather protection, and improvement of thermoacoustic conditions presented problems in the ceiling, with PVC panels coming loose. According to Carraro (2010), irregularities in the finish, such as poorly executed repairs, are mainly related to the lack of material quality or poor workmanship.

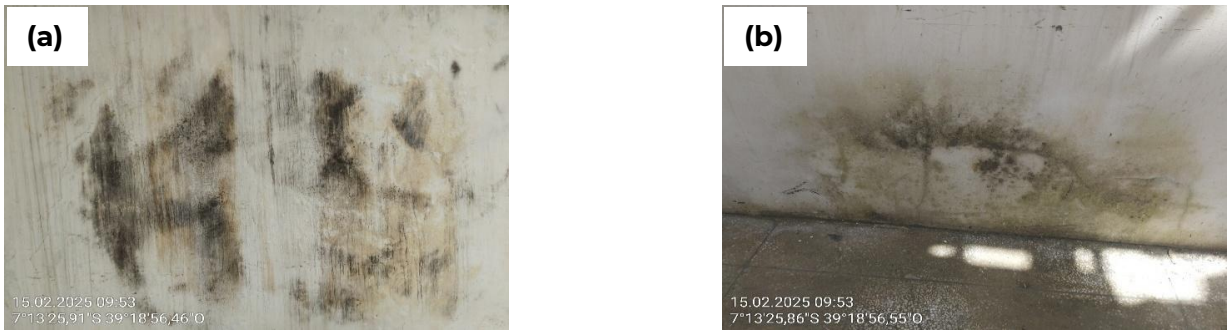

Figure 13 - Infiltration and mold formation

From the analysis of Figure 13, the presence of fungi on the classroom wall can be noted, representing a biological risk. Molds can be prevented during the design phase by adding fungicide to the coating exposed to high humidity, as well as by maintaining environments with natural ventilation and solar radiation to prevent fungal growth (Alucci, Flauzino; Milano, 1988).

Supporting this understanding, Brochado (2016) states that in addition to being a concerning factor for the building, fungi can lead to structural deterioration and affect the performance of certain materials.

The occurrence of fungi may be related to the lack of proper maintenance or repairs in the roofing, hydraulic systems, or waterproofing. Another possible cause of rising damp could be triggered by moisture capillarity in the soil, which is transferred through failures or the absence of adequate waterproofing in the foundation footing or beam (Lima et al., 2018).

This pathological manifestation can generate others, which in turn may lead to plaster detachment. Beyond compromising the aesthetics of the environment, the presence of fungi can negatively impact human health, making the space unhealthy and unsuitable for occupation.

Figure 14 - Diagonal gap above and below window
Opening of approximately 7,0mm

As shown in Figure 14, the cracks are active and have a strong tendency to propagate from the window openings, where there is a considerable reduction in the wall section. To prevent such anomalies, the probable causes are examined, and it is likely that they occurred due to differential foundation settlement, since, in general, the openings are inclined and usually larger, “leaning” toward the point where the greatest settlement occurred (Thomaz, 2020). In this context, another characteristic of cracks caused by settlement is the frequent presence of localized crushing in the form of scales, indicating the shear stresses that produced them. Furthermore, when settlements are significant, a clear variation in crack width can be observed (Thomaz, 2020).

Thomaz (2020) also mentions that differential settlements may result from unbalanced loads; in practice, this can be perfectly identified by cracks starting from the windowsill, approximately at mid-span of the opening.

Still in the analysis of Figure 14, probable causes can also be attributed to the absence of lintels and sills at the lower and upper parts of the window, or possibly the lack of interlocking (bonding) of the blocks. The application of concentrated loads on masonry without the use of lintels and sills to redistribute stresses can lead to the appearance of cracks (Ferreira, 2016).

Cracks may also occur when, even with adequate reinforcement, the imposed load exceeds that anticipated in the structural masonry design.

The following sections will present the pathological manifestations found only in the external areas and internal circulation spaces of the school.

Figure 15 - Crack at the junction between beam and slab

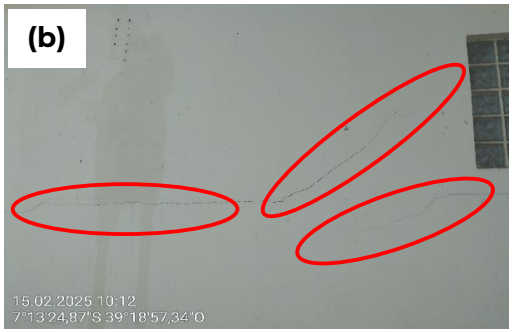

Figure 16 - Horizontal/diagonal cracks

As shown in Figures 15 and 16, the probable causes are also differential foundation settlement, as described in Figures 05 and 14.

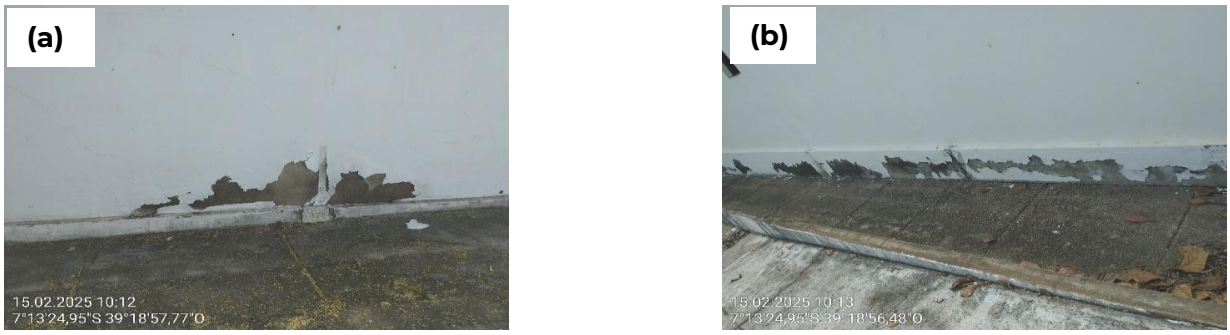

Figure 17 - Paint peeling on the front recess

Figure 18 - Paint peeling on the side wall

The peeling of the paint film, observed in Figures 17 and 18, may result from poor adhesion between the paint film and the mortar coating, solar exposure, and the presence of moisture from rainfall. Polito (2006) states that climatic conditions can contribute to the appearance of paint pathologies caused by relative humidity.

According to Fagundes Neto (2008), paint film peeling may occur when painting is applied over limewash, gypsum, cement, or improperly cured concrete without proper surface preparation. The author also notes that peeling can occur when, in the first painting over plaster, the paint was not properly diluted or there was excess dust on the surface.

Fazenda (1995) comments that another cause of peeling is painting over a heated surface or the reaction of the paint with the substrate, resulting in water-soluble compounds. Peeling may also occur when paint is applied to smooth substrates, such as concrete with release agents or ceramic coatings.

Thomaz (2020) states that in the case of awfully long walls without upper protections such as flashings or coping, detachment of the coating at the top of the wall is common due to water pooling/hygroscopic

expansion of the mortar coating. Detachment of the mortar is also common due to thermal expansion, which is much greater than the expansion of the wall body itself.

Figure 19 - Vertical cracks

Figure 20 - Detachment of the masonry

From the analysis of Figures 19 and 20, the probable causes can be identified. Due to the tensile strength of the bedding mortar and masonry components, as well as the adhesion developed between them, cracks caused by thermal movements may follow the vertical mortar joints or even extend through the masonry components (Thomaz, 2020). As mentioned earlier in this work (Figure 05), in the interface regions between masonry walls and concrete columns, it is recommended to execute bonding with mesh.

In cases where mesh is not available, reinforcements can be placed in the columns using a drill and epoxy-based adhesive to create bonds between the structure and the infill, maintaining the same recommendation of fixing every two courses (Sena et al., 2020).

Caporrino (2018) further states that vertical cracks may also occur at masonry junctions, sections where thickness changes, or regions weakened by the presence of pipes.

Figure 21 – Cracks at the junction of structural elements of columns, beams, and slabs

As observed in Figure 21, the structural framework of the building is likely to be subject to thermal movements, especially in exposed concrete structures. Thomaz (2020) states that the regions most affected are usually the junctions between beams during thermal movements, where internal cracks may appear within the concrete elements and therefore remain undetectable. However, the thermal movement of beams can cause visible cracking in columns; this occurs mainly when the structure lacks expansion joints or when they are poorly designed (openings and spacing). According to Fabiani (1975), the thermal expansion of beams can cause slightly inclined cracks at the ends of columns.

It should also be considered that significant differences in movement occur between the upper and lower surfaces of roof slabs, with the upper surfaces generally subjected to more abrupt and intense movements (Thomaz, 2020).

For solid slabs with large spans, torsional moments that develop near the slab corners can produce diagonal cracks, forming approximately isosceles triangles with the corners. Another type of crack may appear when there is no negative reinforcement between constructively continuous slab panels designed as simply supported, or when the negative reinforcement was undersized or displaced during concreting; in such cases, cracks appear on the upper surface of the slab, approximately following its contour (Thomaz, 2020).

Cracks in beams, as shown in Figure 21, may arise due to the following factors: thermal movement, overloads, excessive structural deformations, foundation settlements, and chemical alterations of materials, such as reinforcement corrosion, for example (Carneiro, D'Ávila; Luís, 2018).

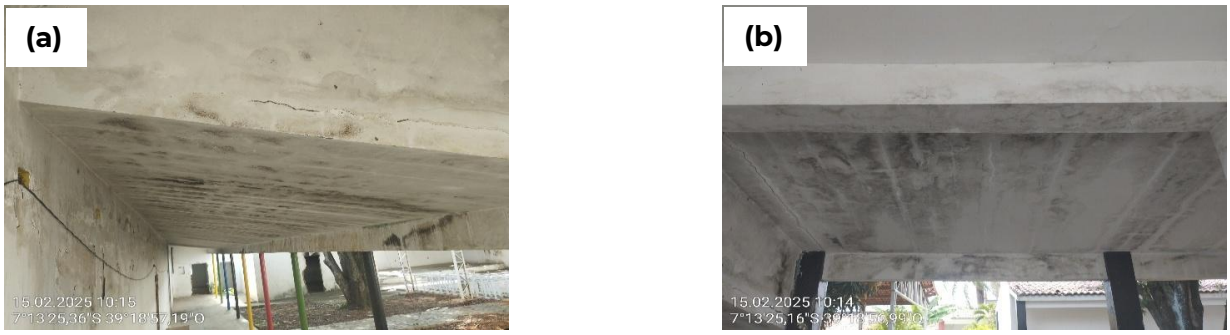

Figure 22 – Dark Spots

The presence of dark stains on the surface, as shown in Figure 22, originates from a group of living organisms (fungi) that proliferate under favorable climatic conditions, such as humid, poorly ventilated, or shaded environments (Fagundes Neto, 2008).

According to Fazenda (1995), the main causes of stain formation are high humidity associated with the presence of decomposing organic materials or plant parasites (vegetation). Ambient temperatures between 0°C and 40°C, relative humidity above 70%, and the presence of oxygen favor the development of fungi and the formation of algae, which invariably occurs in outdoor environments near coastal areas and/or dense vegetation (Fazenda, 1995).

The presence of cracks facilitates fungal growth; moreover, the occurrence of fungi increases dust retention and moisture persistence. This combination of factors constitutes an additional element for fungal proliferation (Fagundes Neto, 2008).

Figure 23 - Mapped fissures and cracks

The cracks and fissures mapped have varied shapes and are distributed across the entire surface, as shown in Figure 23. A possible cause is the shrinkage of the base mortar. The relationship between the probable cause and the anomaly lies in the fact that the mapped cracks/fissures result from an excess of fines in the mortar, that is, a rich mortar, thus causing cracking due to shrinkage. This damage also does not allow for repair, except through the complete removal of the coating (Caporrino, 2018).

Still regarding the mapped cracks, the main originating sources can be cited: mortar shrinkage due to excess fines in the mix, rapid drying, and excessive troweling. They are given this designation because they manifest in a map-like pattern. Many times, they are superficial and can be accentuated by thermal shock, especially on sun-exposed façades (Cincotto, 1989).

4. Conclusion

The main objective of this study was to survey the pathological manifestations in a public school located in the municipality of Juazeiro do Norte-CE, considering both the internal and external areas of the building.

Based on the analyses carried out, it was found that the structural safety of the building is compromised, presenting a series of construction pathologies. Among the main problems identified are cracks, fissures, and fractures of different types, masonry detachment, and advanced-stage gaps. The possible causes of these pathological manifestations include failures in soil compaction, differential foundation settlement, thermal movements, absence of lintels and counter-lintels in windows, lack of maintenance, as well as inadequate execution of previously performed renovations, as evidenced throughout the study.

In addition, cracks and detachment were found in the ceramic coating, as well as fissures and mapped cracks in the industrial flooring. Other problems identified include disintegration of coatings, peeling paint,

detachment of PVC ceiling panels, dark stains, and infiltrations accompanied by mold formation. Given the severity of these manifestations, the fact that the building is interdicted is justified.

Regarding the use of the crack gauge, it was possible to determine the classification of the openings of the anomalies to assess the degree of criticality of the pathological manifestations.

During the development of this study, some limitations were identified. These include the scarcity of information about the renovations carried out throughout the life of the structure, as well as uncertainty regarding the existence or nonexistence of design projects for the building.

Thus, the visual inspection for an initial diagnosis of the problems was effective in identifying damages, although during the analysis of the collected data there may be uncertainty regarding the probable causes, origin, or behavior of the anomalies in order to define the diagnosis. In this sense, to support this diagnosis it is essential to complement with non-destructive tests (ultrasound, radiography—X-rays or gamma rays, rebar detection, among others). As a suggestion for future work, it is recommended to include strategies for structural reinforcement, detailed analyses of the presence and effects of moisture, as well as continuous monitoring of the progression of cracks. These actions may support decision-making regarding the feasibility of use or rehabilitation of the building.

Resumo: A conservação e manutenção de edificações históricas são fundamentais para a preservação do patrimônio cultural e arquitetônico de uma sociedade. A importância de manter essas estruturas em bom estado não apenas resguarda o valor histórico e estético, mas também contribui para o desenvolvimento socioeconômico das regiões em que estão inseridas, promovendo o turismo e a identidade cultural local. O presente trabalho tem como objetivo diagnosticar as manifestações patológicas presentes nas edificações do Polo Turístico da Igreja do Céu em Viçosa do Ceará, priorizar as intervenções necessárias para sua conservação e manutenção. Este Polo Turístico abriga a Capela de Nossa Senhora das Vitórias, que é o ponto mais alto da cidade, situada a 900 metros de altitude, no topo do morro que rodeia a cidade. No alto do templo, destaca-se a imagem do Cristo Redentor A metodologia empregada utiliza a Matriz GUT para a priorização das ações de intervenção com base nos dados coletados e analisados considerando a gravidade, urgência e tendência de cada patologia. A preservação do patrimônio histórico tem um impacto significativo no turismo e na economia local. Inicialmente, foi realizada uma inspeção visual detalhada das edificações, identificando as patologias existentes. Este processo facilitou a alocação de recursos e a programação de intervenções com base na criticidade e no potencial de risco para a segurança, funcionalidade e conservação das edificações. Esta metodologia proporciona um framework detalhado para o diagnóstico e planejamento de ações de conservação no Polo Turístico da Igreja do Céu. A abordagem integrada e fundamentada em normas técnicas e ferramentas analíticas estratégicas permitem uma avaliação precisa das condições das edificações, assegurando intervenções eficazes que respeitam e preservam o valor histórico e cultural do local. A implementação de um plano de ação bem fundamentado é importante para a manutenção de sua integridade estrutural.

Palavras-chave: Inspeção predial; Manifestações patológicas; Matriz GUT.

Abstract: The conservation and maintenance of historical buildings are fundamental for the preservation of a society's cultural and specialized heritage. Maintaining these structures in good condition not only safeguards their historical and aesthetic value but also contributes to the socioeconomic development of the regions in which they are located, promoting tourism and local cultural identity. This work aims to diagnose the pathological manifestations present in the buildings of the Igreja do Céu Tourist Center in Viçosa do Ceará, prioritizing the necessary interventions for their conservation and maintenance. This Tourist Center houses the Chapel of Nossa Senhora das Vitórias, which is the highest point in the city, situated at 900 meters altitude, on the top of the hill surrounding the city. At the top of the temple, the image of Christ the Redeemer stands out. The methodology employed uses the GUT Matrix to prioritize intervention actions based on the data found and detailed, considering the severity, urgency, and trend of each pathology. The preservation of historical heritage has a significant impact on tourism and the local

economy. Initially, a detailed visual inspection of the buildings was carried out, identifying existing pathologies. This process facilitated the allocation of resources and the scheduling of interventions based on the criticality and potential risk to the safety, functionality, and conservation of the buildings. This methodology provides a detailed framework for the diagnosis and planning of conservation actions in the Igreja do Céu Tourist Area. The integrated approach, grounded in technical standards and strategic analytical tools, allows for a precise assessment of the buildings' conditions, ensuring effective interventions that respect and preserve the historical and cultural value of the site. The implementation of a well-founded action plan is important for maintaining its structural integrity.

Keywords: Building inspection; Pathological manifestations; GUT matrix.

1. Introdução

A conservação e manutenção de edificações históricas são fundamentais para a preservação do patrimônio cultural e arquitetônico de uma sociedade. A importância de manter essas estruturas em bom estado não apenas resguarda o valor histórico e estético, mas também contribui para o desenvolvimento socioeconômico das regiões em que estão inseridas, promovendo o turismo e a identidade cultural local (Lourenço; Oliveira 2004; Avelino, 2013). Nesse contexto, o diagnóstico preciso das manifestações patológicas presentes nessas edificações e a priorização de intervenções são essenciais para assegurar sua longevidade e funcionalidade, preservando seu valor histórico.

O Polo Turístico da Igreja do Céu, localizado em Viçosa do Ceará, constitui um exemplo notável de patrimônio histórico que necessita de intervenções constantes para a sua preservação. Com edificações que datam do século XIX, como a Igreja Nossa Senhora das Vitorias, fundada em 1938, a manutenção dessas estruturas envolve desafios significativos devido à idade, aos materiais utilizados e às técnicas construtivas da época (Luz 2015). A falta de intervenções regulares pode resultar na deterioração acelerada dessas edificações, comprometendo sua integridade estrutural e valor histórico (Rodrigues 2012; Silva 2017).

O presente trabalho tem como objetivo diagnosticar as patologias presentes nas edificações do Polo Turístico da Igreja do Céu e estabelecer uma priorização para as intervenções necessárias. A abordagem metodológica integra inspeções visuais detalhadas, análises técnicas e a aplicação da Matriz GUT, oferecendo um framework robusto para o planejamento e execução de ações de conservação (Carvalho 1994; Hédis et al., 2013). Este Polo Turístico abriga a Capela de Nossa Senhora das Vitórias, fundada por Monsenhor José Carneiro da Cunha e dedicada a Nossa Senhora das Vitórias. A capela é o ponto mais alto da cidade, situada a 900 metros de altitude, no topo do morro que rodeia a cidade. No alto do templo, destaca-se a imagem do Cristo Redentor, esculpida pelo italiano Agostinho Odísio Balmes em 1937 e inaugurada pelo Bispo José Tupinambá da Frota, da Diocese de Sobral, em 14 de agosto de 1938.

A igreja passou por duas reformas significativas em menos de 20 anos. A primeira, em 1998, resultou na criação do Polo Turístico, Artesanal e Cultural Igreja do Céu, o qual é o foco deste estudo. A segunda reforma, ocorrida em 2016, incluiu a construção de áreas de lazer, estacionamento, restaurantes e uma área de eventos.

As manifestações patológicas presentes em edificações mais antigas causam sérios problemas à vida útil e à durabilidade das estruturas, manifestando-se em diversos tipos e quantidades. No Polo Turístico Igreja do Céu em Viçosa do Ceará, existem edificações recentes, reformadas em 2019, e outras antigas do século XX, como a Igreja de Nossa Senhora das Vitórias. Esta última, apesar de sua importância histórica, passou por uma reforma entre 2019 e 2020 após a queda de sua torre, um evento que despertou maior interesse pela inspeção do local.

A inspeção predial auxilia na identificação, na classificação e nas recomendações de soluções para essas patologias. Já a análise GUT (Gravidade, Urgência e Tendência) prioriza as ações em termos de gravidade, urgência e tendência, sendo de fácil implementação e baixo custo. Este trabalho tem como objetivo mapear e classificar as patologias presentes nas edificações do Polo Turístico Igreja do Céu através da matriz GUT, visando garantir a preservação e a segurança das estruturas, em um local turístico echistórico.

1.1 Matriz de GUT na construção civil: definição, funcionamento e importância

De acordo com Fávere e Silva (2016) foi frente à necessidade de obter resolução para problemas complexos dentro da indústria americana e também da japonesa, no século XX, mais especificamente por volta de 1980, que Charles H. Kepner e Benjamin B. Trego desenvolveram uma ferramenta que ficou conhecida pela nomenclatura “matriz GUT” com o objetivo de fornecer às indústrias uma forma de apresentar solução ao seus problemas.

Gravidade (G):

Avalia o impacto do problema caso ele não seja resolvido. Um problema é considerado grave se causar danos ou comprometer a segurança e o funcionamento de processos ou sistemas. A gravidade é geralmente avaliada em uma escala de 1 a 5, onde 1 representa um impacto mínimo e 5 indica um impacto extremamente severo.

Urgência (U):

Mede o tempo disponível para resolver o problema antes que ele cause consequências mais graves. Um problema é urgente se exigir uma solução imediata para evitar que a situação se agrave. A urgência também é avaliada em uma escala de 1 a 5, onde 1 significa que o problema pode esperar e 5 indica que precisa ser resolvido imediatamente.

Tendência (T):

Avaliar a probabilidade de o problema piorar com o passar do tempo não for solucionado. Um problema com uma tendência alta pode se agravar rapidamente, aumentando seu impacto e urgência. A tendência é medida em uma escala de 1 a 5, onde 1 representa uma tendência de piora mínima e 5 indica uma tendência de agravamento muito rápida.

Figura 1- Referência de valores da Matriz de GUT

MATRIZ GUT				
Ptos	**G** **Gravidade** Consequências se nada for feito.	**U** **Urgência** Prazo para tomada de decisão.	**T** **Tendência** Proporção do problema no futuro.	**G x U x T**
5	Os prejuízos ou dificuldades são extremamente graves.	É necessária uma ação imediata.	Se nada for feito, o agravamento da situação será imediato.	5 x 5 x 5 **125**
4	Muito graves.	Com alguma urgência.	Vai piorar em curto prazo.	4 x 4 x 4 **64**
3	Graves.	O mais cedo possível.	Vai piorar em médio prazo.	3 x 3 x 3 **27**
2	Pouco graves.	Pode esperar um pouco.	Vai piorar em longo prazo.	2 x 2 x 2 **8**
1	Sem gravidade.	Não tem pressa.	Não vai piorar ou pode até melhorar.	1 x 1 x 1 **1**

1.2 Patologias em edificações históricas

As manifestações patológicas em edificações são problemas construtivos que surgem devido a diversas falhas ao longo das etapas do ciclo de vida da construção. Essas falhas podem ocorrer em diferentes fases, incluindo projeto, fabricação, execução, uso e manutenção. Com base em normas e estudos, como a NBR 15575 e outras literaturas especializadas, é possível identificar e compreender melhor as causas das patologias mais comuns.

Em 2012, o Instituto Brasileiro de Avaliações e Perícias de Engenharia (IBAPE), disponibilizou a Norma de Inspeção Predial Nacional, pela qual é possível se obter diretrizes e critérios para a análise de manifestações patológicas através de vistorias.

A partir desta norma, podemos classificar as patologias quanto à sua natureza, nível e grau. De acordo com o grau de risco, as falhas patológicas são classificadas como:

- Grau crítico, que gera riscos à saúde e segurança, com perda de funcionalidade, desempenho e de vida útil - das estruturas.
- Grau médio, que gera perda precoce do desempenho e funcionamento das estruturas; e,
- Grau mínimo, verificada por pequenas falhas, que não comprometem o desempenho das estruturas, por hora.

Para aplicabilidade das vistorias, o IBAPE também as dividiu em 3 níveis, que são:

- Nível 1: Aplicável às vistorias de grandes canteiros, quando o número de imóveis existentes na área de influência da obra seja muito elevado.
- Nível 2: Que deve contemplar uma descrição básica e objetiva do objeto vistoriado, das anomalias e falhas constatadas e uma ilustração fotográfica suficiente para caracterizar sua tipologia, padrão construtivo, estado de conservação, anomalias e falhas existentes.
- Nível 3: Que contempla todos os elementos relacionados no Nível 2 e apresenta uma completa caracterização de revestimentos de piso, parede e forro, esquadrias e elementos aderidos que sejam significativos, além de todos os elementos construtivos que possam ser relevantes para uma completa descrição do imóvel.

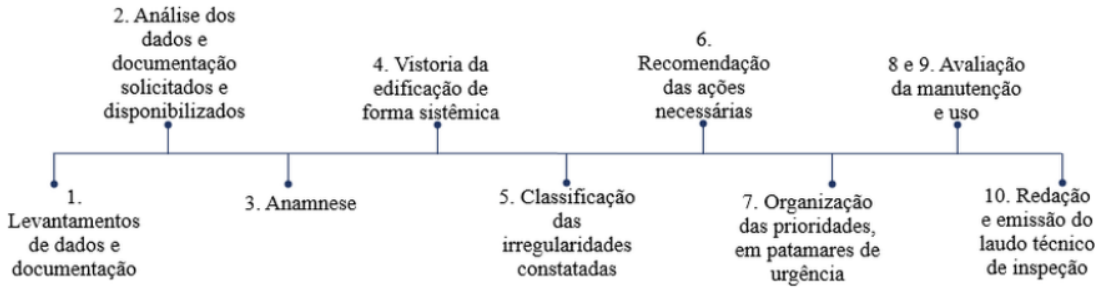
1.3 Classificação das anomalias

De acordo com a NBR 16747:2020, as anomalias podem ser classificadas em diversas categorias, tais como:

- Fissuras e Trincas: São aberturas ou separações na estrutura do edifício que podem indicar problemas estruturais graves.

- Infiltrações: Indicam a presença de água nas superfícies, o que pode levar à degradação dos materiais de construção.

- Corrosão: Degradação de elementos metálicos, geralmente causada por exposição à umidade e agentes corrosivos.



- Destacamento de Revestimentos: Separação de camadas de revestimento das superfícies subjacentes, muitas vezes devido à má aderência ou umidade.

Segundo a NBR 15575 (ABNT, 2013), a vida útil de projeto (VUP) é o período estimado para o qual a construção foi projetada, atendendo aos requisitos de desempenho. Este período pode ser prolongado mediante manutenções corretivas apropriadas. A norma enfatiza que é crucial que os usuários realizem

todas as ações de manutenção para assegurar que a vida útil projetada seja alcançada. Algumas manifestações patológicas podem surgir devido ao uso inadequado ou à falta de manutenção.

A Associação Brasileira de Normas Técnicas (ABNT) estabelece diversas diretrizes para a inspeção e manutenção de edificações. A NBR 16747:2020, por exemplo, detalha os procedimentos para inspeção predial, incluindo conceitos, terminologia e métodos de avaliação (ABNT, 2020). Esta norma é fundamental para assegurar que as inspeções sejam realizadas de forma sistemática e padronizada, garantindo a identificação correta das patologias e a implementação de medidas corretivas eficazes.

Figura 2-Etapas metodológicas da inspeção predial, conforme NBR 16747

Fonte: ABNT (2020)

A NBR 15575:2013 da ABNT estabelece critérios de desempenho para edificações habitacionais, abordando aspectos como segurança, habitabilidade e sustentabilidade. Esta norma é fundamental para a classificação de anomalias e definição de intervenções necessárias para manter o desempenho adequado das edificações ao longo de sua vida útil de projeto (VUP). A adoção dessas diretrizes é especialmente importante em edificações históricas, onde a preservação das características originais deve ser balanceada com a necessidade de garantir segurança e funcionalidade.

1.3.1 Importância na construção civil

A construção civil se beneficia enormemente da Matriz GUT, pois ela permite gerenciar eficientemente os riscos e assegura que os recursos sejam alocados onde mais forem necessários. Ela é utilizada para priorizar reparos em defeitos de construção como fissuras ou infiltrações, decidir sobre atualizações de segurança em edifícios antigos, e programar manutenções preventivas, garantindo que problemas críticos sejam tratados primeiro, conforme sugerido por Meireles (2001) e Sotille (2014) ao discutirem a integração da Matriz GUT com outras metodologias de gestão.

Os principais benefícios da Matriz GUT incluem a capacidade de priorizar de forma objetiva as ações de intervenção, garantindo que os recursos sejam direcionados para as áreas de maior necessidade. A ferramenta também facilita a comunicação entre os diferentes stakeholders envolvidos na preservação das edificações históricas, proporcionando uma base clara e racional para a tomada de decisões. (Scartezini, 2009).

1.4 Técnicas de conservação e restauro

1.4.1 Técnicas invasivas e não invasivas

As técnicas de conservação e restauro podem ser classificadas como invasivas ou não invasivas, dependendo do grau de intervenção necessário. Rodrigues (2012) e Avelino (2013) enfatizam que as

intervenções devem ser minimamente invasivas e, sempre que possível, reversíveis, para preservar as características históricas e arquitetônicas das edificações. Técnicas não invasivas incluem limpeza superficial e reparos menores, enquanto técnicas invasivas podem envolver a substituição de elementos estruturais.

1.4.2 Materiais e métodos compatíveis

A escolha dos materiais e métodos de restauro deve ser compatível com os originais utilizados na construção da edificação. Isso é crucial para manter a integridade histórica e estrutural do edifício. Estudos de caso demonstram que a utilização de materiais inadequados pode levar a novas patologias, agravando os problemas existentes (Silva 2017).

2. Metodologia

Para avaliação das patologias nas edificações do Polo Turístico da Igreja do Céu, foi realizada integração das diretrizes da ABNT NBR 16747:2020 (ABNT 2020) e utilização da Matriz GUT, conforme descrito por Kepner e Tregoe (1981), para a priorização das ações de intervenção. O processo metodológico inclui técnicas de inspeção visual e análise técnica detalhada, objetivando elaborar um plano de ação que atenda às necessidades de conservação, restauro e manutenção das edificações, assegurando a preservação de sua integridade estrutural e valor histórico.

O diagnóstico das condições atuais das edificações e a subsequente priorização das intervenções são divididos nas seguintes etapas:

Inspeção Visual Detalhada: constitui a etapa inicial do diagnóstico, sendo crucial para a identificação preliminar de manifestações patológicas. Esta fase segue recomendações de especialistas (Carvalho 2009; Meireles 2001), adaptadas às peculiaridades das edificações históricas, enfatizando a necessidade de um olhar atento e sistematizado para capturar detalhes que possam indicar a presença de deterioração ou falhas estruturais;

Análise Técnica e Diagnóstico das Patologias: a identificação das causas das patologias é apoiada por uma revisão bibliográfica abrangente, incluindo referências como a NBR 15575 (ABNT 2013), que oferece diretrizes sobre desempenho de edificações habitacionais e critérios para a classificação de anomalias.

E com base nos dados coletados e analisados, as patologias são classificadas e priorizadas utilizando a Matriz GUT. A implementação das ações de intervenção é planejada com base nas prioridades estabelecidas, levando em consideração as melhores práticas em conservação de edificações históricas e as especificidades do patrimônio em estudo. A seleção de técnicas de restauro e reparo é guiada tanto pela eficácia em resolver as patologias identificadas quanto pela compatibilidade com os materiais e métodos construtivos originais das edificações, seguindo princípios de preservação histórica e sustentabilidade.

Esta metodologia proporciona um framework detalhado para o diagnóstico e planejamento de ações de conservação no Polo Turístico da Igreja do Céu. A abordagem integrada e fundamentada em normas técnicas e ferramentas analíticas estratégicas permite uma avaliação precisa das condições das edificações, assegurando intervenções eficazes que respeitam e preservam o valor histórico e cultural do local. A implementação de um plano de ação bem fundamentado e priorizado é crucial para a manutenção da integridade estrutural das edificações e para a continuidade da sua utilização e apreciação por gerações futuras.

3. Resultados e Discussões

Durante a inspeção realizada, foi possível identificar diversas patologias que se repetem em diferentes áreas do Polo Turístico Igreja do Céu.

Tabela 1- Resumo das principais patologias encontradas e suas localizações específicas.

3.1 Manifestações patológicas identificadas

3.1.1 Manchas de Umidade

Presentes em quase todos os ambientes do polo, essas manchas indicam problemas de infiltração e falta de impermeabilização adequada. A umidade constante pode levar à contaminação por fungos, comprometendo a saúde dos frequentadores e a durabilidade das construções.

Figura 4-Manchas de umidade na fachada Sudeste do palco de eventos

Fonte: Autor (2024)

3.1.2 Infiltrações

Devido à falta de acesso às partes internas das lojas e restaurantes na praça de alimentação, as infiltrações foram observadas apenas na Igreja Nossa Senhora das Vitórias. Essas infiltrações podem levar a problemas estruturais e estéticos ao longo do tempo.

3.1.3 Fissuras

Encontradas em 10 ambientes diferentes do polo, incluindo paredes externas e internas de diferentes edificações. Essas fissuras podem ser causadas por manuseio do solo, variações térmicas ou falhas na execução e uso de materiais inadequados.

3.1.4 Trincas

Apresentadas em 9 ambientes, as trincas são um tipo de fissura mais profunda e podem indicar problemas estruturais mais graves que devem ser tratados para evitar maiores danos.

3.1.5 Rachaduras

Identificadas em 4 ambientes, as rachaduras podem comprometer a integridade das edificações, necessitando de atenção mais elevada para evitar riscos maiores.

Figura 5-Rachadura no topo do muro de contenção

Fonte: Autor (2024)

3.1.6 Fendas

As fendas, apresentadas em 2 ambientes, possuem maior dimensão e representam uma preocupação significativa. Encontradas no muro de contenção próximo à pista de skate e na escadaria principal, essas falhas indicam problemas graves e devem ser monitoradas de perto para evitar danos maiores.

3.1.7 Brechas

Apresentada em 1 ambiente, as brechas são aberturas muito grandes que indicam sérios problemas estruturais ou colapsos parciais. Essas brechas representam um risco significativo à integridade estrutural e à segurança dos ocupantes e requerem intervenção. A presença dessas brechas em elementos estruturais e não estruturais pode permitir a infiltração de água, agravando problemas de umidade e comprometendo a durabilidade das construções.

3.1.8 Fundamentos

Apresentados em 5 ambientes, os achados foram identificados em diversas áreas das calçadas ao longo do polo. Esses fundamentos são sinais de problemas no subsolo ou má compactação do solo, que podem comprometer a segurança e acessibilidade do local.

3.1.9 Deslizamentos

Correndo em 1 ambiente, as ameaças indicam instabilidade do solo que pode afetar a segurança das construções e dos visitantes, necessitando de intervenções imediatas quando em áreas de grande movimentação.

3.1.10 Eflorescência

Presente em 4 ambientes, a eflorescência é um sinal de infiltração de água nas paredes, causando o aparecimento de depósitos de sais que comprometem a estética e a integridade dos revestimentos.

3.1.11 Descascamento da pintura

Identificado em 3 ambientes, o descascamento da pintura indica problemas de umidade e infiltração, além de possíveis falhas na qualidade da pintura e revestimento, necessitando de reparos para preservar a aparência e proteção das superfícies.

Figura 6-Descascamento de pintura e eflorescência no palco de evento

Fonte: Autor, (2024)

Para priorizar as ações corretivas e de manutenção no Polo Turístico Igreja do Céu, será utilizada a matriz GUT, uma ferramenta eficaz para a avaliação e classificação de problemas com base em três critérios principais: Gravidade, Urgência e Tendência. A aplicação da matriz GUT permite uma análise sistemática das patologias identificadas, auxiliando na determinação das intervenções mais críticas e imediatas.

- Gravidade (G): Avalia o impacto potencial da patologia, considerando os danos que ela pode causar à estrutura, à funcionalidade e à segurança dos usuários.

- Urgência (U): Determina o tempo disponível para a tomada de ações corretivas, priorizando as patologias que requerem intervenções imediatas.

- Tendência (T): Analisa a probabilidade de agravamento da patologia ao longo do tempo, considerando a velocidade com que o problema pode se tornar mais sério.

A seguir, será apresentada a classificação das principais patologias encontradas no Polo Turístico Igreja do Céu através da matriz GUT, proporcionando uma visão clara das prioridades de manutenção e reparo necessárias para garantir a integridade e segurança do local:

Figura 7-Manifestações Patológicas Identificadas no Pólo Turístico Igreja do Céu

MPI 01	Infiltrações e Marcas de Umidade no Palco de shows
MPI 02	Descascamento de Pintura e Eflorescência no Palco de Eventos

Fonte: Autor (2024).

Para tratar as trincas e fissuras identificadas, recomenda-se:

-Monitoramento Regular: Acompanhar o desenvolvimento das trincas e fissuras com inspeções periódicas e utilizar técnicas de monitoramento, como marcadores de trinca, para avaliar a evolução e identificar a necessidade de intervenções imediatas.

-Ensaios Não Destrutivos: Realizar ensaios não destrutivos, como ultrassom e termografia, para avaliar o estado interno da estrutura sem causar danos adicionais.

-Reparos Estruturais: Onde necessário, executar reparos estruturais, incluindo a selagem das trincas com materiais adequados e a aplicação de reforços para estabilizar a estrutura.

-Reforço da Fundação: Em caso de movimentação da fundação, pode ser necessário reforçar a fundação da igreja para evitar novas movimentações e assegurar a estabilidade da edificação.

Para as rachaduras e brechas na escadaria, deve-se proceder com:

- A investigação Geotécnica: Realizar um estudo geotécnico para avaliar as condições do solo e identificar a extensão do problema.

- Recompactação do Solo: Caso a compactação inadequada seja confirmada, proceder à recompactação do solo com técnicas apropriadas.
- Melhoria da Drenagem: Implementar um sistema de drenagem eficiente para evitar a acumulação de água e a subsequente desestabilização do solo.
- Reparo da escadaria: Reconstruir as áreas afetadas do piso e muretas, assegurando que a fundação e o solo subjacente estejam adequadamente tratados.
E para correção do afundamento do solo, deve-se recompactar o solo, reforçar o muro de contenção e melhorar a drenagem.

4. Conclusão

Este trabalho apresentou um diagnóstico detalhado das patologias presentes nas edificações do Polo Turístico da Igreja do Céu, em Viçosa do Ceará, utilizando uma metodologia integrada que incluiu inspeções visuais detalhadas e a aplicação da Matriz GUT para a priorização das intervenções necessárias. A pesquisa evidenciou a importância de uma abordagem sistemática e fundamentada em normas técnicas para garantir a conservação e manutenção eficazes de edificações históricas, assegurando a preservação do valor cultural e arquitetônico do local.
Os resultados obtidos destacaram a necessidade de intervenções urgentes em algumas áreas críticas, devido à gravidade das patologias identificadas, como infiltrações, fissuras e destacamento de revestimentos. A aplicação da Matriz GUT foi fundamental para facilitar a alocação de recursos e a programação de ações corretivas, assegurando que as intervenções fossem realizadas de maneira eficiente e direcionada, priorizando a segurança, funcionalidade e preservação das edificações.
As principais intervenções prioritárias são as fendas presentes no muro de contenção, que apresentam o maior grau de risco devido ao seu potencial de comprometimento estrutural significativo. Em seguida, vêm as brechas presentes na escadaria, que também geram riscos graves à segurança dos usuários. É igualmente crucial dar atenção às rachaduras presentes na Igreja Nossa Senhora das Vitórias, pois este é um local onde já ocorreu um incidente de desabamento, ressaltando a necessidade de medidas preventivas rigorosas.
A recuperação de revestimentos deteriorados é importante para manter a integridade estética e histórica das edificações, garantindo a compatibilidade dos novos materiais com os originais. A prevenção de eflorescências e bolores requer a aplicação de tratamentos antifúngicos e hidrofóbicos, a fim de reduzir a umidade e prevenir a formação de bolores e eflorescências.
A manutenção contínua e a inspeção regular das edificações são igualmente importantes para monitorar a eficácia das intervenções e prevenir o surgimento de novas patologias. A adoção de um plano de manutenção preventiva é essencial para prolongar a vida útil das construções e evitar a deterioração acelerada.
Portanto, a execução de um plano de ação bem fundamentado e priorizado é crucial para a manutenção da integridade estrutural das edificações do Polo Turístico da Igreja do Céu e para a continuidade de sua utilização e apreciação pelas gerações futuras. A preservação eficaz das edificações históricas não só garante a proteção de um legado arquitetônico inestimável, mas também fortalece o vínculo da comunidade com sua herança cultural, impulsionando o turismo e o desenvolvimento socioeconômico da área.

USE OF THE GUT MATRIX IN THE ANALYSIS OF PATHOLOGICAL MANIFESTATIONS IN HOUSING UNITS OF THE MINHA CASA MINHA VIDA PROGRAM: A CASE STUDY

Lucas Menezes de FARIAS[1], **Jefferson Luiz Alves MARINHO**[2]

[1] Universidad Regional do Cariri – URCA, Juazeiro do Norte-CE, Brazil, lucasmenezes547@gmail.com
[2] Universidad Regional do Cariri – URCA, Juazeiro do Norte-CE, Brazil, jeff.marinho@urca.br

Abstract: In Brazil, the production of social housing is highly concentrated in the *Minha Casa Minha Vida* Program (PMCMV), aimed at low-income families. This Federal Government Program is part of a broad housing policy designed to eradicate the housing deficit, which, according to the João Pinheiro Foundation (2023), amounts to 5.97 million homes, with the Southeast and Northeast regions concentrating most of this deficit. Various pathological manifestations are frequently identified in these housing units, such as cracks, fractures, fissures, and leaks, often occurring in the early stages of use. This study aims to apply the GUT Matrix methodology (Gravity, Urgency, and Trend) in the analysis of pathological manifestations, using a sample of 7 (seven) data points from a total of 37 (thirty-seven) housing units in the Manoel Raimundo de Santana Filho Residential Complex of the PMCMV, located in Juazeiro do Norte - CE. The data were obtained through a company outsourced by *Caixa Econômica Federal*, and a documentary analysis was conducted on the residential unit projects (floor plan and subdivision plan), technical reports, inspection reports, recovery budgets, as well as photographic records of the inspected units. After the analysis, the pathological manifestations were classified and quantified through visual inspection, and based on this, a priority chart was prepared using the GUT method. It was observed that the pathological manifestation related to differential foundation settlement has the highest priority level, and that cracks, fractures, and leaks are the most frequent manifestations. It was possible to conclude the effectiveness of the GUT matrix as a tool for developing an efficient recovery plan, considering the degree of priority for repairing the affected units, especially those that compromise the safety of the building, its users, third parties, as well as its aesthetics.
Keywords: Pathological Manifestations. GUT Matrix. *Minha Casa Minha Vida* Program.

1. Introduction

The construction sector plays a crucial role in the country's economic development, as it generates a significant number of jobs, contributing to the reduction of unemployment and helping to address the housing deficit.

The *Minha Casa Minha Vida* Program (PMCMV) is a housing initiative created by the Federal Government in March 2009, managed by the Ministry of Cities with the participation of collegiate bodies responsible for the program's financing funds. These entities provide subsidies and reduced interest rates for housing loans in both urban and rural areas, targeting low-income families and aiming to reduce Brazil's housing deficit (Brazil, 2023).

Beyond the financial support conditions offered by PMCMV, it is crucial to emphasize that housing quality plays a fundamental role in making the investment worthwhile. Although engineering technologies and the construction materials industry have evolved, various types of pathological manifestations are still observed in PMCMV buildings, and their early appearance is the focus of this research.

The emergence of pathological manifestations within a short period of use in social housing has motivated several academic studies on the subject, given that PMCMV has significant representation in the country's economy, driving both the real estate sector and the construction industry itself, and generating numerous direct and indirect jobs.

In this context, the implementation of the program has been consolidated as a public policy to reduce Brazil's housing deficit. Currently, in the city of Juazeiro do Norte-CE, for example, projects under construction include the Residencial Mirante da Serra I and II, located in the Pedrinhas neighborhood, totaling 384 housing units, and the Residencial Beata Maria de Araújo I and II, located in the São José neighborhood, with 424 units. Together, these two developments comprise 808 housing units under construction in Juazeiro do Norte, scheduled to be delivered to the population this year.

According to Sena *et al*. (2020), pathological manifestations are understood as degradations identified in buildings, which may arise during the construction phase (due to the use of inappropriate methods or materials), during project design, or over time because of misuse or inadequate use of the building.

In general, Marinho and Mesquita (2022) state that the results converge toward the finding that problems arising from pathological manifestations range from minor damage to compromising the safety of buildings, potentially culminating in structural collapse. In this regard, Aguiar *et al*. (2022) argue that knowledge and treatment of building failures contribute to extending its service life, while also providing significant safety for users. Supporting this view, Resende *et al*. (2022) affirm that by investigating and understanding these manifestations, it is possible to identify the causes of deterioration and take measures to prevent further damage to the building and financial losses to owners.

Within this context, pathological manifestations may be related to improper use of the building, lack of maintenance, natural material wear, exposure to adverse weather conditions, or design and construction errors. These manifestations can affect the stability, safety, and functionality of the building, as well as reduce its durability (Santos Júnior; Santos; Santos, 2023).

There are several processes and methods for identifying pathological manifestations in construction, ranging from visual analysis—consisting of inspecting the surface of structures for signs of failures or damage—to more complex tests such as ultrasonography, thermography, and chemical analyses (Santos Júnior; Santos; Santos, 2023).

In this regard, Camargo and Ferrari (2021) state that non-destructive testing (NDT) techniques allow for the evaluation of the quality and integrity of a building without compromising its structure and are widely used for various purposes in the construction industry.

Thus, risk management of anomalies and pathologies is applied when it becomes necessary to prioritize actions among a range of alternatives. From the inspection of a structure, anomalies, failures, and defects are identified, but corrective actions must be prioritized (Knapp; Olivan, 2021).

A methodology that establishes a risk criterion for anomalies and pathologies, translating qualitative assessment into a quantitative indicator of building performance, enables comparative, uniform, and impartial classification. Standardized evaluation criteria based on pre-established parameters make it possible to systematize risk analyses in an analytical manner (Knapp; Olivan, 2021).

Accordingly, the authors further state that the application of the GUT method (Gravity, Urgency, and Trend) makes it possible to compare the performance of the same structure throughout its service life (maintenance management) and/or to compare multiple structures (investment prioritization criteria).

The GUT Matrix methodology aligns with the objectives of NBR 15575-1:2024 – Residential Buildings – Performance – Part 1: General Requirements (ABNT, 2024) and reinforces the importance of disseminating best engineering practices and their role in defending housing quality in Brazil.

Therefore, the application of the GUT Matrix is essential for recognizing the priority of resolving damages found in a building, identifying the most critical item and the need for urgent repairs. Conversely, failure to carry out maintenance may result in more severe damage, leading to higher costs and greater technical demands (Aguiar *et al*., 2022).

In this sense, the main objective of this study is to apply the GUT Matrix methodology as a management tool in the analysis of pathological manifestations, using a sample of 7 (seven) data points from a total of 37 (thirty-seven) housing units in the *Conjunto Residencial Manoel Raimundo de Santana Filho* of the PMCMV, in the city of Juazeiro do Norte - CE.

2. Materials and Methods

2.1 Methodological Procedures

The methodological steps applied in this study were carried out using data provided by a company outsourced by *Caixa Econômica Federal*. These included: residential unit projects (floor plans and subdivision plans), technical reports, inspection reports, and photographic records of the analyzed housing units.

During the inspections, the cell phone camera was used to capture panoramic and detailed photographs of the pathological manifestations under study. A crack gauge, a rubber hammer, and a clipboard were also used to assist with the necessary notes.

The remaining methodological steps were subdivided into two stages. After data analysis, the pathological manifestations were classified and quantified through visual inspection, and based on this, a priority chart

of pathological manifestations was prepared using the GUT method. Following the analysis, the results—whose specific details will be presented in the Results and Discussion section—were consolidated.

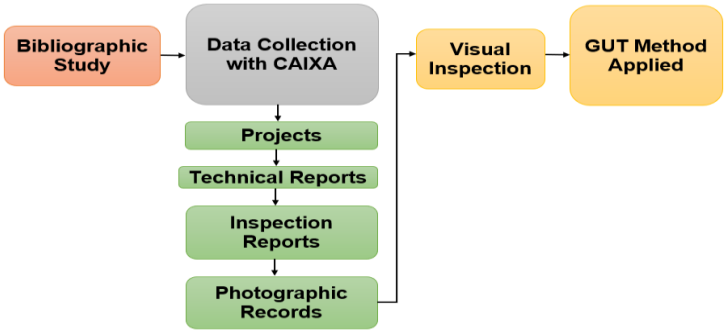

Figure 1 – Flowchart of the Research Stages

2.2 Specification of the GUT Method

The method basically consists of listing anomalies and failures in columns and then assigning each item a score from 1 to 10, depending on the degree of Gravity, Urgency, and Trend. In this study, 1 represents the lowest index for the parameters adopted in the matrix, while 10 represents the highest. Aguiar *et al*. (2022) state that, at the end of the scoring process, it becomes necessary to calculate a number that represents the verification result, thereby determining the priority level for solving the problem. In other words, the item with the highest score will have the greatest priority in addressing the issue.

Through easily interpretable tables, Verzola, Marchiori, and Aragon (2014) established characteristics as parameters for assigning weights to each anomaly, considering both criteria and degree. Based on Tables 1, 2, and 3, it is possible to visualize the main definitions, according to the authors, for the elements of Gravity, Urgency, and Trend in the GUT Matrix.

When classifying **Gravity**, one must consider the possible risks and losses to users. The definition of a problem considered critical was assigned to the levels: Total and High; the designation of a problem considered regular was assigned to the level: Medium; and the definition of a problem considered minimal was assigned to the levels: Low and None, as illustrated in Table 1.

Table 1 – GUT Classification for Gravity

Degree	Degree definition	Note
TOTAL	Risk of death, irreversible impact with excessive loss of performance, extremely high financial loss.	10
TALL	Risk of harm to users, recoverable damage to the environment and the building.	8
MÉDIUM	Health risk to users caused by system degradation, reversible environmental damage, average financial loss.	6
LOW	No risk to users' health, low environmental degradation, need to replace some systems, low financial loss.	3
NONE	No risk to health or physical well-being, minimal environmental deterioration, no damage of value.	1

Regarding **Urgency**, the definition of each level was based on how significant the manifestation is, the time required for the problem to be resolved, and the speed with which the issue must undergo intervention. Accordingly, Table 2 represents the situation described.

Table 2 – GUT Classification for Urgency

Degree	Degree definition	Note
TOTAL	Immediate event, need for property interdiction without extra deadlines.	10
TALL	Imminent event, urgent intervention.	8
MÉDIUM	Adversity expected soon, need to intervene quickly.	6
LOW	Initialization of an incident, intervention still in the form of plans.	3
NONE	Unexpected adversity, but monitoring is necessary for future maintenance.	1

For the topic of **Trend**, the level was defined according to the likelihood of the problem worsening, as well as the possibility of its reduction or disappearance over time, as shown in Table 3.

Table 3 – GUT Classification for Trend

Degree	Degree definition	Note
TOTAL	Progress of the condition immediately, with possible worsening at any time.	10
TALL	Evolution of the situation about to occur.	8
MÉDIUM	Medium-term evolution.	6
LOW	Possible long-term evolution. It may occur. Delayed situation.	3
NONE	Stabilized situation, with no progression of the case.	1

After assigning weights (from 1 to 10) to each item (**Gravity, Urgency, and Trend**), the level of each problem was classified across the three functions, and the product of their respective values was calculated (**G × U × T**). Subsequently, at the end of the scoring process, it becomes necessary to determine a number that represents the verification result, thereby establishing the priority level of the problem. In other words, the item with the highest score will have the greatest priority in resolving the issue.

2.3 Selection of the Residential Development

The research conducted was a case study, for which the *Conjunto Residencial Manoel Raimundo de Santana Filho* (intended for families with incomes up to R$ 1,600 – Range I) was selected. It is in the *Betolândia* neighborhood in the municipality of Juazeiro do Norte-CE. The development has the following geographic coordinates: 7° 12’ 47” South latitude (S) and 39° 18’ 55” West longitude (W). The main justification for choosing this development was the availability of data from *Caixa Econômica Federal – CAIXA*. In addition, the selection criteria included a project that, at the time, had been built less than five (5) years earlier and had been occupied for more than one (1) year, meaning it was still covered by Civil, Professional,

and Material Liability Insurance (RCPM). The housing units were delivered to residents in the beginning of the second semester of 2014.

The development consists of 18 blocks, within which 713 residential units are distributed. Of these, 36 units were adapted for Persons with Disabilities (PWD). The houses are single-story, built with raft foundations, ceramic brick masonry, and roofs made of wooden structures with ceramic tiles. Regarding finishing standards, the houses were delivered with commercial-grade ceramic flooring, latex-painted walls, PVC panel ceilings (without slabs), ceramic wall coverings in bathrooms and kitchens up to 1.80 m in height, aluminum exterior doors, semi-hollow wooden interior doors, and aluminum/glass windows.

Each housing unit (HU) has a built area of 43.85 m², situated on lots measuring 6 m in width by 20 m in depth, totaling 120 m². The internal layout includes: a porch, living/dining room, two bedrooms, a social bathroom, and a kitchen, as shown in Figure 2 below.

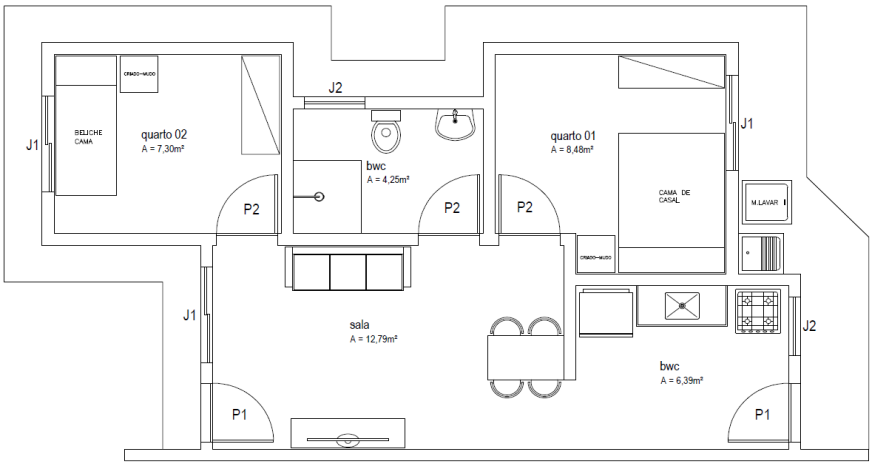

Figure 2 – Floor plan of a housing unit

Given this, the selection of the housing units used in the sample was based on the number of residents who filed Reports of Pathological Manifestations (BOMP) with *Caixa Econômica Federal* in 2017. According to the PMCMV owners' rights and duties handbook, responsibility for construction defects lies with the developer, not with *CAIXA*. However, if the developer fails to respond, residents may seek assistance from *Caixa Econômica Federal*, the Consumer Protection and Defense Program (PROCON), or through legal action.

In this context, of the 713 units in the development, only 37 filed reports with the financing institution due to the presence of pathological manifestations in their units. As a result, *CAIXA's* technical team visited the site to conduct technical inspections of the units, which later produced data through inspection reports for the preparation of the GUT Matrix.

The inspections covered both the internal and external areas of the housing units and were carried out between December 2017 and February 2018. A non-destructive technique of visual inspection was used to verify the presence of pathological manifestations in the units, collecting data and photographic records of each one.

During the inspections, some basic interviews were also conducted with the residents regarding the state of conservation, maintenance, and occurrence of pathological manifestations.

To determine the classification of openings (cracks, splits, fractures, gaps, and breaches), the methodology of Oliveira (2012) was applied, as presented in Table 4, and determined through visual inspection using a crack gauge.

Table 4 – Classification of Cracks

Anomalies	Openings (mm)
Fissure	Up to 0,5
Crack	0,5 to 1,5
Fracture	1,5 to 5,0
Gap	5,0 to 10,0
Breach	Above 10,0

A total of 37 housing units were inspected, from which a subsample of 7 data points was selected, considering the repetition of damages. In this way, the sample set was drawn from different streets and blocks to ensure representation of the pathological manifestations, as presented in Table 5.

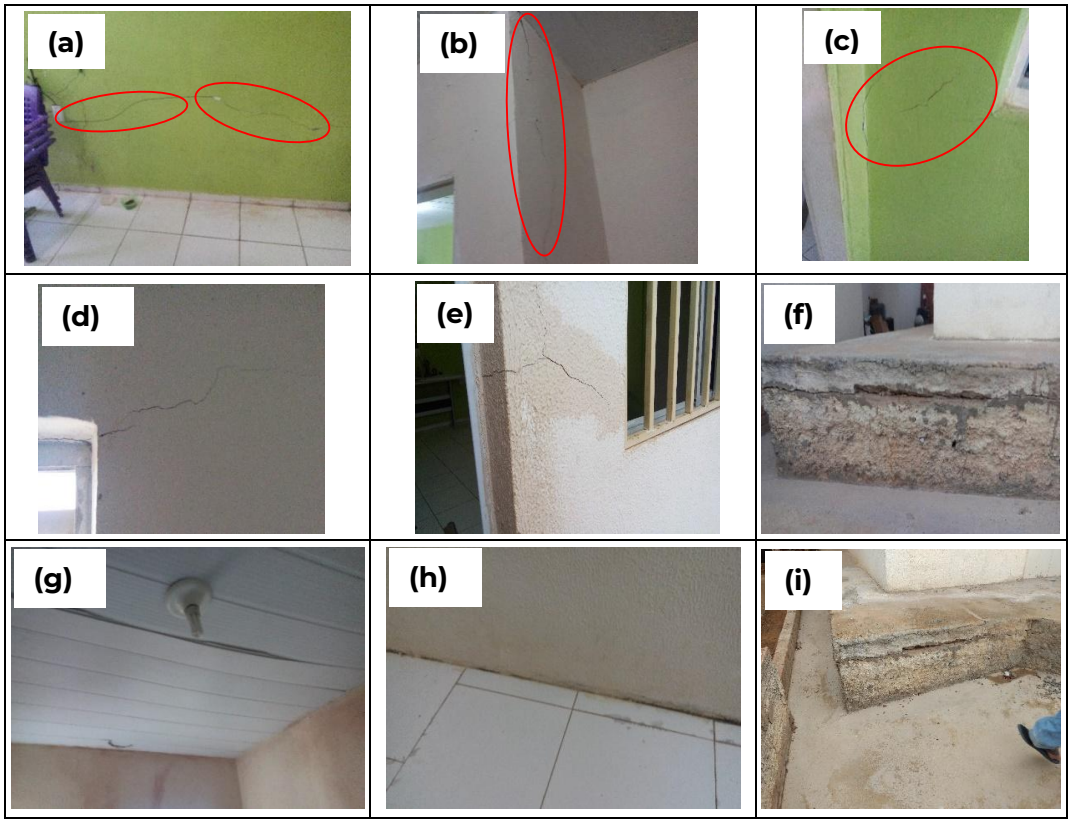

Table 5 – Determination of the Research Sample

ADDRESS	BLOCKS	UNITS	ESTIMATED AGE
Street 1	A	3	4
Street 2	B	2	4
Street 3	C	2	4
Street 5	E	4	4
Street 7	G	2	4
TOTAL	-	**13**	-

After data collection, the records were organized for tabulation and subsequent analysis. For tabulation, Excel was used to create tables, facilitating the analysis and interpretation of the results. All documentary data and photographic records were provided by *ENGEAP – Avaliações e Perícias Ltda.*, a company outsourced by *Caixa Econômica Federal*.

3 Results and Discussion

After inspections carried out in 37 housing units, 7 samples were taken to verify the conditions and identify pathological manifestations, with photographic records made of each one, as shown in the following Figures. Subsequently, Tables 6 and 7 were prepared, containing the application and prioritization matrix for repairing the manifestations using the GUT method. It is worth noting that pathological problems not clearly visible in the photographs were highlighted with circular shapes to indicate the exact location of the anomaly.

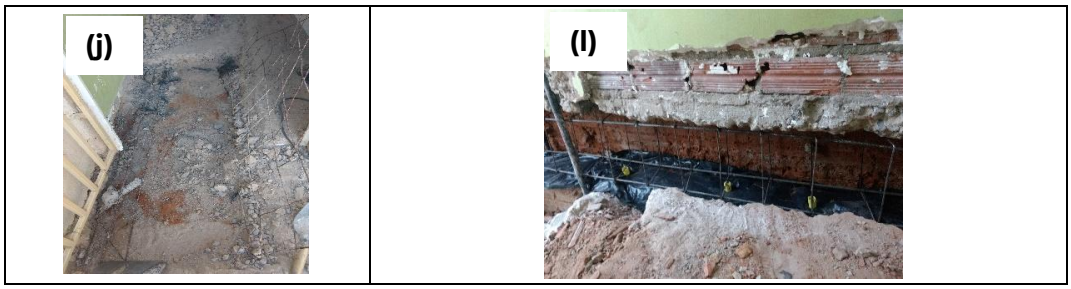

Figure 3 – Pathological Manifestations Identified at Street 2, n°. 30

(a, b) Cracks; (c, d, e) Fissures; (f, i) Differential settlement of the foundation masonry; (g) Deformation of the PVC ceiling; (h) Detachment of the ceramic coating and stains; (j) Inconsistency of the raft foundation; (l) Execution of structural reinforcement in the foundation.

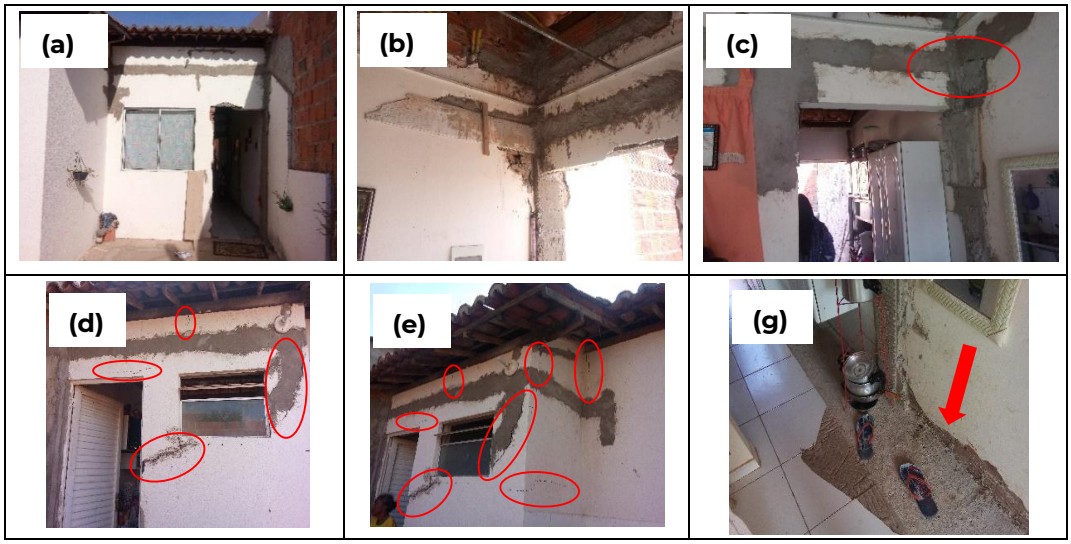

Figure 4 – Pathological Manifestations Identified at Street 5, n° 7

(a, b, c, d, e) Cracks; (g) Ceramic tiles fractured because of structural foundation repair.

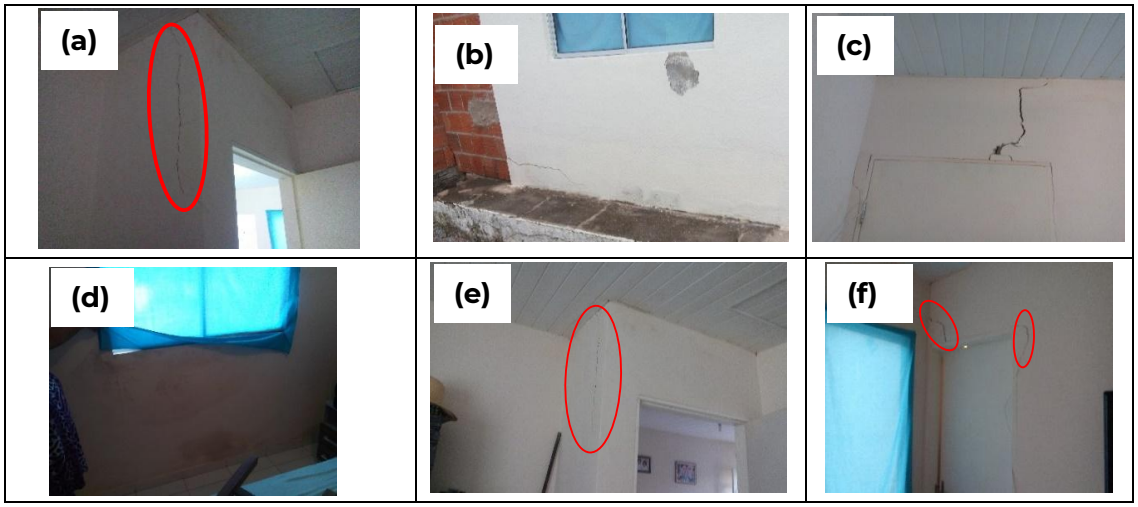

Figure 5 – Pathological Manifestations Identified at Street 2, n°. 24

(a, b, c, e, f) Cracks; (d) Damp stains from wall infiltration.

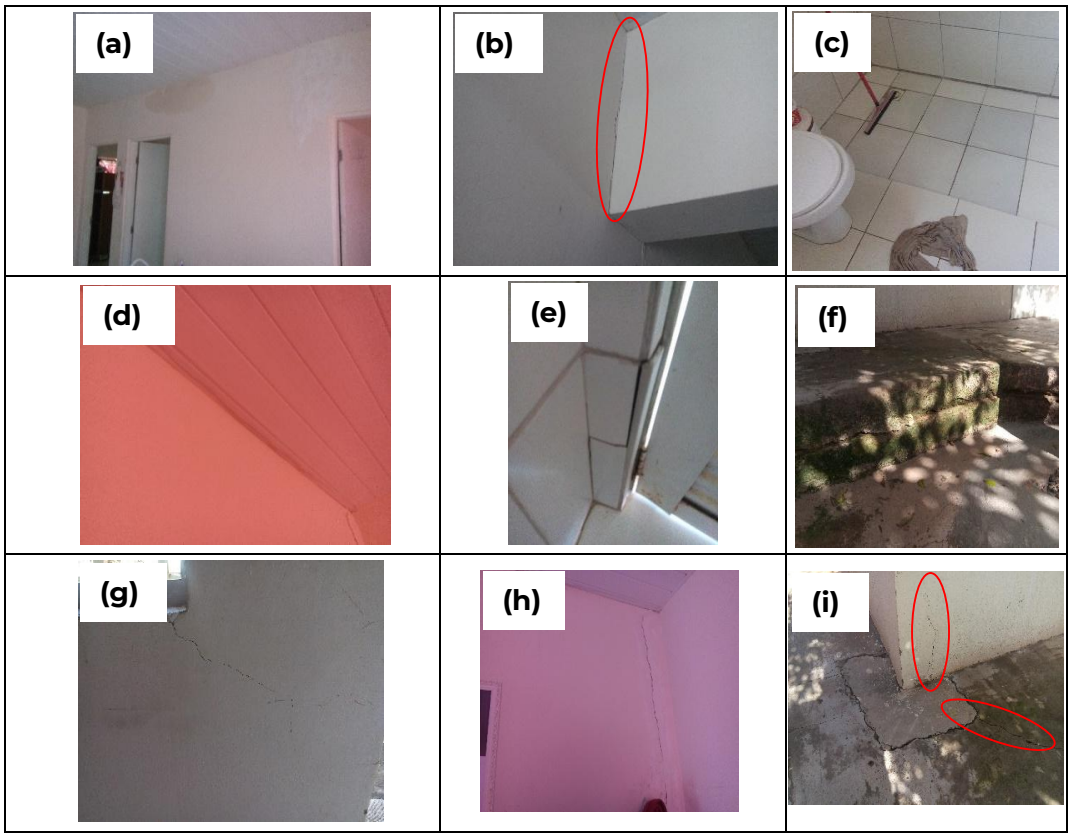

Figure 6 – Pathological Manifestations Identified at Street 3, n°. 18

(a) Infiltration in the interior walls (living room and bedrooms); (b, f, h, i) Cracks; (c) Infiltration and discoloration of the bathroom coating (floor and wall); (d) PVC ceiling in the bedroom with misaligned panels; (e) Detachment of ceramic wall covering in the kitchen; (g) Fissures.

Figure 7 – Pathological Manifestations Identified at Street 1, n°. 31

(a, b) Cracks; (c) Paint deterioration caused by infiltration; (d) Deformation of the PVC ceiling.

Figure 8 – Pathological Manifestations Identified at Street 5, n°. 19

(a, b, c, e) Wall infiltration; (d) Damaged PVC ceiling in Bedroom 1; (f) Leakage from the shower valve.

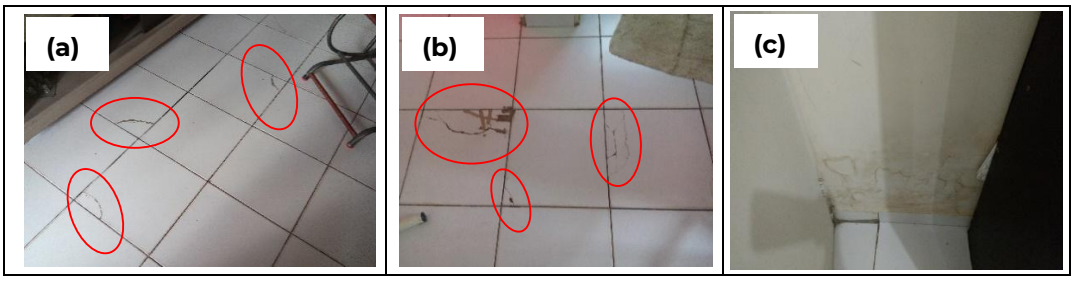

Figure 9 – Pathological Manifestations Identified at Street 7, n°. 61

(a, b) Cracked and worn ceramic flooring; (c) Wall infiltration.

Based on the data collected and the analysis performed, the GUT chart was prepared, indicating the incidence of the diagnosed pathological manifestations, and assigning scores for the method's criteria, along with the resulting product. Finally, the repair priority was established according to the value obtained from the product G×U×T, as shown in Table 6.

Table 6 – Application Matrix of the GUT Method

Item	Housing Unit	Incidence	Gravity	Urgency	Trend	GxUxT	Priority
1	STREET 2, N° 30	High	8	10	8	640	1
2	STREET 5, N° 07	High	8	8	8	512	2
3	STREET 2, N° 24	High	6	8	8	384	3
4	STREET 3, N° 18	High	6	8	8	384	3
8	STREET 1, N° 31	High	6	6	8	288	4
12	STREET 5, N° 19	Medium	6	6	6	216	5
34	STREET 7, N° 61	Low	3	3	3	27	6

Regarding the classification of the incidence level in Table 6, it was established according to the total score in the priority chart, which was based on each level presented in Tables 1 to 3 of subsection 2.2, while also considering the pathological manifestations with the highest incidence in each unit and those requiring greater attention for damage repair/control.

Therefore, the units that presented a higher number of pathological problems compared to the others were classified as *high incidence*. These included: fissures, cracks, fractures, damp stains from wall infiltration,

leaks/infiltration, discoloration of bathroom floors and/or ceramic wall coverings, worn ceramic flooring, fractured ceramic tiles with broken/cracked plates, and rust stains. The other units, which presented fewer pathological problems among those cited, along with isolated issues that were not recurrent in each unit, were classified as *medium* and *low incidence*.

As can still be observed in Table 6, some pathological manifestations have the same degree of priority. For this reason, Table 7 was prepared, in which the manifestations were grouped with their respective diagnoses, in order of priority.

Table 7 – Prioritization for Repair of Pathological Manifestations

Degree of Priority	Identification	Main Pathological Manifestations Identified
1°	STREET 2, N° 30	Structural inconsistency of the raft foundation and differential settlement of the base masonry, medium incidence of cracks, high incidence of fissures. PVC ceiling deformations.
2°	STREET 5, N° 07	High incidence of severe cracks.
3°	STREET 2, N° 24	High incidence of cracks (2 severe) and medium incidence of fissures.
	STREET 3, N° 18	High incidence of cracks (new appearances after the property's repair) and medium incidence of fissures.
4°	STREET 1, N° 31	Medium incidence of cracks, fissures, and hairline fractures.
5°	STREET 5, N° 19	High incidence of damp stains from wall infiltration.
6°	STREET 7, N° 61	High incidence of cracked and worn ceramic flooring.

According to the data from Tables 6 and 7, the pathological manifestations with the highest incidence are wall infiltrations, cracks, fissures, and fractures of various types (inclined, vertical, and horizontal). Regarding the foundations, specifically the raft foundation used in the construction of the PMCMV houses, it is inferred that the manifestations related to the inconsistency of the raft and the differential settlement of the base masonry (Street 2, No. 30) must be addressed first, as they demand greater attention for damage repair and pathology control. These are the most serious issues, precisely because they obtained the highest scores in the GUT Matrix calculation.

There are numerous occurrences of cracks, fissures, and fractures identified in the study area. In this sense, occupying second place in the corrective maintenance priority order is the unit at Street 5, No. 7, which is in a critical condition, presenting many severe cracks. In third place, the units at Street 2, No. 24 and Street 3, No. 18, showed the highest number of cracks (9 and 11, respectively), in addition to a medium incidence of fissures and other pathological manifestations.

The other units with cracks, fissures, and fractures were classified in fourth place, as they generally presented a higher frequency of occurrences, and consequently, a medium incidence. These anomalies were predominantly identified in living rooms and bedrooms. The greatest occurrences were observed in sections with openings, such as wall corners and door frames. This type of fissure may be caused by the absence of reinforcement and the abrupt closing of doors, which can generate stress levels above the wall's admissible limit.

In fifth place in the priority order are infiltrations in internal and external walls, as well as leaks/infiltrations and discoloration of bathroom floors/ceramic coverings, classified as medium damage. Lower-priority damages, which do not require immediate treatment, included cracked, broken, and worn ceramic flooring. In the subsystem of coverings, pathological manifestations (5th and 6th places) were also observed, such as paint stains, damaged PVC ceiling panels, detached ceramic tiles, and color changes.

According to Carraro (2010), irregularities in finishing, such as paint stains and poorly executed repairs, are mainly associated with low-quality materials or inadequate workmanship.

By analyzing the studied sample, it was possible to identify that within four years after the delivery of the houses to their owners (end of the second semester of 2014), all units analyzed presented some type of

pathological manifestation. Since the units were still covered by the Civil, Professional, and Material Liability Insurance (RCPM) at the time the damages appeared, the construction company repaired the residences that presented problems within the five-year warranty period after delivery.

From these results, visual inspection proved to provide valuable data, becoming an extremely useful tool in the evaluation and recognition of pathological manifestations in the studied development. However, integrating other control tools beyond visual assessment, such as the GUT Matrix, was fundamental to complement the results and increase the reliability of this study.

4 Conclusion

The main objective of this study was to apply the GUT Matrix methodology as a management tool in the analysis of pathological manifestations, using a sample of 7 cases from a total of 37 housing units in the Manoel Raimundo de Santana Filho Residential Complex of the PMCMV program, located in Juazeiro do Norte, Ceará.

It was found that the most frequent pathological manifestations in the units were cracks (some of them severe and occurring at high frequency), followed by fissures and fractures, which also showed a significant incidence. The absence of lintels and counter-lintels contributed to the appearance of diagonal fissures/cracks in the walls. The lack of these structural elements over time intensifies the opening of fissures/cracks, which, depending on the material, can cause significant damage due to overloads.

Several infiltrations in internal and external walls, as well as leaks and discoloration of bathroom floors/ceramic coverings, were also identified. Such damages may worsen and compromise the stability of the units if corrective measures are not implemented. It is essential that these problems be identified and treated as quickly as possible to avoid further structural damage and financial losses for the owners. Cracked, broken, and worn ceramic floors were also highly visible. Their recovery requires complete replacement of the material, highlighting the low quality of the materials used and resulting in high additional costs for replacement within a short period.

Regarding the use of the GUT method to rank manifestations by priority level, it was possible to establish a hierarchy of risks, inferring that pathologies related to raft foundation inconsistency and differential settlement of the base masonry demand the greatest urgency for corrective maintenance.

Overall, the pathological problems in the housing units of the analyzed PMCMV residential complex show similarities regardless of the different regions of Brazil. Although the PMCMV provides affordable housing, long-term quality has proven deficient. Proper identification not only assists in solving problems but can also prevent their recurrence in the future, thereby ensuring durability and safety of the constructed structures.

Based on the results obtained in this study, it is possible to establish a strategic plan for correcting the most critical pathological manifestations first, followed by those with the highest incidence, which deteriorate materials and structural elements in terms of both aesthetics and functionality.

It can be concluded that the GUT Matrix is a valuable strategic planning tool that, through visual inspections, supports decision-making regarding possible interventions to repair structural damages. However, the evaluation of structural conditions is a complex subject, and since this tool relies on visual inspection, it has limitations. It is crucial that professionals conducting and analyzing inspections possess knowledge and experience in building pathology to ensure coherent evaluations that reflect the reality of the observed damages.

Thus, visual inspection combined with the GUT Matrix for an initial diagnosis of problems is effective in identifying damages, although during data analysis there may be uncertainty regarding probable causes, origins, or the behavior of anomalies. In this sense, complementary non-destructive tests (such as ultrasound, radiography—X-ray or gamma rays—, and rebar detection) are fundamental to support diagnosis.

Resumo: Diversos fatores podem influenciar a degradação dos pavimentos rodoviários, entre eles as condições climáticas e a ausência de manutenção. A ocorrência de chuvas pode favorecer o surgimento de defeitos, pois contribui para a formação de buracos e compromete a resistência à derrapagem, elevando o risco de aquaplanagem e acidentes. Para que as manutenções sejam realizadas no período adequado, torna-se necessário conhecer os defeitos existentes e compreender como estes impactam as condições de trafegabilidade e segurança dos usuários, possibilitando a escolha de intervenções que assegurem níveis satisfatórios de serventia do pavimento. Diante disso, o presente trabalho tem o objetivo de caracterizar os defeitos de um pavimento rodoviário flexível nas estações seca e chuvosa e o impacto na variação do conforto ao rolamento em função dessas condições sazonais. Para tanto, foram realizados registros por vídeomonitoramento de três trechos rodoviários, totalizando 88 km, que permitiram uma análise comparativa das condições superficiais entre as estações seca e chuvosa. Adicionalmente, realizou-se uma avaliação subjetiva por meio do Valor de Serventia Atual (VSA). Verificaram-se 140 ocorrências de defeitos, entre buracos, trincas e fissuras. Observou-se que os remendos evoluíram para buracos devido ao acúmulo de água pluvial e as trincas existentes no período seco tornaram-se buracos em cinco meses, pois a infiltração de água acelerou o desgaste da estrutura. Quanto ao VSA, a rodovia apresentou condições funcionais boas ou ótimas na estação seca, degradando-se para níveis regulares ou péssimos no período chuvoso. Concluiu-se que o maior surgimento de defeitos, principalmente buracos, ocorreu durante o período chuvoso. O VSA evidenciou a evolução dos defeitos e as condições de rolamento dos trechos inspecionados. Por fim, a sazonalidade climática contribuiu para a redução do nível de serventia funcional dos pavimentos flexíveis, acompanhando o aumento da incidência de defeitos.

Palavras-Chaves: Condição de rolamento; Avaliação funcional; Condições sazonais; Valor de Serventia Atual.

1. Introdução

O clima e a ausência de manutenção são fatores que podem influenciar a degradação dos pavimentos rodoviários. Variações extremas de temperatura e de chuvas exercem um impacto na resistência dos pavimentos, uma vez que podem alterar as características de rigidez das camadas e do subleito. A água penetra na interface entre o asfalto e o agregado, e a membrana asfáltica começa a se desprender dos agregados, que então se soltam e formam defeitos na superfície.

Essas variações ambientais têm contribuído para a deterioração prematura dos pavimentos flexíveis, resultando em fissuras, buracos, trilhas de rodas e desagregação. A combinação de fatores climáticos e de tráfego cria um ambiente desafiador para a preservação da condição funcional e estrutural do pavimento (Castro, Silva e Lange, 2014; Jaafar, 2019). Esse quadro exige intervenções cada vez mais frequentes, o que não apenas aumenta os custos de manutenção, mas também prejudica o fluxo de tráfego e compromete a segurança dos usuários (Al-Samahi *et al*., 2024).

A ocorrência desses defeitos na superfície de um pavimento é um indicativo de ineficiência funcional ou estrutural. Dessa forma, os pavimentos precisam ser monitorados continuamente, a fim de gerar informações que subsidiem os Sistemas de Gerência de Pavimentos (SGP), orientando as intervenções na rodovia e suporte para a implantação de novas tecnologias de projeto, construção, manutenção e reabilitação (Haas, Hudson e Zaniewski, 1994).

A avaliação de pavimentos constitui uma etapa fundamental para identificar as intervenções necessárias à melhoria do conforto e da segurança dos usuários. Um dos métodos empregados para essa finalidade é o Levantamento Visual Contínuo – LVC (DNIT, 2003a). Como exemplo, tem-se a rodovia federal brasileira analisada neste estudo, que apresenta trechos que, durante a quadra chuvosa, manifestam diversos defeitos, como buracos e trincas. Após esse período, observa-se que são realizadas intervenções de remendo e recapeamento, como forma de manutenção corretiva. No entanto, sabe-se que a definição de intervenções capazes de garantir níveis satisfatórios de serventia requer a compreensão dos mecanismos de surgimento dos defeitos e de seu comportamento frente às condições ambientais. Nesse contexto, o presente trabalho tem o objetivo de caracterizar os defeitos de um pavimento rodoviário flexível nas estações seca e chuvosa e o impacto na variação do conforto ao rolamento em função dessas condições sazonais.

2. Fundamentação teórica

O principal objetivo da pavimentação é garantir a trafegabilidade em qualquer época do ano e em quaisquer condições climáticas, e proporcionar conforto e segurança aos usuários. Quando o solo natural não é resistente o suficiente para suportar a repetição das cargas das rodas sem sofrer deformações significativas, torna-se necessário construir uma estrutura chamada pavimento. Ela é, portanto, construída sobre o subleito para suportar as cargas dos veículos e distribuir as solicitações em suas diversas camadas, limitando as tensões e deformações, a fim de garantir um desempenho adequado do pavimento por um longo período (Bernucci *et al*., 2022).

Entretanto, ao longo da vida útil, os pavimentos estão sujeitos a um processo de deterioração que reduz suas capacidades estrutural e funcional, em decorrência da ação combinada do tráfego e de fatores ambientais (Antunes, Guimarães e Rocha, 2021; Bernucci et al., 2022). Nesse contexto, torna-se importante compreender a origem, os tipos e os mecanismos de evolução dessas falhas, de modo a subsidiar a adoção de estratégias eficazes de prevenção, correção e manutenção (Santana *et al*., 2025).

As condições ambientais adversas representam desafios para a manutenção de pavimentos flexíveis. As temperaturas extremas do ar ou as chuvas extensas em determinadas regiões, causam a degradação estrutural e funcional das camadas asfálticas levando ao aparecimento de buracos, de fissuras e de trilhas de roda (Wu, Pang e Zhu, 2024). Sabe-se que o número de irregularidades e defeitos varia entre as estações do ano (sazonalidade climática), sendo mais intenso nos períodos chuvosos, quando o pavimento se torna mais suscetível a esse tipo de ocorrência (Castro, Silva e Lange, 2014).

As precipitações, associadas a uma drenagem deficiente dos pavimentos, influenciam o surgimento de danos, a redução da resistência estrutural, o aumento da rugosidade e o aparecimento de defeitos o que

resulta na diminuição da vida útil do pavimento e no aumento dos custos de reabilitação (Abdollahi, Kutay e Lanotte, 2024). Dessa forma, é possível perceber que uma drenagem deficiente na rodovia causa problemas, prejudicando o tráfego e diminuindo a segurança.

Os principais defeitos superficiais encontrados em pavimentos flexíveis incluem exsudação, desgaste, fissuramento e trincamento de fadiga, transversal, longitudinal, em bloco e por propagação de juntas (Domingues, 1993; Bernucci *et al*., 2022). Além disso, também são recorrentes defeitos como remendos, panelas, depressões e o afundamento em trilha de roda, que comprometem as condições funcionais e estruturais do pavimento.

A previsão dos defeitos, das irregularidades e dos custos a longo prazo das atividades de manutenção e reabilitação é difícil devido à complexa interação de fatores tráfego, material e as variabilidades climáticas. Dadas essas limitações, existe uma necessidade de mais coleta de dados *in situ* e pesquisas para melhorar a precisão das avaliações de deterioração de pavimentos e aprimorar o planejamento de resiliência (Hong e Prozzi, 2024. Peng *et al*., 2025).

A localização, a escala, a severidade e o mapeamento das deteriorações constituem aspectos cruciais para os Sistemas de Gerenciamento de Pavimentos (SGP) (Hosseini e Smadi, 2021). Devido ao tempo e aos recursos necessários, as inspeções vêm sendo substituídas por abordagens mecanizadas, que incluem desde sensores a laser de alta velocidade, sem contato, até equipamentos capazes de capturar imagens em vídeo da superfície do pavimento (Choi, 2020).

Uma das alternativas de aferir a condição superficial (funcional) do pavimento é por meio do Valor da Serventia Atual (VSA) um parâmetro subjetivo de avaliação. Esse método indica o grau de conforto e suavidade de rolamento proporcionado pelo pavimento. Para isso, atribui-se uma numeração de 0 a 5, resultante da média de notas de avaliadores em um determinado trecho, em um dado momento da vida do pavimento (DNIT, 2003a). Esse método apresenta como limite de aceitabilidade a nota 2,5 para as vias de alto volume de tráfego e 2,0 para as demais. Quando o VSA atinge nota abaixo desse patamar, uma intervenção de manutenção corretiva deve ser realizada, de modo a transformar o índice em um valor superior. Por outro lado, quando o pavimento apresenta o VSA acima deste valor, deve-se realizar manutenção preventiva periódica para manter a condição de rolamento em níveis adequados (DNIT, 2003a).

3. Método de pesquisa

O presente estudo foi dividido nas seguintes etapas: (i) escolha dos trechos a serem inspecionados; (ii) realização de videomonitoramento nos segmentos em dois períodos distintos; (iii) obtenção de dados climáticos (pluviométricos) dos trechos; (iv) detecção dos defeitos a partir das imagens obtidas; (v) determinação do Valor de Serventia Atual (VSA), conforme o DNIT (2003a); e (vi) comparação dos defeitos identificados e da condição funcional do pavimento entre os períodos analisados. A Figura 1 apresenta o fluxograma das etapas realizadas.

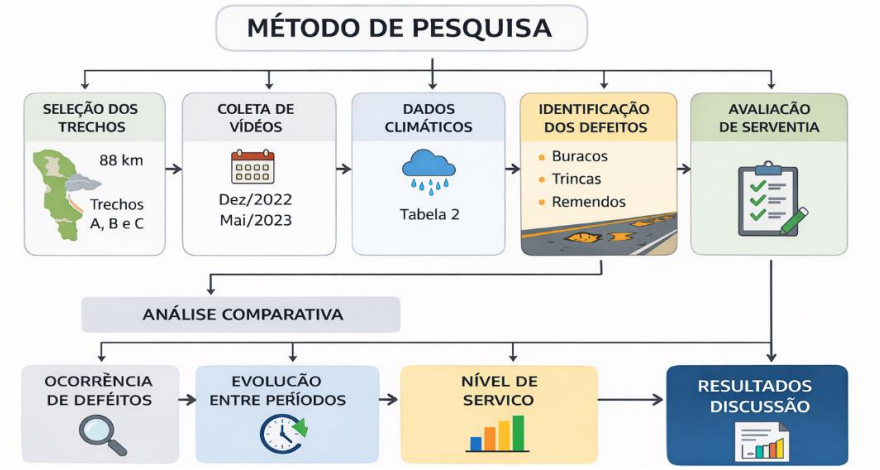

Figura 1 – Fluxograma das etapas realizadas

Escolheu-se um trecho de uma rodovia federal localizada no estado do Ceará, nordeste do Brasil, entre o município de Boa Viagem e de Fortaleza, com extensão de 200 Km. O trecho foi escolhido por ser uma importante rota de integração inter-regional e escoamento industrial e agropecuário. O trecho foi divido em 3 (três) segmentos, denominados de A, B e C (Tabela 1).

Tabela 1 – Trechos que foram analisados da rodovia federal – Ceará

Segmento	Km inicial	Km Final	Distância percorrida (Km)
A	365	333	32
B	301	265	36
C	233	213	20

A pesquisa teve início com a coleta de vídeos nos segmentos no mês de dezembro de 2022 e em maio de 2023 (nos mesmos segmentos da rodovia). A escolha do mês de dezembro corresponde ao período de o final da estação seca e o final da estação chuvosa. Por sua vez, o mês de maio marca o término do período chuvoso na região (Tabela 2). Buscando identificar diferenças relacionadas à sazonalidade climática. A partir dos dados apresentados na Tabela 2, buscou-se correlacionar as condições climáticas observadas nos respectivos períodos com a ocorrência e a evolução dos defeitos no pavimento.

Tabela 2 - Dados pluviométricos de municípios passados pela rodovia federal em estudo

Segmento	2022	2023					
	Dezembro	Janeiro	Fevereiro	Março	Abril	Maio	Total
A	21,5	295,3	167,5	469,7	468	271,2	1693,2
	17,6	208,1	148,2	290,8	206	148,5	1019,2
B	16,2	174	133,3	119,5	178,	92,6	713,6
C	33,5	182	0	147,5	120,5	14	464
	22	153	12	181	144,2	54,2	566,4

(Fonte: FUNCEME, 2023).

Os vídeos foram obtidos por meio de uma câmera de smartphone acoplado no painel de um veículo, com o auxílio de um suporte, ao longo de uma faixa da pista de rolamento da rodovia. Neste estudo, desconsideraram-se os defeitos presentes no acostamento. Nas análises, foram considerados defeitos do tipo trincas, fissuras, buracos, ondulações e escorregamento.

No caso dos defeitos de buracos, foi realizada uma distinção própria envolvendo os buracos, devido ao seu impacto causado na rodovia como também a sua quantidade de vezes apresentado, que serão: evolução da trinca para buraco, crescimento dos buracos, surgimento de buraco no remendo, surgimento de buraco em pavimento estável e trincas severas;

Esses cinco tipos de defeitos relacionados a buracos foram registrados em uma ficha, a fim de quantificar a frequência com que ocorrem, além do registro fotográfico. A partir disso, foi possível identificar os defeitos mais comuns e as fases em que os buracos se manifestam.

Além da análise de defeitos específicos, foi realizada uma avaliação abrangente da rodovia com base no Valor de Serventia Atual (VSA) conforme DNIT (2003a). Durante essa análise, dois avaliadores, presentes no veículo durante a obtenção dos vídeos, atribuíram notas (Tabela 3) a trechos a cada 2 km. Essa abordagem permitiu não apenas avaliar defeitos específicos, mas também obter uma visão geral da qualidade funcional da rodovia.

Tabela 3 – VSA e conceito funcional da condição superficial do pavimento (DNIT, 2003a)

VSA	Conceito	Cor
≥ 4,0	Ótimo	
3,0 – 3,9	Bom	
2,0 – 2,9	Regular	
1,0 – 1,9	Ruim	
< 1,0	Péssimo	

A partir dos resultados obtidos, foram realizadas três análises entre os dois períodos (dezembro de 2022 e maio de 2023): (i) verificação e comparação da ocorrência de defeitos; (ii) análise das condições de rolamento

do pavimento (VSA) e comparação entre os períodos; e (iii) avaliação da influência das condições climáticas na condição funcional do pavimento. Por meio do videomonitoramento, buscou-se identificar as mudanças ocorridas ao longo desse intervalo, especialmente quanto à evolução dos defeitos, ao aumento de severidade e ao surgimento de novas manifestações.

Em seguida, com base nos valores de VSA, aplicou-se o teste t pareado de Student, adotando-se como hipótese nula (H_0) a inexistência de diferença entre os valores observados nos meses de dezembro e maio, e como hipótese alternativa (H_1) a existência de diferença entre esses períodos, considerando um nível de significância de 5% ($\alpha = 0,05$).

Por fim, analisou-se a relação entre a precipitação registrada no mês de dezembro e os valores de VSA nos trechos A, B e C. Para isso, foi elaborado um gráfico de dispersão com base nas médias por agrupamento, sendo o coeficiente de correlação (r) utilizado como medida de associação entre a precipitação e o VSA.

4. Resultados e discussão

Após análise dos vídeos registrados em dezembro de 2022 e maio de 2023, torna-se evidente a ocorrência de mudanças na pavimentação entre as inspeções, com uma variedade de defeitos em todo o trecho. Foi observado ao menos um caso de cada tipo de defeito (DNIT, 2003b) nos vídeos analisados. Esses defeitos englobam trincas, fissuras, buracos, ondulações e escorregamentos. Além disso, há particularidades nos defeitos, como questões relacionadas à drenagem e problemas específicos com os remendos. Os buracos destacam-se como os mais frequentes.

No segmento A, observou-se, no primeiro levantamento realizado em dezembro de 2022, a presença de um defeito do tipo remendo, decorrente de uma manutenção anterior (Figura 2A). Nota-se que uma possível má execução resultou em uma superfície ligeiramente mais elevada, o que comprometeu o escoamento da água em direção ao acostamento, favorecendo seu acúmulo sobre a área remendada. Em decorrência dessa condição, verificou-se que, no levantamento realizado em maio de 2023 (Figura 2B), parte do remendo apresentou desagregação, ocasionando o surgimento de buracos e trincas.

Figura 2 - (A) Ocorrência de remendo e problemas de drenagem na faixa de rolamento (dezembro/2022). (B) Ocorrência de buracos e trincas (maio/2023).

Situação semelhante foi observada no segmento B (Figura 3A), no qual um remendo executado em dezembro de 2022, voltou a apresentar buracos e trincas (Figura 3B). Esse comportamento indica que a intervenção realizada atuou apenas como uma solução temporária, sendo insuficiente para eliminar a causa do defeito e impedir sua reincidência. Ainda no segmento B, observa-se que buracos de baixa severidade acumula água após a ocorrência de precipitação (Figura 4A), favorecendo a infiltração e sua evolução para defeitos mais severos, como evidenciado na Figura 4B.

Figura 3 - (A) Ocorrência de remendo (dezembro/2022). (B) Ocorrência de buracos e trincas (maio/2023).

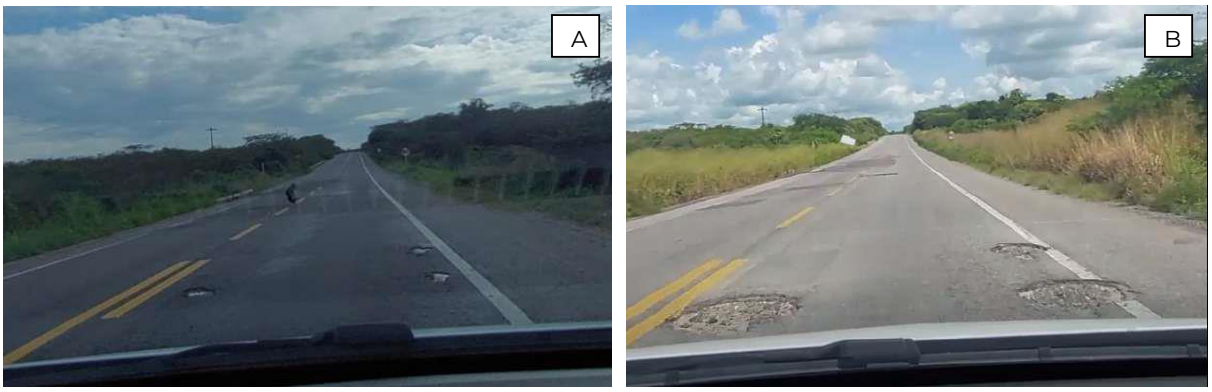

Figura 4 - (A) Ocorrência de buracos (dezembro/2022). (B) Crescimento dos buracos (maio/2023).

Outro defeito frequente nos segmentos inspecionados foram as trincas. Observou-se que algumas dessas trincas (Figura 5A), ao início das precipitações, evoluíram para defeitos do tipo buraco (Figura 5B). Isso ocorre porque a água da chuva infiltra-se nas camadas do pavimento, iniciando pelo revestimento, com o desprendimento de agregados, e avançando para as camadas inferiores. Notou-se que todos os locais da rodovia que possuía trincas se transformaram em buracos.

Figura 5 - (A) Ocorrência de trinca (dezembro/2022). B) Ocorrência de buracos e trincas (maio/2023).

Sabe-se que os remendos nem sempre evoluem para buracos (Barbosa Neto, 2023). No entanto, observou-se que, em cinco meses, um remendo em condições regulares (Figura 6A) se deteriorou, dando origem a buracos (Figura 6B), o que compromete o conforto e a segurança dos usuários. Ressalta-se que os buracos

não se restringiram às áreas remendadas, ocorrendo também em regiões adjacentes, o que indica suscetibilidade a problemas nessas zonas (Figura 6B).

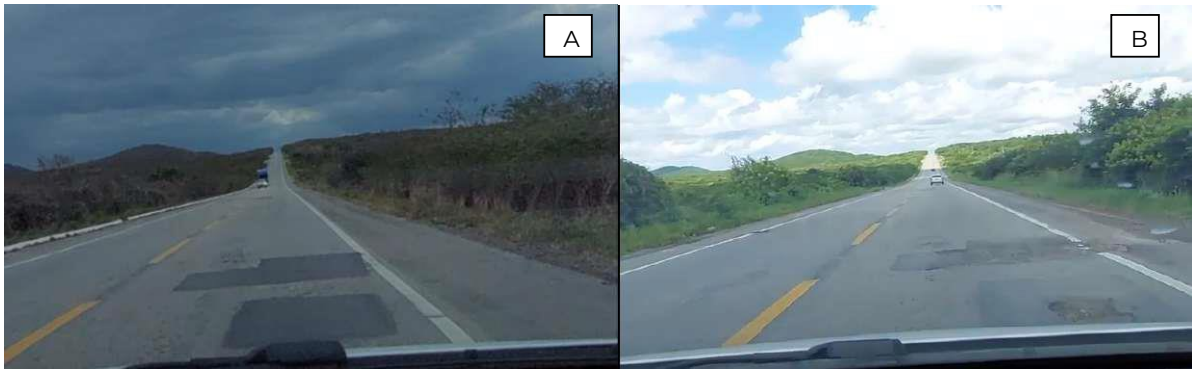

Figura 6 - (A) Ocorrência de Remendo (dezembro/2022). B) Ocorrência de surgimento de buracos (maio/2023).

Na inspeção realizada em maio de 2023, término do período chuvoso, foram observados 21, 65 e 54 defeitos nos segmentos A, B e C, respectivamente. Registram-se poucos intervalos de quilometragem que não apresentaram defeitos. Em alguns trechos, registraram-se mais de 10 defeitos relacionados a buracos (defeito predominante após a quadra chuvosa). Como exemplo, o Segmento C apresentou 2,70 defeitos por quilômetro (Tabela 4).

Tabela 4 - Relação entre o número de defeitos de cada trecho por km em maio

Segmento	Defeito / Km
A	0,66
B	1,81
C	2,70

Na Tabela 5, apresenta-se o total de defeitos registrados nos três segmentos, ao longo dos 88 km analisados. Observa-se uma discrepância do defeito buraco a partir do remendo em relação aos demais, indicando a necessidade de maior atenção quanto à necessidade de manutenção corretiva. Sua elevada ocorrência está associada ao caráter temporário dos remendos, que demandam intervenções frequentes.

Tabela 5 - Evolução dos defeitos do tipo buraco entre dezembro (2022) e maio (2023)

Tipo de defeito	Total de ocorrência
Crescimento de buraco	13
Buracos a partir de trincas	29
Buracos a partir de remendos	63
Surgimentos de buracos	22
Trinca severa	13
Total	**140**

As Tabelas 6, 7 e 8 apresentam os VSA referentes à condição superficial dos trechos avaliados por meio do método subjetivo nos dois períodos distintos. Ao comparar dezembro de 2022 com maio de 2023, observa-se uma redução geral nas médias, indicando diminuição do nível de conforto funcional segundo a percepção dos avaliadores. Essa queda está associada ao aumento do número de defeitos ao longo do período. No Segmento A, a variação média foi de 0,4 pontos, enquanto nos segmentos B e C as reduções foram de 1,9 e 1,1 pontos, respectivamente. Dessa forma, o Segmento A manteve sua condição funcional, enquanto os segmentos B e C apresentaram maior presença de defeitos e menor conforto ao rolamento, com possível redução do nível de desempenho.

Tabela 6 - Nota do VSA em relação ao Segmento A

Entre os Km		Segmento A

215	213	4,0	4,4	4,2	Ótimo	0,5	0,3	0,4	Péssimo

De acordo com Tabela 6, em dezembro de 2022 as médias variaram entre 3 e 4, correspondendo a conceitos entre bom (31,25%) e ótimo (68,75%), refletindo a baixa incidência de defeitos. Predominavam remendos, fissuras e trincas isoladas, sem impactos na dirigibilidade. Por sua vez, em maio de 2023, as médias variaram entre 2 e 4, com trechos classificados como regular (12,50%), indicando agravamento das condições funcionais. Verificou-se que a presença de buracos impactou diretamente a redução das notas. Ainda assim, o Segmento A manteve, em geral, desempenho satisfatório, com predominância de conceitos bom (50,00%) e ótimo (37,50%).

Por outro lado, nos Segmentos B e C (Tabelas 7 e 8) observou-se maior incidência de defeitos após o período chuvoso, com consequente aumento das classificações ruim e péssimo, evidenciando redução do conforto de trafegabilidade. Destaca-se o segmento B, que apresentou os maiores percentuais de trechos com nível funcional ruim (33,33%). Em determinados locais (entre os km 289 e 287), o nível de serviço reduziu de ótimo para ruim (Tabela 7). Essa queda pode ser explicada pelo maior volume de tráfego e pela condição prévia do pavimento (dezembro/2022), com presença de fissuras e trincas, cuja infiltração de água acelerou a degradação da trafegabilidade no segmento (surgimento de buracos e remendos realizados na manutenção).

No segmento C (Tabela 8), destaca-se uma exceção entre os km 233 e 227, onde houve aumento nas médias em função de um recapeamento asfáltico. Apesar da melhoria local, essa intervenção foi pontual e insuficiente frente à extensão total analisada. Nos demais trechos, manteve-se a tendência de queda nas médias entre os meses de dezembro e maio, indicando a necessidade de intervenções mais abrangentes.

A Tabela 9 apresenta o resumo dos resultados obtidos para os segmentos A, B e C, considerando os valores médios de VSA nos períodos de dezembro/2022 e maio/2023, bem como a variação observada e a significância estatística (p-valor). O Segmento A apresentou uma diminuição de -0,45, indicando menor sensibilidade às variações sazonais. Em contrapartida, o segmento B apresentou a maior queda (-1,72), evidenciando maior quantidade de defeitos ou irregularidades provocadas pelas precipitações e problema de drenagem. Por sua vez, o segmento C apresentou redução de -0,94, presença de locais críticos surgidos no período chuvoso.

Tabela 9 - Síntese dos resultados estatísticos e funcionais

Segmento	VSA Dezembro /2022	VSA Maio /2023	Variação	p-valor	Decisão
A	4,06	3,61	-0,45	0,003	Rejeita H_0
B	3,73	2,01	-1,74	0,0001	Rejeita H_0
C	4,11	3,17	-0,94	0,01	Rejeita H_0

Ainda de acordo com a Tabela 9, verificou-se que todos os segmentos apresentaram redução do VSA no período chuvoso (maio/2023), sendo essa diferença estatisticamente significativa, com p-valores inferiores a 0,05 em todos os casos. Dessa forma, rejeita-se a hipótese nula, concluindo-se que há diferença significativa entre os períodos analisados, evidenciando a influência da sazonalidade na condição funcional dos pavimentos.

Em seguida, ao correlacionar valores de precipitação e os valores de VSA dos segmentos em dois períodos (dezembro/2022 e acumulado de maio/2023), obteve-se os gráficos das Figuras 7 e 8. A correlação entre a precipitação de dezembro e o VSA foi igual a r = 0,83. Por sua vez, a correlação entre a precipitação acumulada até maio/2023 e o VSA foi r = 0,47, caracterizando uma relação positiva moderada. Esses resultados sugerem que maiores volumes de precipitação não implicam, necessariamente, em menores valores de VSA, evidenciando que o desempenho funcional do pavimento também é influenciado por outros fatores, como condições estruturais, qualidade dos materiais e intervenções de manutenção.

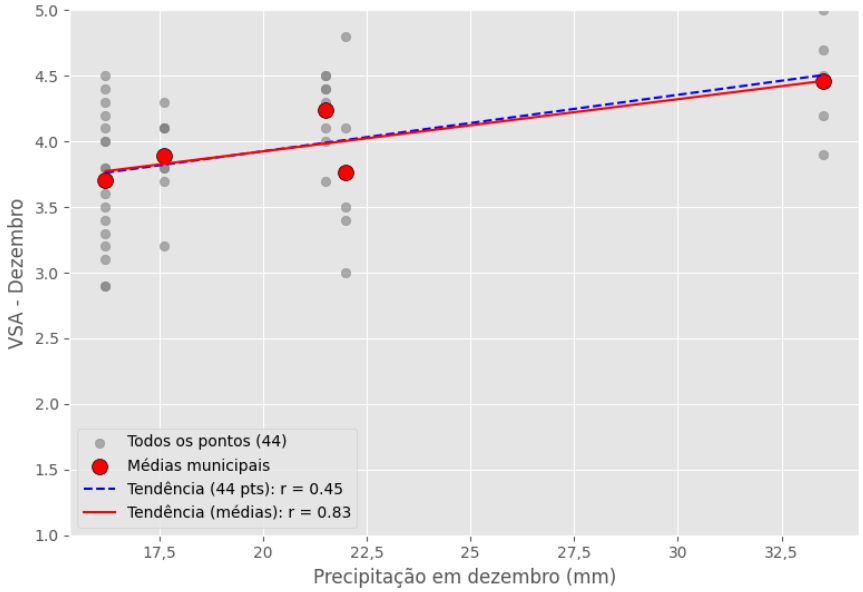

Figura 7 - Relação entre precipitação de dezembro/2022 e VSA

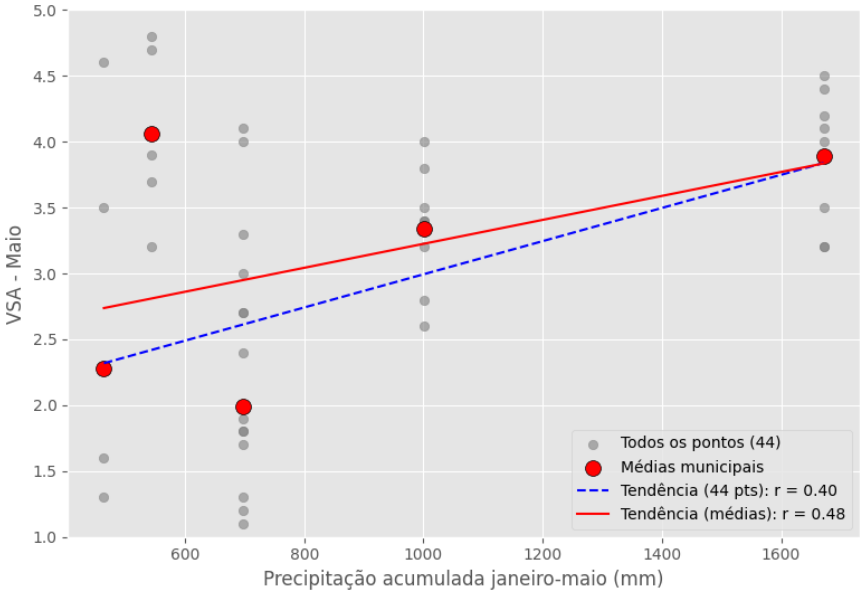

Figura 8 - Relação entre precipitação acumulada de janeiro/2023 a maio/2023 e VSA

De forma geral, os resultados indicam que a sazonalidade, especificamente as precipitações, exerce influência na condição funcional dos pavimentos, promovendo a redução do conforto ao rolamento devido ao aumento de defeitos e irregularidades superficiais, corroborando com os estudos realizados por Castro, Silva e Lange (2014). Além disso, a variabilidade entre os trechos analisados evidencia a necessidade de estratégias de manutenção diferenciadas, considerando as características estruturais e condições locais de drenagem.

5. Conclusão

No contexto da caracterização dos defeitos de um pavimento rodoviário flexível em dois períodos distintos, os resultados evidenciaram a presença de defeitos independentemente da época de inspeção. Constata-se que esses defeitos não estão associados apenas a um período específico. Ao longo do intervalo de tempo

analisado (cinco meses), observa-se a evolução da severidade e o surgimento de novos defeitos, associados à infiltração de água e à recorrente deterioração dos remendos, o que evidencia o caráter, muitas vezes, temporário dessas intervenções. Esse cenário indica a necessidade de incorporar a variabilidade sazonal nas estratégias de manutenção e reabilitação.

A sazonalidade climática contribuiu para a redução do nível de serventia funcional dos pavimentos flexíveis, acompanhando o aumento da incidência de defeitos. Embora tenha sido observada correlação entre precipitação e a serventia ao longo dos períodos analisados, o desempenho funcional do pavimento não depende exclusivamente dos índices pluviométricos das estações seca e chuvosa, sendo também influenciado por fatores como eficiência das ações de manutenção. Assim, concluiu-se que a variabilidade dos defeitos e da condição funcional evidencia a necessidade de adoção de estratégias de manutenção mais adequadas ao período do ano, bem como maior atenção aos sistemas de drenagem e à execução correta de intervenções corretivas, especialmente os remendos.

Agradecimento

O primeiro autor agradece a Coordenação de Aperfeiçoamento de Pessoal de Nível Superior - Brasil (CAPES) pela bolsa concedida que contribuiu para a elaboração deste trabalho.

Abstract: Substandard housing is often characterised by construction deficiencies, lack of technical assistance and the presence of recurring pathological manifestations that compromise the safety, durability and habitability of buildings. In this context, housing improvement programmes focused on rehabilitation represent a relevant strategy for mitigating processes of deterioration and extending the service life of existing buildings. This article analyses the main pathological manifestations identified in substandard housing and evaluates the effectiveness of the rehabilitation measures adopted under the Housing Improvement Programme of the Companhia de Desenvolvimento Habitacional do Distrito Federal, Brazil. This is an applied and descriptive study, with a mixed-methods approach, developed through multiple instrumental case studies of completed works. Technical diagnoses, detailed designs, specifications, budget spreadsheets, photographic reports and records of on-site inspections were analysed. The pathological manifestations were classified into technical categories, related to the rehabilitation measures adopted, and assessed in terms of occurrence, coverage, cost and criticality. To this end, a condition scale based on the Dutch standard NEN 2767 was used, and a Pathological Criticality Index (PCI) was developed, enabling the identified damage to be ranked. The results highlight the predominance of moisture-related pathologies, which presented the highest levels of criticality and constituted the main mechanism of degradation in the analysed units. The integrated analysis of manifestations, interventions and costs demonstrated that the most critical defects also account for significant investment demands, reinforcing the importance of technical prioritisation strategies. It is concluded that interventions guided by technical diagnosis contribute to mitigating pathologies, improving performance conditions and extending the service life of buildings, consolidating housing improvement works as a strategic tool for the rehabilitation of the substandard housing stock.

Keywords: Building pathology; housing rehabilitation; social housing; building deterioration; service life of buildings.

1. Introduction

Housing precarity in Brazil constitutes a persistent problem, associated with historical processes of exclusionary urbanisation, informal construction and the insufficiency of comprehensive public policies. Although Technical Assistance in Social Housing (Athis) programmes, provided for by Federal Law No. 11,888/2008 (Brazil, 2008), have expanded access to design and technical guidance for low-income families, the qualitative deficit in housing remains significant, particularly with regard to structural safety, sanitary conditions, minimum performance and the durability of buildings.

A large proportion of substandard housing exhibits pathological defects resulting from informal construction, inappropriate use of materials, lack of waterproofing, structural deficiencies, makeshift

building services and successive alterations carried out without technical supervision. These defects compromise habitability, accelerate deterioration processes, reduce the service life of building systems and increase risks to residents' health and safety.

In this context, the rehabilitation of the existing housing stock, through housing improvement programmes, is a key strategy for mitigating damage, restoring minimum performance standards and extending the service life of buildings. In the Distrito Federal, these initiatives are carried out by the Diretoria de Assistência Técnica (Diate) of the Companhia de Desenvolvimento Habitacional do Distrito Federal (Codhab-DF), particularly through the Housing Improvements Programme (Codhab-DF, 2025). This work is aligned with the guidelines of the District Plan for Social Housing (Plandhis), which recognises housing quality as a dimension that goes beyond the physical condition of the building, also encompassing infrastructure, urban integration, services and residents' living conditions (GDF, 2023).

Recent literature on building pathology highlights the importance of technical inspections, databases and systematic records for identifying recurring patterns of defects throughout the life cycle of buildings. Review studies indicate that moisture consistently features among the most frequent categories of pathological manifestations, associated with problems of stability, cracking and component degradation (Berg Oppedal; Kvande, 2024). Reviews of residential buildings also demonstrate that defects result from the interaction between technical, human and environmental factors, requiring analyses that go beyond the description of symptoms and consider the building system, the context of use and the mechanisms of degradation (Mésároš *et al*., 2024).

In the field of social housing, studies on post-occupancy evaluation, co-production and maintenance indicate that technical diagnosis must be linked to an understanding of usage and residents' needs, helping to guide more effective interventions, extend the service life of buildings and inform public housing policies (Garrefa *et al*., 2021; Villa *et al*., 2022; Petersen; Silva; González, 2023). In Brazilian social housing, the presence of moisture and the poor quality of the building envelope are associated with environmental discomfort, health risks and the worsening of inadequate living conditions, reinforcing the need to treat moisture as a central mechanism from diagnosis through to the definition of solutions (Simões; Labaki; Leder, 2025; Simões; Leder; Labaki, 2021).

Despite these advances, there are still few studies that integrate, within a single analytical procedure, the identification of pathological manifestations, their technical classification, the correspondence with rehabilitation measures, the severity of the damage, and the costs associated with interventions in public housing improvement programmes. This gap is particularly relevant in contexts of substandard housing, where decision-making requires technical criteria capable of supporting the prioritisation of actions, the efficient allocation of resources, and the evaluation of the effectiveness of the solutions adopted.

In light of this, this article aims to analyse the main defects identified in substandard housing prior to interventions and to assess, from a technical perspective, the effectiveness of the rehabilitation measures adopted under the Codhab-DF Housing Improvement Programme. The study's contribution lies in systematising the relationship between diagnosis, intervention and cost, based on six case studies, using a condition rating scale based on the Dutch Standard for the Assessment of the Condition of the Built Environment (NEN 2767), coding of the manifestations and measures adopted, and the proposal of a Pathological Criticality Index (PCI) designed to support technical prioritisation in housing programmes.

2. Methodology

This research is characterised as applied, descriptive in nature, with a mixed-methods approach and a qualitative focus, supported by documentary analysis, technical inspections and quantitative systematisation of the pathological manifestations observed. The study was conducted through multiple instrumental case studies, selected from completed projects under the Housing Improvement Programme of the Companhia de Desenvolvimento Habitacional do Distrito Federal (Codhab-DF).

Six housing units located in Região Administrativa XXV – Cidade Estrutural, Distrito Federal, were analysed. The units were identified as Case 1 to Case 6, in order to preserve the residents' identity. The selection criteria included: completion of the works; availability of complete technical documentation; existence of a pre-intervention assessment; photographic records; budget spreadsheets; and technical supervision of the interventions by the lead author during execution.

The documentary basis comprised pre-intervention technical assessments, detailed design drawings, descriptive specifications, calculation reports, budget spreadsheets, and technical and photographic reports produced throughout the works. These documents made it possible to characterise the initial construction conditions, identify pathological manifestations, relate them to the affected areas, verify the solutions adopted, and estimate the costs associated with the categories of intervention.

The technical inspections were guided by the principles of ABNT NBR 16747:2020, which establishes guidelines, concepts, terminology and procedures for building inspection, based on sensory analysis carried out by a qualified professional (ABNT, 2020). In this study, the standard was used as a reference to organise the survey, guide the systematic assessment of building elements and identify the irregularities observed. The inspections took place during the term of the works contracts, through weekly technical visits, involving visual inspection of rooms, building systems and services, photographic documentation of the defects and monitoring of the rehabilitation measures.

The pathological manifestations were classified into four technical categories: structural, moisture, building services and materials, taking into account the predominantly affected construction system and the main mechanism of degradation. To enable systematic cross-referencing between diagnosis and intervention, each defect was assigned a specific code, comprising the category abbreviation and sequential numbering: STR for structural defects, MOI for moisture-related defects, SER for building services, and MAT for materials. The rehabilitation measures were also coded according to the same logic, allowing the creation of a correspondence matrix between defect, technical solution, and intervention category.

The classification of the condition of the manifestations was carried out with the support of NEN 2767, the Dutch standard for assessing the condition of the built environment, which proposes a methodology for the objective determination of the technical condition of building components, based on the identification and classification of defects (NEN, 2019). In this study, the six-level condition scale provided for by the standard was adopted, in which grade 1 corresponds to excellent condition, grade 2 to good condition, grade 3 to reasonable condition, grade 4 to poor condition, grade 5 to severe condition and grade 6 to very poor condition. The assignment of grades took into account photographic records, technical reports and field observations, assessing the apparent severity of the defect, its extent within the environment and its potential impact on safety, habitability, performance and durability.

The overall occurrence of defects was calculated by considering the number of rooms affected in relation to the total number of rooms analysed in the six case studies, according to Equation (1):

$$o = \frac{N}{T} \times 100\ [\%] \tag{1}$$

where "o" corresponds to the occurrence of the defect; "N" corresponds to the number of affected rooms; and "T" corresponds to the total number of rooms analysed.

In addition to the overall occurrence, the prevalence of pathological categories in each case study was calculated, considering the number of rooms affected by a given category in relation to the total number of rooms in the respective housing unit. The prevalence, expressed as a percentage, was calculated using Equation (2):

$$a = \frac{n}{t} \times 100\ [\%] \tag{2}$$

where "a" corresponds to the coverage of the category in the analysed case; "n" corresponds to the number of rooms affected; and "t" corresponds to the total number of rooms in the housing unit.

To assess the technical relevance of the defects, a Pathological Criticality Index (PCI) was developed, calculated by weighting the occurrence of the defect by the technical weight assigned to the corresponding category. The weights were defined based on the potential impact of each category on the building's safety, habitability, operation and durability. Thus, the following weights were adopted: structural = 4; moisture = 4; building services = 3; and materials = 2. The PCI was normalised by dividing by 4, so as to produce values between 0 and 1, as per Equation (3):

$$ICP = \frac{o \times w_c}{4} \quad (3)$$

where "PCI" corresponds to the Pathological Criticality Index; "o" corresponds to the occurrence of the manifestation in decimal form; and "w_c" corresponds to the technical weighting of the category.

The economic analysis was carried out using the project budget spreadsheets, with the works grouped according to the previously defined pathology and intervention categories. The costs were linked to the corresponding rehabilitation measures, allowing the percentage share of each category in the total cost of the works to be estimated. This stage made it possible to relate technical criticality and economic impact, contributing to the identification of the categories with the greatest weight in decision-making and resource allocation.

The effectiveness of the interventions was assessed by comparing the pre-intervention conditions, as recorded in the initial technical assessments and photographic reports, with the post-intervention conditions, as verified from the final records and the documentation certifying completion of the works. The following were considered as evidence of effectiveness: mitigation or elimination of the identified pathological manifestations; restoration of deteriorated elements; improvement in safety, sanitary conditions and functionality; upgrading of building services; and potential contribution to extending the service life of the buildings.

Methodological validation was achieved through triangulation of three sources of evidence: technical documentation of the works, field inspections with photographic records, and budget spreadsheets. The convergence of these sources made it possible to verify the correspondence between diagnosis, the technical solution implemented and the associated cost. Furthermore, the combined use of ABNT NBR 16747 as a reference for building inspection and NEN 2767 as a condition scale contributed to greater standardisation, traceability and reproducibility of the analytical procedure.

3. Results

3.1 Characterisation of the housing units and interventions

Table 1 presents the characterisation of the six case studies, including area, number of occupants, existing rooms before and after the interventions, and total cost of the works. The units analysed are single-family, single-storey dwellings located in Cidade Estrutural, in the Distrito Federal, and exhibit conditions typical of urban substandard housing, characterised by informal extensions, a lack of ongoing technical support, makeshift construction solutions and the progressive deterioration of building systems.

The costs of the interventions ranged from R$ 39,220.04 to R$ 68,831.35, indicating varying levels of complexity in the works. Whilst some cases involved predominantly specific repairs, such as the restoration of cladding, the upgrading of building services and moisture control, others required more extensive interventions, including spatial reconfiguration, the enlargement of rooms, roof repairs and the restoration of structural elements.

Table 1 – Characterisation of the case studies analysed

Case	Description / Total area	Rooms (description / total)		Cost of intervention (R$)
		Pre-intervention	Post-intervention	
1	Single-family detached house, 4 occupants (46.22 m²)	Living room, kitchen, bathroom, hallway, 2 bedrooms, outdoor area (7)	Living room, kitchen, bathroom, hallway, 2 bedrooms, utility room, outdoor area (8)	41,644.84
2	Single-family detached house, 2 occupants (41.35 m²)	Living room, kitchen, bathroom, hallway, 2 bedrooms, outdoor area (7)	Living room, kitchen, bathroom, hallway, 2 bedrooms, outdoor area (7)	39,220.04
3	Single-family detached house, 5 occupants (67.00 m²)	Living room, kitchen, bathroom, hallway, 2 bedrooms, outdoor area (7)	Living room, kitchen, bathroom, hallway, 2 bedrooms, outdoor area (8)	49,561.03
4	Single-family detached house, 4 occupants (70.73 m²)	Living room, kitchen, bathroom, hallway, 2 bedrooms, outdoor area (7)	Living room, kitchen, bathroom, hallway, 2 bedrooms, garage, outdoor area (8)	50,724.85
5	Single-family detached house, 2 occupants (52.97 m²)	Living room, kitchen, bathroom, bedroom, outdoor area (5)	Living room, kitchen, bathroom, 2 bedrooms, hallway, ventilation shaft, outdoor area (8)	68,831.35
6	Single-family detached house, 9 occupants (56.64 m²)	Living room, kitchen, bathroom, hallway, 2 bedrooms, outdoor area (7)	Living room, kitchen, bathroom, hallway, 3 bedrooms, utility room, outdoor area (9)	54,422.13

Source: Authors.

A comparison of conditions before and after the intervention shows that the housing improvements were not limited to repairing structural damage. In some cases, the works also promoted functional adaptations, such as the creation of new spaces, the reorganisation of utility areas, improved circulation, and an expansion of the dwelling's usable capacity. Thus, the interventions served a dual purpose: mitigating pathological manifestations and enhancing the functional quality of the housing units.

3.2 Recurring pathological manifestations prior to the intervention

Analysis of pre-intervention conditions revealed the presence of recurring pathological manifestations in all cases analysed. These defects reflect both the ageing and natural degradation of materials and the lack of technical expertise in the original construction process, in successive extensions, and in maintenance work over time.

The observed defects were grouped into four technical categories: structural deficiencies, moisture-related pathologies, inadequacies in building services, and progressive material degradation. This classification enabled the damage to be organised according to the affected construction system and the predominant mechanism of degradation, facilitating the subsequent relationship between diagnosis, rehabilitation measures and intervention costs. Figure 1 presents examples of the manifestations observed.

Structural and construction defects included cracks and fissures in masonry, deformations in structural and roofing elements, inadequate gutters and flashings, and improvised or undersized elements. Although not all occurrences posed an immediate risk, they indicated degradation processes with the potential to worsen.

Moisture-related defects constituted the most common and technically most significant category. Mould, mildew, stains, water ingress, waterproofing failures, rising damp, paint saponification, corrosion of window frames and displacement of cladding were observed. This damage was associated with the absence or inadequacy of waterproofing, deterioration of roofing and makeshift construction solutions.

Deficiencies in building services involved electrical, plumbing and sanitary installations carried out in an improvised manner, with exposed wiring, a lack of protective devices, precarious networks and deteriorated pipework. Such conditions compromise functional performance and increase safety risks for residents.

The progressive degradation of materials included disintegration, deterioration of components, corrosion of metal elements and displacement of cladding. In many cases, these manifestations were associated with the combined effects of moisture, ageing of materials, exposure to the elements and lack of maintenance.

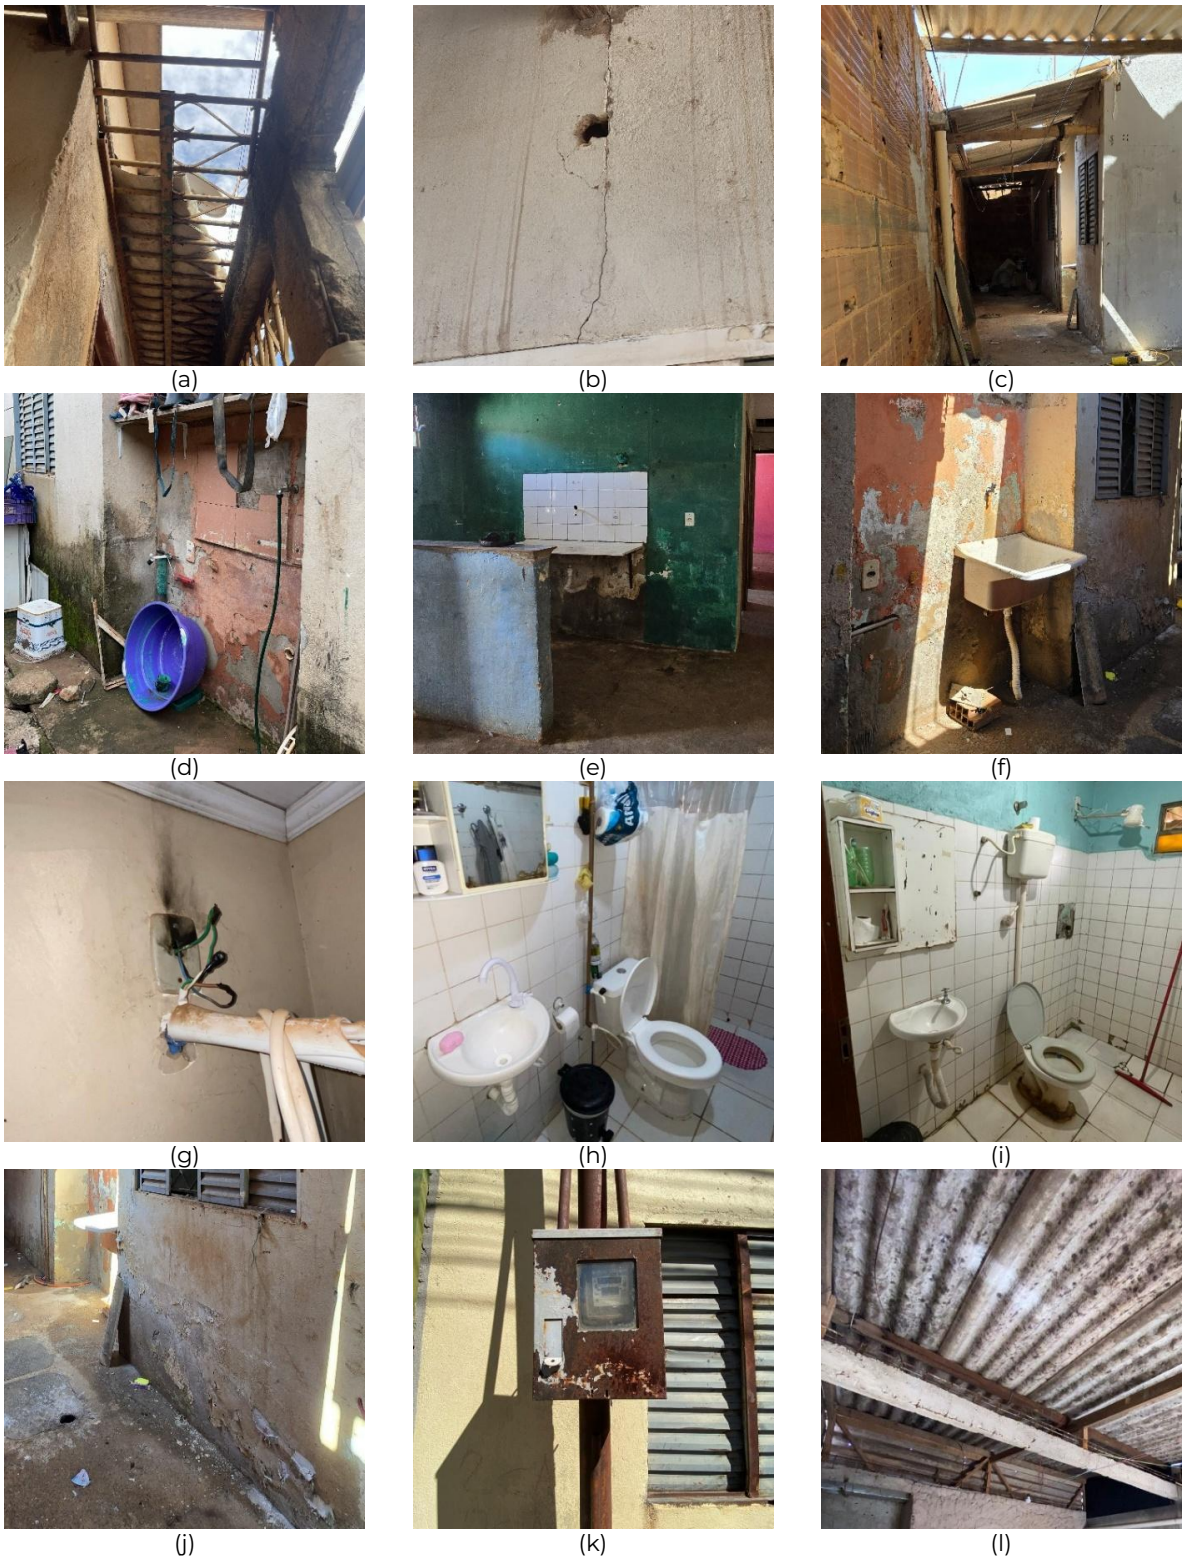

Figure 1 – Examples of pathological manifestations identified in the dwellings analysed: (a–c) structural deficiencies; (d–f) moisture-related pathologies; (g–i) inadequate building services; (j–l) progressive degradation of materials

Considering the occurrence of these defects in the analysed spaces, it was observed that the most frequent damage was associated with moisture and building services. The most common manifestations were mould and mildew, paint saponification, makeshift or inadequate electrical installations, corrosion of metal window frames and rising damp due to capillary action. This pattern indicates that moisture is the main source of damage in the units analysed, acting as the primary mechanism associated with leaks, roof failures, capillary action, deterioration of cladding, corrosion, rotting of window frames and degradation of paintwork.

3.3 Rehabilitation measures adopted in the analysed projects

The rehabilitation measures adopted were defined based on the technical diagnosis of the existing structural conditions and sought to directly address the identified pathological manifestations. To enable a systematic analysis of this relationship, the manifestations and solutions were coded according to their technical nature, maintaining correspondence between the categories of structure, moisture, building services, and materials.

Table 2 presents the correspondence matrix between observed defects and the rehabilitation measures adopted. This matrix demonstrates that the interventions were not treated as isolated actions, but as technical responses tailored to the degradation mechanisms identified in each case.

Table 2 – Pathological manifestations observed and respective rehabilitation measures

Observed manifestations			Rehabilitation measures adopted	
Category	**Description**	**Code**	**Description**	**Code**
Structural	Inadequate gutters, flashings and copings	STR1	Repair/replacement of gutters, flashings and downpipes	STR-S1
Structural	Inadequate roofing (slope, pitch)	STR2	Repair/replacement of roof components	STR-S2
Structural	Deformation of structural elements	STR3	Repair of damaged structural elements	STR-S3
Structural	Cracks and fissures	STR4	Repair of damage to masonry and sealing with repair mortar	STR-S4
Structural	Structural instability	STR5	Repair of damaged structural elements or reinforcement	STR-S5
Moisture	Rotting of wooden window frames	MOI1	Replacement of damaged window and door frames	MAT-S1
Moisture	Corrosion of reinforcement	MOI2	Cleaning, treatment and repair with structural mortar	MAT-S2
Moisture	Corrosion of metal window frames	MOI3	Cleaning and painting or replacement of damaged window and door frames	MAT-S3
Moisture	Peeling of finishes due to moisture	MOI4	Cleaning, waterproofing and restoration of finishes	MOI-S1
Moisture	Fungi, mould and mildew	MOI5	Cleaning, waterproofing and restoration of finishes	MOI-S1
Moisture	Water ingress (rainwater or leaks)	MOI6	Waterproofing and roof repair	MOI-S2
Moisture	Paint saponification	MOI7	Finish restoration	MOI-S3
Moisture	Rising damp (capillary action)	MOI8	Wall waterproofing and capillary barrier	MOI-S4
Building services	Makeshift or inadequate electrical installations	SER1	Inspection and replacement of electrical installations	SER-S1
Building services	Improvised or inadequate plumbing installations	SER2	Inspection and replacement of plumbing components	SER-S2
Building services	Improvised or inadequate sanitary installations	SER3	Inspection and replacement of sanitary components	SER-S3
Materials	Disaggregation	MAT1	Reconstruction of structural elements and cladding	MAT-S5
Materials	Detachment of finishes due to material degradation	MAT2	Finish restoration	MAT-S6
Materials	Deterioration	MAT3	Repair of damaged structural elements or replacement	MAT-S7

Source: Authors.

Analysis of the matrix shows that a significant proportion of the solutions adopted focused on moisture control measures, restoration of cladding, roof repairs, replacement of damaged window and door frames, and upgrading of building services. These measures indicate that the rehabilitation of the units required integrated interventions across different building systems, confirming that the observed damage resulted from combined degradation processes rather than isolated incidents.

3.4 Coverage of categories, measures adopted and intervention costs

Table 3 lists, for each case study, the categories of pathology, the identified manifestations, the coverage of the categories within the environments, the rehabilitation measures adopted and the estimated cost of these measures in relation to the total cost of the works.

Table 3 – Relationship between pathological manifestations, rehabilitation measures and cost

Case	Pathology category	Manifestations	Coverage (a)	Rehabilitation measures adopted	Estimated cost of the measures adopted	
					(R$)	% of total cost
1	Structural	STR1	14.29%	STR-S1	4,100.00	9.85%
	Moisture	MOI3, MOI5, MOI7, MOI8	85.71%	MAT-S3, MOI-S1, MOI-S3, MOI-S4	12,500.00	30.02%
	Building services	SER1, SER2	85.71%	SER-S1, SER-S2	8,200.00	19.69%
	Materials	MAT1, MAT3	14.29%	MAT-S5, MAT-S7	14,300.00	34.34%
2	Structural	STR1	14.29%	STR-S1	3,900.00	9.94%
	Moisture	MOI1, MOI2, MOI3, MOI4, MOI5, MOI6, MOI7, MOI8	85.71%	MAT-S1, MAT-S2, MAT-S3, MOI-S1, MOI-S2, MOI-S3, MOI-S4	11,800.00	30.09%
	Building services	SER1, SER2, SER3	85.71%	SER-S1, SER-S2, SER-S3	7,800.00	19.89%
	Materials	MAT1, MAT2, MAT3	42.86%	MAT-S5, MAT-S6, MAT-S7	13,700.00	34.93%
3	Structural	STR1, STR2, STR3, STR4, STR5	14.29%	STR-S1, STR-S2, STR-S3, STR-S4, STR-S5	6,000.00	12.11%
	Moisture	MOI1, MOI2, MOI3, MOI4, MOI5, MOI6, MOI7, MOI8	100.00%	MAT-S1, MAT-S2, MAT-S3, MOI-S1, MOI-S2, MOI-S3, MOI-S4	14,900.00	30.06%
	Building services	SER1, SER2, SER3	57.14%	SER-S1, SER-S2, SER-S3	9,000.00	18.16%
	Materials	MAT1, MAT2, MAT3	28.57%	MAT-S5, MAT-S6, MAT-S7	14,900.00	30.06%
4	Structural	STR1, STR2	85.71%	STR-S1, STR-S2	5,100.00	10.05%
	Moisture	MOI1, MOI3, MOI4, MOI5, MOI6, MOI7, MOI8	85.71%	MAT-S1, MAT-S3, MOI-S1, MOI-S2, MOI-S3, MOI-S4	15,200.00	29.97%
	Building services	SER1, SER2, SER3	85.71%	SER-S1, SER-S2, SER-S3	10,100.00	19.91%
	Materials	MAT1, MAT2, MAT3	42.86%	MAT-S5, MAT-S6, MAT-S7	17,800.00	35.09%
5	Structural	STR1, STR2, STR3, STR4, STR5	60.00%	STR-S1, STR-S2, STR-S3, STR-S4, STR-S5	9,600.00	13.95%
	Moisture	MOI2, MOI3, MOI4, MOI5, MOI6, MOI7, MOI8	60.00%	MAT-S2, MAT-S3, MOI-S1, MOI-S2, MOI-S3, MOI-S4	19,100.00	27.75%
	Building services	SER1, SER2, SER3	80.00%	SER-S1, SER-S2, SER-S3	12,700.00	18.45%
	Materials	MAT1, MAT2, MAT3	60.00%	MAT-S5, MAT-S6, MAT-S7	15,900.00	23.10%
6	Structural	STR1, STR2, STR3, STR4, STR5	85.71%	STR-S1, STR-S2, STR-S3, STR-S4, STR-S5	9,800.00	18.01%
	Moisture	MOI1, MOI2, MOI3, MOI4, MOI5, MOI7, MOI8	85.71%	MAT-S1, MAT-S2, MAT-S3, MOI-S1, MOI-S3, MOI-S4	16,400.00	30.13%
	Building services	SER1, SER2, SER3	57.14%	SER-S1, SER-S2, SER-S3	9,600.00	17.64%
	Materials	MAT1, MAT2, MAT3	42.86%	MAT-S5, MAT-S6, MAT-S7	10,900.00	20.03%

Source: Authors.

The cost analysis shows that interventions related to moisture accounted for a significant proportion of the investment in all cases, with figures close to 30% of the total cost of the works. This result confirms that moisture was not only the most common category from a technical point of view, but also one of the most significant from an economic perspective.

Interventions in building services also accounted for a significant share of the costs, mainly due to the need to overhaul and replace electrical, plumbing and sanitary systems. Costs associated with structural categories, however, varied more markedly between cases, indicating different levels of complexity in the interventions. In cases involving extensions, more extensive roof repairs or restoration of structural elements, the proportion of this category was higher.

These results allow us to distinguish two main patterns of intervention. The first corresponds to specific rehabilitation measures, focused mainly on moisture control, restoration of finishes, replacement of window frames and upgrading of building services. The second corresponds to more extensive interventions, involving spatial reconfiguration, the enlargement of rooms, structural review and a broader restoration of building systems. This distinction is relevant for public housing improvement programmes, as it indicates that the prioritisation of works should consider not only the frequency of damage, but also the technical complexity and economic impact of the solutions.

3.5 Pathological Criticality Index

Based on the systematisation of occurrences by room and the technical weighting of the categories, the Pathological Criticality Index (PCI) was developed, with the aim of ranking the manifestations according to their relevance to the performance, safety, habitability and durability of buildings.

Table 4 presents the PCI calculated for each identified manifestation, ordered from highest to lowest value.

Table 4 – Pathological Criticality Index (PCI)

Manifestations observed	Category	Weight	Occurrence	PCI
Fungi, mould and mildew	Moisture	4	82.5%	0.83
Saponification in paint	Moisture	4	75.0%	0.75
Corrosion of metal window frames	Moisture	4	57.5%	0.58
Makeshift or inadequate electrical installations	Building services	3	75.0%	0.56
Rising damp (by capillary action)	Moisture	4	55.0%	0.55
Inadequate roofing (slope, pitch)	Structural	4	40.0%	0.40
Rotting of wooden window frames	Moisture	4	30.0%	0.30
Displacement of cladding (due to moisture)	Moisture	4	30.0%	0.30
Improvised or inadequate plumbing installations	Building services	3	37.5%	0.28
Inadequate gutters, flashings and downpipes	Structural	4	22.5%	0.23
Water ingress (rainwater or leaks)	Moisture	4	22.5%	0.23
Cracks and fissures	Structural	4	17.5%	0.18
Displacement of coatings (due to material degradation)	Materials	2	35.0%	0.18
Improvised or inadequate sanitary installations	Building services	3	22.5%	0.17
Deformation of structural elements	Structural	4	12.5%	0.13
Structural instability	Structural	4	10.0%	0.10
Reinforcement corrosion	Moisture	4	10.0%	0.10
Deterioration	Materials	2	20.0%	0.10
Disaggregation	Materials	2	15.0%	0.08

Source: Authors.

Application of the index showed that the most critical defects are strongly associated with moisture. Fungi, mould and mildew; paint saponification; corrosion of metal window frames; and rising damp feature among the most critical defects, confirming that moisture acts as the dominant mechanism of degradation in the units analysed. Furthermore, makeshift or inadequate electrical installations also presented a high level of criticality, due to their high frequency of occurrence and the risk associated with residents' safety.

The PCI made it possible to go beyond simply counting occurrences, providing a technical hierarchy of the manifestations. This prioritisation aids decision-making in housing improvement programmes, as it helps

identify which defects should be prioritised according to their recurrence, severity and potential impact on the safety and durability of buildings.

Taken together, the results indicate that the precarious construction conditions of the analysed units are expressed through recurrent, interdependent and cumulative damage. Moisture stood out as the main mechanism of degradation, both due to the frequency of associated manifestations and its influence on other categories of damage, as well as its impact on the costs of interventions. The association between occurrence, extent, cost and criticality enabled the technical survey to be transformed into a prioritisation tool, with potential for application in public housing improvement programmes.

4. Discussion

The results show that the pathological manifestations observed in the dwellings analysed are not isolated occurrences, but reflect cumulative processes of deterioration associated with informal construction, a lack of technical assistance and insufficient preventive maintenance. This pattern reinforces the need for rehabilitation approaches based on systematic technical diagnosis, particularly in contexts of substandard housing, where different building systems tend to exhibit simultaneous failures.

Among the categories analysed, moisture stood out as the primary mechanism of degradation. Its recurrence and association with secondary manifestations, such as mould, mildew, paint saponification, corrosion of window frames, displacement of cladding and rising damp, indicate that this phenomenon should not be treated as an isolated pathology, but as an underlying driver of deterioration. This finding is consistent with recent literature, which identifies moisture as one of the most frequent categories of defects in residential buildings, associated with failures in design, construction, waterproofing, ventilation and maintenance.

The concentration of these manifestations in kitchens, bathrooms and outdoor areas reinforces this interpretation, indicating the influence of exposure to water, plumbing and sanitary installations, insufficient ventilation and direct exposure to weathering. Thus, the analysis of these defects must consider not only their overall frequency, but also their location within the domestic space and their relationship to the day-to-day use of the dwelling.

The analysis of rehabilitation measures demonstrated that the interventions carried out addressed different aspects of deterioration, encompassing roof repairs, waterproofing, restoration of cladding, replacement of window frames, upgrading of building services and, in some cases, structural restoration and spatial reconfiguration. This set of actions demonstrates that housing improvement, when guided by technical diagnosis, goes beyond the logic of superficial repair and constitutes a strategy for the rehabilitation of the built stock.

The incorporation of cost analysis enhanced the study's contribution by demonstrating that the most recurrent and critical defects are also associated with significant portions of the construction investment. Interventions related to moisture accounted for a significant share of the costs, indicating that the prevention and appropriate treatment of this issue can directly impact the efficiency of public resource allocation.

In this regard, the Pathological Criticality Index (PCI) proved useful as a tool to support technical prioritisation. By combining the occurrence and technical weight of the categories, the index allows defects to be ranked not only by frequency but also by their potential impact on safety, habitability, functionality and durability. The triangulation of technical documentation, field inspections, photographic records and budget spreadsheets lent greater consistency to the procedure, whilst the combined use of ABNT NBR 16747 and NEN 2767 contributed to greater standardisation and traceability of the analysis.

Finally, the results reinforce the role of housing improvements as a strategic public policy tool. By intervening in existing units, these programmes contribute to risk mitigation, the improvement of

habitability conditions, the extension of the service life of buildings and the upgrading of substandard housing stock.

5. Conclusions

This study demonstrated that the substandard dwellings analysed exhibit recurring pathological manifestations, associated mainly with moisture, material degradation, inadequacies in building services and, to a lesser extent, structural deficiencies. Among these categories, moisture stood out as the primary mechanism of degradation, both due to the frequency of associated manifestations and its capacity to trigger secondary damage to finishes, window frames, paintwork, structural elements and living conditions.

The rehabilitation measures proved effective in mitigating the identified pathologies, especially when guided by technical diagnosis and tailored to different building systems. The interventions involved waterproofing, roof inspections, upgrading of building services, replacement of deteriorated components, restoration of cladding and, in some cases, spatial reconfiguration and structural repair.

The main contribution of the study lies in the integrated systematisation of pathological manifestations, rehabilitation measures, condition ratings, coverage, costs and criticality. The combined use of ABNT NBR 16747, NEN 2767 and the Pathological Criticality Index (PCI) enabled the development of an analytical procedure applicable to the technical prioritisation of interventions in public housing improvement programmes.

The cost analysis showed that the most critical pathologies are also associated with significant investment requirements, particularly those related to moisture and building services. Thus, the incorporation of criteria regarding occurrence, coverage, criticality and cost can contribute to greater efficiency in the allocation of public resources and to more informed decisions in contexts of budgetary constraints.

From a public policy perspective, the results confirm the potential of housing improvements as a strategy for rehabilitating the existing building stock, contributing to extending the service life of buildings, improving safety, sanitary conditions and functionality, and reducing housing inadequacy. Limitations include the limited number of cases, the geographical focus on Cidade Estrutural, and the absence of longitudinal monitoring. Future studies could expand the sample and incorporate post-occupancy assessments at different time intervals.

Abstract: Assessing the structural integrity of old timber structures, which requires reliable estimates of their elastic properties, remains a major challenge for in situ inspection. Current non-destructive techniques generally focus on identifying only the elastic moduli associated with the principal orthotropic directions, without enabling a full determination of the stiffness matrix components. This study proposes an ultrasound-based identification strategy aimed at estimating the complete set of elastic properties of wood under realistic inspection constraints. In an ideal configuration, ultrasonic wave velocities are measured along multiple propagation directions within the three principal orthotropy planes (LR, LT and RT), enabling full mechanical characterization. However, such configurations are rarely achievable in practice due to limited access to timber elements. To address this issue, a complete and well-distributed data set is first considered as a reference, and then progressively degraded to emulate realistic in situ inspection conditions. All available data are subsequently incorporated into an optimization procedure using the Direct algorithm to estimate the elastic properties of wood. The algorithm seeks to minimize the gaps between theoretical wave velocities, computed using Christoffel's equation, and experimental velocities estimated using Hankinson's formula. The sensitivity of the identified properties to the number and orientation of the measurement points is analyzed systematically. The results showed that reducing the measurement angle from 3° to 30° can induce deviations ranging from 0.1% to 4.6% for longitudinal moduli and from 2% to 24% for shear moduli in the RT plane. The study also revealed critical propagation angles that significantly impact the identifiability and reliability of elastic properties. These findings provide practical guidance on optimizing ultrasonic measurement strategies for estimating the mechanical properties of timber structures under in situ conditions.

Keywords: Timber structures, ultrasound, inspection conditions, elastic properties, optimization

1. Introduction

In the past, wood was extensively used in the construction of buildings and engineering structures that now constitute a valuable cultural and historical heritage. Preserving this heritage requires regular inspection and, when necessary, repair or replacement of damaged structural elements that may compromise structural safety. In this context, in-situ assessment of timber structures has become increasingly important, requiring reliable estimation of the physical and mechanical properties of wood without causing damage to the structure. Wood is a natural material characterized by anisotropy and hygroscopic behaviour. Its physical, thermal, and mechanical properties depend significantly on environmental conditions, particularly moisture content, Forest Products Laboratory (2010). Due to its cellular structure, wood is defined by three principal material directions: longitudinal (L), radial (R), and tangential (T). The orthotropic elastic behaviour of wood is described by twelve elastic constants, of which nine are independent. These nine parameters

include the three moduli of elasticity (E_L, E_R, E_T) in the principal directions, the three shear moduli (G_{LR}, G_{LT}, G_{RT}), and the three Poisson's ratios (v_{LR}, v_{LT}, v_{RT}), in the planes of orthotropic symmetry.

Accurate determination of these elastic constants is essential for predicting structural behaviour and assessing structural integrity. However, traditional mechanical testing methods are destructive and therefore unsuitable for in-situ applications. Consequently, non-destructive technique (NDT) techniques have been widely investigated for timber characterization. Several methods have been proposed in the literature, including measurements of density, moisture content, and degradation level, Bahrami *et al.* (2025); Kasal and Anthony (2004); Jaskowska-Lemańska and Wałach (2023); Wang *et al.* (2021); Vössing and Niederleithinger (2018).

Among non-destructive techniques, ultrasonic methods have proven particularly effective for evaluating elastic properties of wood. These methods rely on measuring wave propagation velocities, which can be related to material stiffness and density. Due to the orthotropic nature of wood, wave propagation velocities depend on the direction of propagation. This directional dependence has been described using empirical relationships, such as Hankinson (1921) and more recent two-dimensional models proposed by van Wijk *et al.* (2019), as well as three-dimensional empirical formulations proposed by Afoutou *et al.* (2023). Christoffel (1877) established some equations which give a relationship between the elastic stiffness tensor, density and direction of propagation, on the one hand, and wave velocities, on the other. Solving the Christoffel's equations yields three wave velocities corresponding to quasi-longitudinal and quasi-transverse waves. In an anisotropic medium, these solutions correspond to phase velocities and must be converted to group velocities before being compared with the experimental velocities as demonstrated in Abedi *et al.* (2019). This combination of analytical and empirical approaches is particularly well suited to inverse stiffness matrix determination.

Despite its theoretical robustness, the practical implementation of the Christoffel-based approach under in situ conditions remains challenging. In practice, current in-situ measurements often focus on determining elastic moduli along the principal orthotropic directions. However, such measurements do not allow full determination of the stiffness matrix. Laboratory-based techniques such as resonant ultrasonic spectroscopy used by Longo *et al.* (2012) and immersion methods in Bucur and Rasolofosaon (1998) enable complete characterization of elastic constants. Nevertheless, these methods require controlled laboratory conditions and cannot be applied to existing structures. To overcome these limitations, a novel approach was proposed for identifying the complete stiffness matrix using compression waves measured in multiple directions by Afoutou *et al.* (2024). The ideal characterization would be based on regular measurements of ultrasonic wave propagation velocities in multiple directions, covering the full range of mechanical properties. However, in real inspection scenarios, access to all surfaces of timber elements is often limited. Furthermore, several factors such as moisture gradients, heterogeneity, geometric irregularities, and measurement uncertainties influence wave velocities and complicate parameter identification. Therefore, it is essential to investigate the influence of measurement configuration and directional coverage on the accuracy of identified elastic properties. In particular, the number and distribution of measurement angles may significantly affect the stability of inverse identification methods based on the Christoffel model.

The present study aims to evaluate in-situ inspection strategies for identifying the complete set of mechanical properties of timber structures, with particular emphasis on the influence of measurement angles. The study first assumes an ideal dataset with an identical number of measurements in each principal orthotropic plane (LR, LT, and RT). Subsequently, the dataset is progressively degraded to simulate realistic inspection conditions and evaluate the robustness of the identification method. The paper is organized as follows. Section II presents the theoretical background of wave propagation in anisotropic elastic media and introduces the Christoffel formulation. Section III describes the methodology used for elastic property identification and optimization. Section IV presents and discusses the results obtained under different configurations.

2. Wave propagation in an elastic medium

The propagation of waves is defined by the following equation, Royer and Dieulesaint (1996):

$$\rho \cdot \frac{\partial^2 u_i}{\partial t^2} = C_{ijkl} \cdot \frac{\partial^2 u_l}{\partial x_j \partial x_k} \tag{1}$$

where u_i and u_l denote the displacement components of a materiel point M defined by its coordinates x_j in a Cartesian reference. ρ is the material density, assumed to be homogeneous like C_{ijkl}, which represents the components of elastic stiffness tensor C, in accordance with the following Hooke's law:

$$\underline{\sigma} = C \cdot \underline{\varepsilon} \text{ or } \sigma_{ij} = C_{ijkl} \cdot \varepsilon_{kl} \text{ with } (i,j,k,l) \in \{1,2,3\}^4 \tag{2}$$

σ_{ij} and ε_{kl} are the components of the stress and strain tensors, $\underline{\sigma}$ and $\underline{\varepsilon}$, respectively. The solution to Equation (1) actually takes the form of a progressive plane wave, as exhibited in the following expression, Cuxac (1991):

$$\vec{u}(\overrightarrow{OM}, t) = \vec{U} \cdot g\left(\omega \cdot t - \vec{k} \cdot \overrightarrow{OM}\right) \tag{3}$$

$\vec{U}$ is the maximum displacement vector corrected by function g. $\vec{k}$ designates the wave vector, which is dependent on wave type (compression or shear waves); it is oriented by the unit propagation direction vector $\vec{n}$, hence:

$$\vec{k} = k_\phi \cdot \vec{n} \tag{4}$$

k_ϕ is the unit wave vector and can be written as:

$$k_\phi = \frac{2\pi}{\lambda} = \frac{\omega}{V_\phi} \tag{5}$$

Where, ω is the wave pulsation, V_ϕ phase velocity for compression waves ($\phi = p$) and for either horizontal or vertical shear waves ($\phi = S_h$ or $\phi = S_v$, respectively) and λ is the wavelength associated, as defined in the local reference shown in Figure 1.

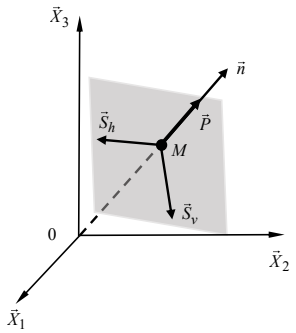

Figure 1 – Local reference Afoutou *et al*. (2024)

The solution to the dynamic wave propagation equation (3) assumes he typical indicial form below:

$$u_i = U_i \cdot exp\left(\omega \cdot t - k_\phi \cdot n_j \cdot x_j\right) \tag{6}$$

Introducing expression (6) into the left-hand term of (1) yields:

$$\rho \cdot \frac{\partial^2 u_i}{\partial t^2} = \rho \cdot \omega^2 \cdot \left[U_i \cdot exp\left(\omega \cdot t - k_\phi \cdot n_j \cdot x_j\right)\right] \tag{7}$$

Similarly, the right-hand term of (1) becomes:

$$\frac{\partial^2 u_l}{\partial x_j \partial x_k} = k_\phi^2 \cdot n_j \cdot n_k \cdot \left[U_l \cdot exp\left(\omega \cdot t - k_\phi \cdot n_j \cdot x_j\right)\right] \tag{8}$$

By combining expressions (7) and (8), relation (1) is replaced by:

$$\rho \cdot \omega^2 \cdot U_i = C_{ijkl} \cdot k_\phi^2 \cdot n_j \cdot n_k \cdot U_l \tag{9}$$

As described in (Bucur 2023), the expression (9) can be rewritten according to Christoffel's notations:

$$\begin{bmatrix} \Gamma_{11} - \rho \cdot V_\phi^2 & \Gamma_{12} & \Gamma_{13} \\ \Gamma_{12} & \Gamma_{22} - \rho \cdot V_\phi^2 & \Gamma_{23} \\ \Gamma_{13} & \Gamma_{23} & \Gamma_{33} - \rho \cdot V_\phi^2 \end{bmatrix} \cdot \begin{pmatrix} U_1 \\ U_2 \\ U_3 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix} \tag{10}$$

According to the general case, the solution to the system in (10) is obtained by calculating the eigenvalues of the matrix system. In this case, three values or V_ϕ, corresponding to one compressive and two shear wave velocities, are deduced from solving the characteristic polynomial given by the following expression:

$$det \begin{bmatrix} \Gamma_{11} - \rho V_\phi & \Gamma_{12} & \Gamma_{13} \\ \Gamma_{12} & \Gamma_{22} - \rho V_\phi & \Gamma_{23} \\ \Gamma_{13} & \Gamma_{23} & \Gamma_{33} - \rho V_\phi \end{bmatrix} = 0 \tag{11}$$

For anisotropic materials, it has been demonstrated that wave polarisation is related to phase velocity, propagation direction and stiffness constants. For a pure longitudinal wave, the angle between the displacement vector and the normal to the wave is 0°, whereas for pure shear waves, the angle between the propagation and polarisation vectors is $\pi/2$. This angle varies when the propagation direction deviates from the material's principal directions, Bucur (2023). Knowing the phase velocities and directions of the phase velocity vectors makes it possible to deduce the slowness surface of the group velocities. However, since measurements used to derive elastic constants are taken in assumed planes of symmetry, the angle between group and phase velocities remains confined to that plane. The two-dimensional relationship between the group velocity V_g, and the phase velocity V_Φ, in these planes of symmetry can be found in Postma (1955) and in Abedi *et al.* (2019) as follows:

$$V_g = \sqrt{V_\emptyset^2 + \frac{\partial V_\emptyset}{\partial \emptyset}} \tag{12}$$

where $\emptyset$ represents the angle of the phase vector V in the plane of symmetry. The group angle θ in this plane is given by:

$$\theta = \emptyset + \tanh^{-1}\left[\frac{\partial V_\emptyset / \partial \emptyset}{V_\emptyset}\right] \tag{13}$$

3. Procedure for elastic property determination

3.1. Material and selection of experimental velocities

To illustrate the tree's growth, we identify three principal directions (L, R, and T) and three orthotropic planes (LR, LT, and RT), as shown in Figure 2.

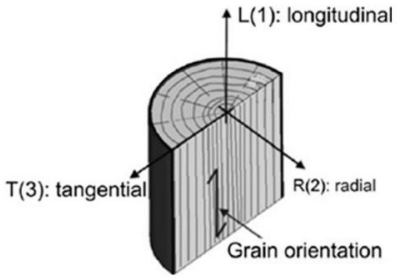

Figure 2 – Principal directions of wood Bucur (2023)

For the rest of the study, Let's define the symmetry axes of wood L, R and T as axes 1, 2 and 3. The velocities and the corresponding stiffnesses are noted as:

$V_L=V_{LL}= V_{11}$, $V_R=V_{RR}= V_{22}$, $V_T=V_{TT}= V_{33}$, $V_{TR}= V_{44}$, $V_{LT}= V_{55}$, $V_{LR} = V_{66}$ and $C_{LL} = C_{11}$, $C_{RR}= C_{22}$, $C_{TT}= C_{33}$, $C_{TR} = C_{44}$, $C_{LT} = C_{55}$, $C_{LR}= C_{66}$.

Since working with the elastic constants (E, v, and G) is most convenient, we will present the compliance matrix, the inverse of the stiffness matrix.

The components of the compliance matrix, [S] = [C] $^{-1}$, are derived as follows:

$$[S] = \begin{bmatrix} \frac{1}{E_L} & -\frac{\nu_{RL}}{E_R} & -\frac{\nu_{TL}}{E_T} & 0 & 0 & 0 \\ -\frac{\nu_{RL}}{E_R} & \frac{1}{E_R} & -\frac{\nu_{TR}}{E_T} & 0 & 0 & 0 \\ -\frac{\nu_{TL}}{E_T} & -\frac{\nu_{TR}}{E_T} & \frac{1}{E_T} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{1}{G_{RT}} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{1}{G_{LT}} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{1}{G_{LR}} \end{bmatrix} \quad (14)$$

We considered the material to be homogeneous and orthotropic, with a constant and homogeneous density throughout the region of interest. The density is assumed to be 450 kg/m³. The elastic properties of interest are summarized in Table 1.

Table 1 – Material properties of softwood, Guitard (1987).

E_L (GPa)	E_R (GPa)	E_T (GPa)	ν_{LR}	ν_{RT}	ν_{TL}	G_{LR} (GPa)	G_{RT} (GPa)	G_{TL} (GPa)
13.1	1	0.636	0.39	0.51	0.02	0.861	0.084	0.745

The elastic property values in the above table will serve as a reference for interpreting the optimization results.

As mentioned in Section 2, our approach involves working systematically within orthotropic planes to optimize the elastic properties.

We used Hankinson's empirical model to generate experimental velocities as a function of propagation angles in each of the three orthotropic planes (LR, LT, and RT). Hankinson's 2D model in an xy plane is expressed as follows:

$$V_{Hank}^{xy} = \frac{V_x \cdot V_y}{V_x \cdot (\sin \alpha_{xy})^{n_{xy}} + V_y \cdot (\cos \alpha_{xy})^{n_{xy}}} \quad (15)$$

V_x and V_y designate the wave velocities in the x and y directions, respectively, and n_{xy} is Hankinson's empirical exponent.

To determine V_L, V_R, V_T, and the three calibration coefficients, we first performed an optimization between the analytical group velocities derived from Christoffel and the velocities derived from Hankinson's empirical model. The values obtained are 5550 m/s, 1650 m/s, and 1310 m/s for the longitudinal velocity V_L, radial velocity V_R, and tangential velocity V_T, respectively. The scaling coefficients for n_{RT}, n_{LT}, and n_{LR} are 1.55, 1.38, and 1.41, respectively. However, this approach generates measurement noise, as the equivalent isotropic theoretical velocities using $V_i = \sqrt{E_i/\rho}$ would yield values of 5395 m/s, 1490 m/s, and 1190 m/s, respectively for the longitudinal, radial, and tangential directions.

Given that equation (15) is continuous, the velocities at defined angular increments are extracted from the empirical velocities obtained to reflect in situ conditions. We have considered six configurations based on the extraction angle increments of the empirical velocities, as summarized in Table 2.

Table 2 – Different configurations tested as function of angle

Configurations	Angles increments	Number of data per plane
C1	3°	61
C2	10°	19
C3	15°	13
C4	30°	7
C5	45°	5
C6	15° without V_L	11 in LR and LT; 13 in RT

Taking the C5 configuration as an example, the velocities used in the elastic property optimization process are summarized in Table 3.

Table 3 – Examples of empirical velocities

Angles (°)	Velocity (m/s) in LR plane	Velocity (m/s) in LT plane	Velocity (m/s) in RT plane
0	5500	5500	1650
45	2069	1707	1250
90	1650	1310	1310
135	2069	1707	1250
180	5500	5500	1650

3.2. Cost Function and Optimization Algorithm

The flowchart in Figure 3 describes the steps used to determine the elastic properties. In short, the cost function deviation defined in following equation was minimized. This function aims to minimize the average deviation across all three planes. The DIRECT algorithm was employed.

$$\overline{f} = \frac{1}{nb}\left(\sum_{i=1}^{nb}\left(V_p^{xy}(\alpha,\theta) - V_{Hank}^{xy}(\alpha,\theta)\right)\right) \quad (16)$$

Where nb is the number of angular combinations chosen in the process of optimizing the elastic properties. For example, for an angular step of 45°, nb = 15.

The dividing rectangles (DIRECT) is a global optimization algorithm designed to solve complex problems where the aim is to minimize a function without knowing its exact form. It is especially useful when precise variable boundaries must be met. Further details can be found in Jones and Martins (2021). A threshold value of 10^{-4} was set for the convergence.

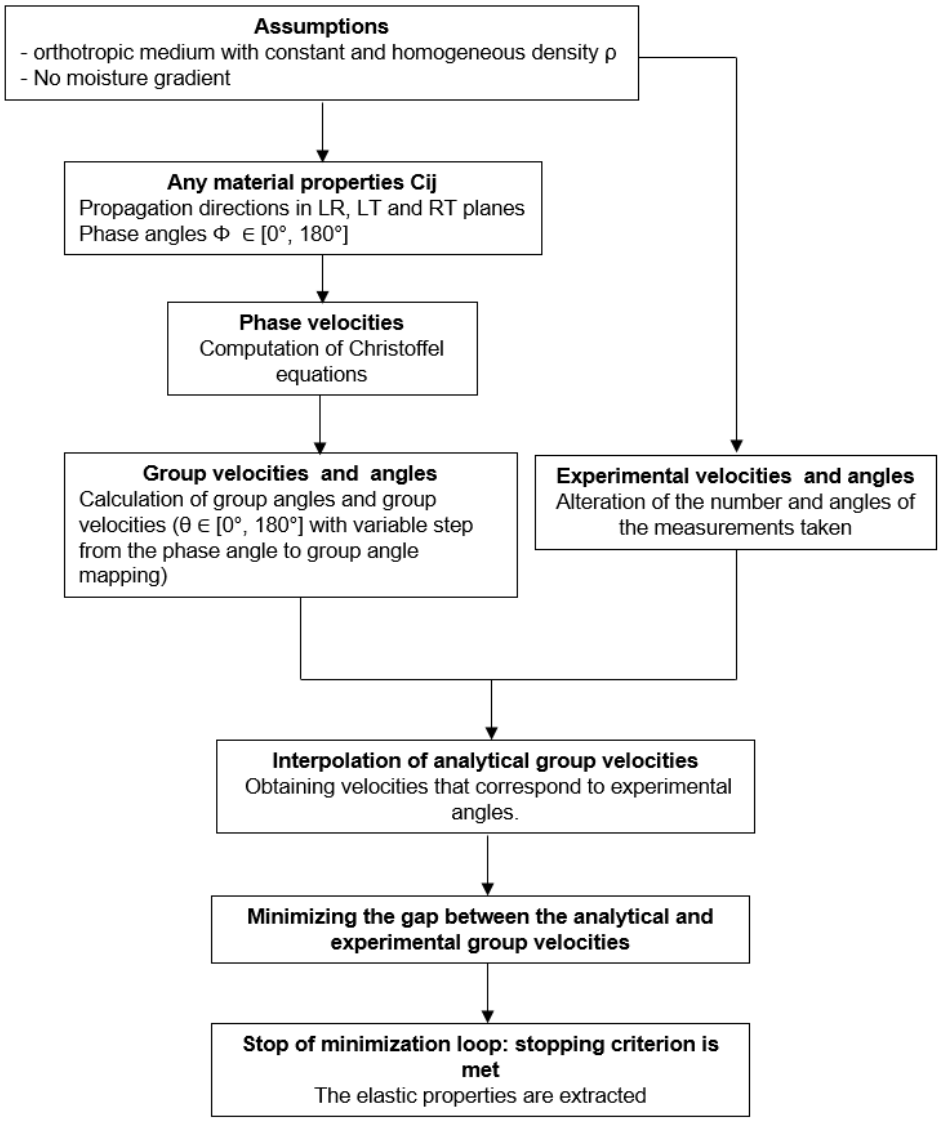

Figure 3 – Flowchart of elastic properties determination

4. Results and Discussion

Figure 4 shows the optimized velocities for the configuration C5 that yield the best values for the desired parameters. These velocities are plotted alongside the analytical Christoffel velocities (Vg_target), which are

calculated using the reference properties from Table 1. The velocities (Vg_C5) represent the experimental velocities. We found that the optimized velocities are in line with the reference velocities with a value of $\overline{f}$ equal to 15 (m/s), indicating correct optimization.

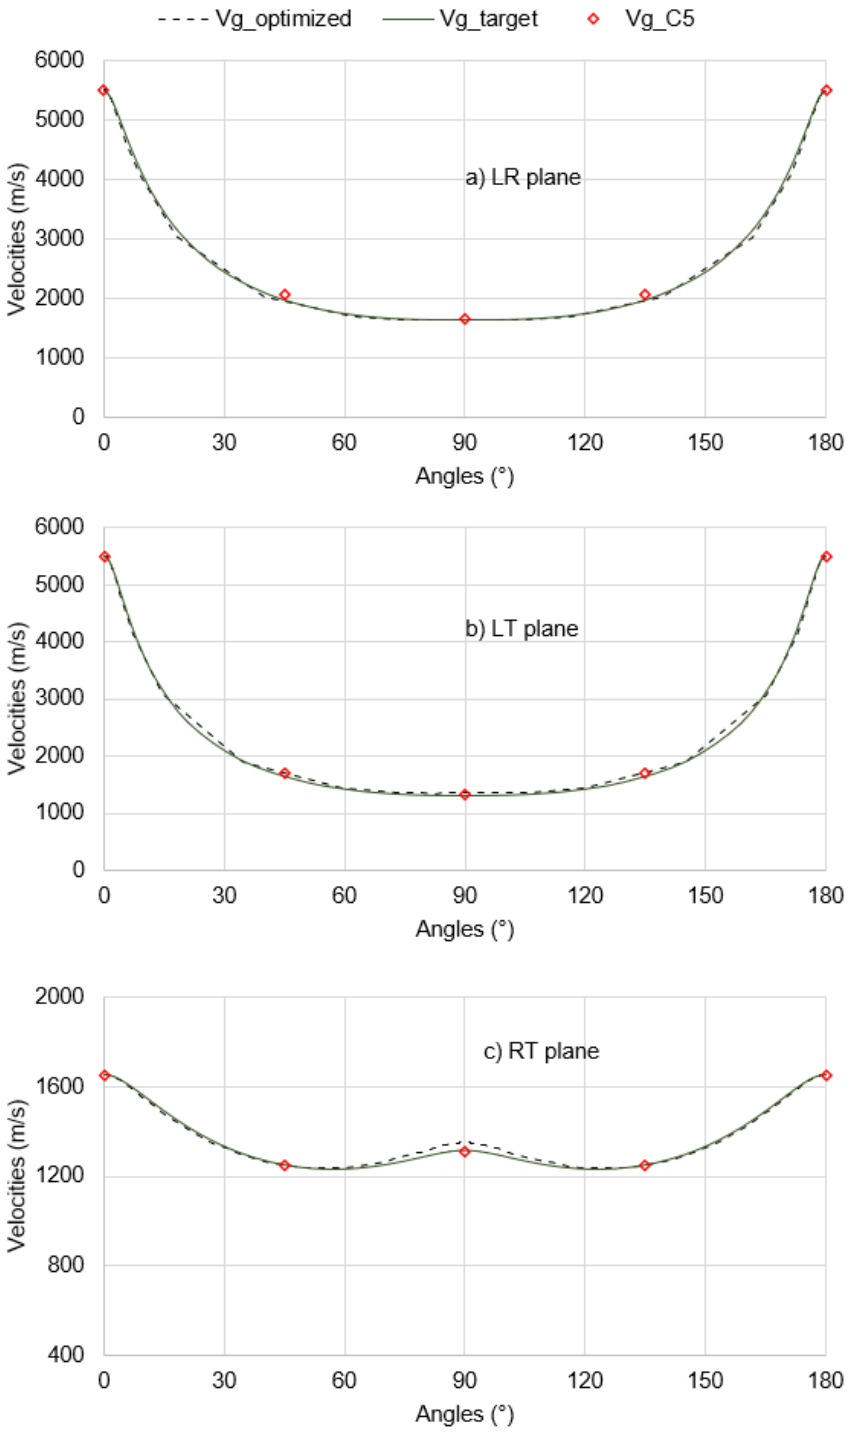

Figure 4 – Example of combination C5 velocities, displayed alongside the optimized and analytical references velocities.

Table 4 summarizes the corresponding elastic properties and the complete set of results for the other configurations.

The results showed that reducing the measurement angle from 3° to 30° (configurations C1 and C4) can lead to relative deviations ranging from 0.1% to 4.6% for longitudinal modules and from 2% to 24% for shear modules in the RT plane.

Specifically, relative deviations of E_L remain below 5%, regardless of the angle increment, except for configuration C6, which yields a relative deviation of 14.2%. This is expected, as no values are provided in the input data along the longitudinal direction (V_L). Regarding the radial modulus (E_R), all configurations except C2 and C6 (with angle increments of 10° and 45°, respectively) yield relative deviations of around 10%. For the modulus in the tangential direction (E_T), configuration C1 (3° pitch) is the best, and configuration C6 yielded the largest relative deviation.

Table 4 –Optimized elastic property values

Configurations	E_L (GPa)	E_R (GPa)	E_T (GPa)	ν_{LR}	ν_{RT}	ν_{TL}	G_{LR} (GPa)	G_{RT} (GPa)	G_{TL} (GPa)
C1	13.111	1.093	0.656	0.498	0.422	0.040	0.998	0.085	0.848
C2	13.037	0.938	0.567	0.409	0.570	0.039	0.998	0.061	0.842
C3	13.037	1.110	0.695	0.498	0.400	0.030	0.998	0.099	0.842

C5	13.556	1.050	0.700	0.102	0.467	0.010	0.885	0.063	0.747
C6	14.963	0.894	0.537	0.483	0.593	0.040	0.998	0.070	0.833

Regarding the Poisson's ratios, it is best to verify all inequalities in the following equation described in Bucur and Najafi (2003), to ensure the stiffness matrix is non-negative.

$$\begin{cases} 1 - \nu_{ij}\nu_{ji} > 0 \ \text{ with } \ i \neq j \text{ and } i,j \in \{L,R,T\}^2 \\ |\nu_{ij}| < \sqrt{\dfrac{E_i}{E_j}} \ \text{ with } \ i \neq j \text{ and } i,j \in \{L,R,T\}^2 \\ 1 - \nu_{LR}\nu_{RL} - \nu_{LT}\nu_{TL} - \nu_{RT}\nu_{TR} - 2\nu_{LR}\nu_{RT}\nu_{TL} > 0 \end{cases} \quad (17)$$

We found that all optimized values satisfy these inequalities, indicating the robustness of the optimization procedure.

Finally, the relative deviations for the shear moduli are large, except for the G_{LR} (2.8%), G_{TL} (0.2%), and G_{RT} (1.7%) configurations, respectively, for C5, C5, and C1. These large deviations explain why it is difficult to obtain shear moduli with a single configuration. However, the C5 configuration appears to be the most suitable. However, the order ($G_{LR} > G_{LT} >> G_{RT}$) holds true for all optimized values.

The study also identified critical propagation angles that significantly impact the identifiability and reliability of elastic properties. This is the case for the 45° angle. These results provide practical recommendations for optimizing ultrasonic measurement strategies aimed at estimating the mechanical properties of timber structures under in situ conditions. While the overall behavior of the nine parameters combined is very interesting (see the curves in Figure 4), optimizing nine parameters is risky due to the potential for local minima, even when a global algorithm is used.

5. Conclusion

This study examined an ultrasonic-based approach for determining the complete stiffness matrix of wood. The study began with an ideal dataset in which propagation directions were uniformly distributed. The

measurement configurations were then progressively degraded to evaluate their influence on the robustness of the identified elastic properties. The findings indicated that augmenting the angular increment from 3° to 30° results in relative deviations ranging from 0.1% to 4.6% for longitudinal moduli and from 2% to 24% for shear moduli in the RT plane. While the longitudinal elastic moduli demonstrated relative stability, the shear moduli exhibited greater sensitivity to measurement configuration. This observation underscores the challenge of accurately identifying these parameters using limited directional data.

The analysis further demonstrated that specific propagation angles, notably around 45°, significantly influence the identifiability and reliability of elastic properties. Despite these limitations, the optimization procedure based on the Direct algorithm and Christoffel's equation demonstrated good robustness, as confirmed by the preservation of expected stiffness relationships. In consideration of the findings, the results provide practical recommendations for optimizing ultrasonic measurement strategies in in-situ timber inspection.

Subsequent research will concentrate on enhancing the robustness of the inverse identification procedure, particularly in the context of estimating multiple parameters concurrently. Furthermore, extending the methodology to surface wave measurements has the potential to improve accessibility in real structures and enhance the reliability of shear modulus estimation. Finally, experimental validation on real timber structures and the integration of measurement uncertainties will be essential steps toward practical field applications.

PROGRESSIVE FAILURE ANALYSIS IN ELEVATED SWIMMING POOL WATERPROOFING SYSTEMS: A DIAGNOSTIC FRAMEWORK FOR CORRELATING EXECUTIVE NON-CONFORMITIES AND WATERTIGHTNESS LOSS MECHANISMS

Micaéle Brandão Silva[1], Marília Araujo[2]

[1] Instituto Nova Engenharia, São Paulo, Brasil, (engenharia@innovapredial.com.br)

[2] Instituto Nova Engenharia, São Paulo, Brasil, (marilia_carla10@hotmail.com)

Abstract: Elevated swimming pools represent a particularly demanding construction typology, in which the interaction between reinforced concrete structures, waterproofing membranes and mechanical protection layers creates a complex multi-layer system that is highly sensitive to execution deviations. Despite the recognised importance of execution quality on waterproofing performance, the technical literature lacks field-documented case studies that systematically correlate quantified executive non-conformities such as mechanical protection layer thickness deviation and reinforcement omission with progressive watertightness loss mechanisms in this specific construction typology. This study presents a forensic diagnostic investigation of a recurrent waterproofing failure in an elevated swimming pool, applying an integrated methodology comprising technical anamnesis, analysis of architectural and waterproofing designs, design-to-execution comparison, systematic visual survey, percussion-based non-destructive testing, inspection window opening and damage mapping. The investigation identified that the mechanical protection layer was executed at 5 cm instead of the 3 cm specified, generating an estimated interfacial overload of 80 to 130 kg/m² calculated from the mortar unit weight of 2,100 kg/m³ and amplified by the complete absence of the reinforcing plastic mesh required by the design. Combined with inadequate treatment of singular points, absence of mandatory watertightness testing records and lack of specialised technical supervision, these deviations triggered a progressive degradation mechanism leading to generalised loss of adhesion, coating detachment and structural impacts extending to the basement level. The original contribution of this study is a replicable forensic diagnostic framework specifically structured for elevated swimming pool waterproofing systems, integrating causal chain analysis; amage mapping and a preventive technical protocol grounded in normative criteria. The findings demonstrate that the waterproofing failure in this case originated not from material inadequacy but from a systemic breakdown in execution quality control, and that technical supervision at the initial stages would have prevented the observed pathological progression.

Keywords: building pathology; waterproofing systems; swimming pools; watertightness loss; failure analysis; construction process.

1. Introduction

The waterproofing system consists of a set of construction operations and techniques (services), comprising one or more layers, whose purpose is to protect buildings against the deleterious action of fluids, vapours and moisture (ABNT NBR 9575, 2010). In this context, watertightness constitutes an essential habitability requirement in buildings, with direct effects on the durability and functionality of construction systems, as addressed in NBR 15575 (2024) through criteria applicable to façades, roofs, floors of wet areas and hydraulic sanitary installations (ABNT NBR 15575, 2024). Water acts as a transport vehicle and electrolyte in concrete. Its uncontrolled presence accelerates chloride and sulphate diffusion; promoting reinforcement depassivation and expansive reactions that drastically compromise structural service life, as detailed in the technical literature of Neville (2011). Despite technological advances in waterproofing materials and systems, failure occurrence remains recurrent in civil construction. The incidence of cracks and early failures in buildings is closely related to deficiencies in technological control and operational errors during the execution phase, frequently surpassing failures originating in the design stages. (Thomaz, 2002). The effectiveness of a waterproofing system is conditioned on the perfect harmony between design guidelines and rigour in the technical detailing in the field (Storte, 1989). Picchi (1986) further states that waterproofing

is considered a specialised service within civil construction, requiring considerable experience, in which details play an important role and where even minimal localised failures can compromise the entire system. The selection of the waterproofing system is conditioned by a set of variables involving substrate characteristics, the type and regime of water action by percolation, positive or negative pressure and the susceptibility of the constructive element to movement and cracking, being determined according to the load imposed by the fluid on the construction parts requiring watertightness (ABNT NBR 9575, 2010, item 5). Pirondi (1992) had already warned of the need to adapt materials and techniques to the specific conditions of each structure, distinguishing situations subject to counter-pressure from those with free drainage. Even when the specified solution is technically adequate, its effectiveness is directly conditioned on correct execution, adequate treatment of critical points and watertightness testing (ABNT NBR 9574, 2008). From the perspective of building pathology, watertightness loss results from a multifactorial process involving design, execution and technological control failures (Thomaz, 2002), acting as a triggering agent for leaching, efflorescence, loss of interlayer adhesion and reinforcement corrosion (Neville, 2011). Diagnostic engineering, integrating technical inspection, historical survey and field investigation, is therefore essential for distinguishing apparent symptoms from underlying degradation mechanisms and defining effective intervention strategies (ABNT NBR 16747, 2020). Although executive deficiencies as the primary origin of waterproofing failures are well established in the literature (Thomaz, 2002; Picchi, 1986), and Carretero-Ayuso & de Brito (2016) have numerically demonstrated the importance of prior supervision in bituminous membrane systems, existing studies focus on roofs and façades. To the authors knowledge, no field-documented study has established a quantified causal chain with measured layer thicknesses, calculated interfacial overloads and non-destructive test results correlating executive non-conformities with progressive watertightness loss specifically in elevated swimming pool systems, a typology subject to permanent hydrostatic pressure and multi-layer mechanical constraints not present in roofing applications. The present study addresses this gap. In this context, the present study presents a case study of recurrent failures in an elevated swimming pool waterproofing system, focusing on root cause analysis associated with execution stages. The research seeks to correlate the observed non-conformities with deviations in the construction process, highlighting the influence of execution on system performance. As a contribution, it proposes preventive technical guidelines grounded in the integration of design, execution and technological control, with a view to reducing the incidence of pathological manifestations and improving the durability and performance of waterproofing systems in swimming pools.

2. Literature Review

In civil construction, waterproofing carried out correctly represents approximately 3% of the construction cost; when executed incorrectly, this percentage can rise to 10%; due to the need to remove finishing coatings to correct failures (Granato, 2002). Satisfactory or perfect guarantee and the absolute performance of a waterproofing product are not linked solely to standardisation guaranteed by bodies and institutions Pirondi (1992). Surveys carried out in Brazil show that approximately 40% of pathological manifestations found in inspections could have been avoided during design elaboration; most design failures are not identified during construction execution, and the most common errors are consequences of the lack of information; description and explanation in the design (Grandiski, 2004). However good the materials used in waterproofing an area, if applied by non-specialised teams, the usefulness of the system will be compromised Mello (2005). Observing that the majority of pathological manifestations in buildings are caused by moisture problems, it is of paramount importance to address this topic, with a view to drawing attention to or even raising awareness, not only among construction companies but also among academics, of the importance of this type of service throughout construction (Bernhoeft; Melhado, 2009).

2.1 Pathology of waterproofing systems

The technical literature shows that executive deficiencies constitute the primary origin of failures in waterproofing systems, with pathological manifestations resulting from the interaction between execution

failures, environmental exposure and structural behaviour (Thomaz, 2002; Bértolo, 2001). The continuous presence of moisture in concrete activates chloride and sulphate ion transport mechanisms that intensify deterioration and compromise structural service life Neville (2011). In elevated swimming pool systems, this mechanism operates under permanently saturated conditions, making the consequences of watertightness loss disproportionately severe compared to intermittently exposed systems. As established by Souza & Ripper (2009), inadequate waterproofing execution is directly linked to progressive structural degradation through reinforcement corrosion, leaching and loss of interlayer adhesion a causal chain fully confirmed in the present case study. Silva & Oliveira (2018) demonstrated that accurate identification of pathological manifestations is a prerequisite for effective system selection and service life extension a finding that underscores the diagnostic value of the forensic methodology applied in this study. Geometric discontinuities in waterproofing systems interfaces, penetrations and joints concentrate stresses and represent the primary loci of pathological initiation, as established by ABNT NBR 9575 (2010) and widely documented by Thomaz (2002), a pattern consistently confirmed in field investigations, including the present case study. The technical criteria established by ABNT NBR 9574 (2008) for the execution of waterproofing systems substrate preparation, layer thickness control, singular point treatment and mandatory watertightness testing represent not merely regulatory requirements but minimum conditions for system performance. Non-conformity with any of these criteria does not simply reduce performance margins; it initiates the degradation chain described above. The critical implication, confirmed by this case study, is that the technical adequacy of the specified materials is rendered irrelevant by executive non-conformity: a technically correct design executed incorrectly performs no better than an inadequate one.

3. Methodology

3.1 Anamnesis and historical survey

Structured technical anamnesis conducted through direct interviews with the building manager, maintenance team and responsible engineer reconstructed the pathological history prior to physical inspection. The pool presented an infiltration history since post-delivery, having been subjected to multiple palliative repair attempts without specialised technical supervision, including localised membrane patching and partial coating replacement, without achieving definitive resolution. This recurrence pattern is consistent with the absence of root cause identification in previous interventions, since palliative repairs applied over a systemically compromised waterproofing layer cannot restore watertightness capacity (IBI, 2023). Critically, the anamnesis confirmed the complete absence of specialised technical supervision (conformity assessment) during original execution a primary risk factor for executive non-conformity, as active quality control at each critical stage is required by ABNT NBR 9574 (2008) and highlighted by Picchi (1986).

3.2 Documentary analysis and design-to-execution comparison

The second stage comprised systematic analysis of all available technical documentation, including architectural, structural and hydraulic designs, and most critically, the waterproofing design prepared in accordance with ABNT NBR 9575 (2010). Documentary analysis served a dual purpose: to establish the technical baseline against which field conditions would be compared, and to identify the design intent regarding layer thicknesses, reinforcement specification, singular point detailing and testing requirements. The waterproofing design specified a double asphalt membrane system a technically appropriate solution for elevated swimming pools given its flexibility under structural movement with a mechanical protection layer of 3 cm thickness, reinforced with plastic mesh positioned at every 1.5 cm within the layer. The design-to-execution comparison methodology followed the criteria established by ABNT NBR 16747 (2020) and the normative guidelines of ABNT NBR 9574 (2008), identifying deviations across four critical parameters: layer thickness; reinforcement specification compliance, singular point detailing and testing documentation.

Each deviation was classified by type, magnitude and potential consequence, enabling the construction of a causal matrix linking executive non-conformities to observed pathological manifestations.

3.3 Field inspection and non-destructive testing

Field inspection followed a pre-defined protocol covering all accessible surfaces vertical walls, horizontal slab, wall–slab interfaces, drain and pipe penetrations, movement joints and adjacent basement elements integrating three complementary methods:

(a) Systematic visual survey across 100% of accessible surfaces, with photographic documentation. Manifestations were classified by type (efflorescence, detachment, hollow sound, cracking, corrosion), location, extent and severity, following ABNT NBR 16747 (2020) and IBI (2023).
(b) Percussion-based non-destructive testing across all accessible wall and floor surfaces to identify adhesion loss regions. Hollow sound response was confirmed across more than 60% of the tested vertical wall surfaces.

(c) Inspection window opening at three locations on vertical walls and one at the wall–slab interface, enabling direct measurement of layer thicknesses, confirmation of reinforcing mesh positioning and examination of the membrane condition beneath the protection layer. Moisture presence was assessed through indirect indicators efflorescence deposits, moisture staining on basement ceiling elements and corrosion product staining at reinforcement locations given that the pool was already dewatered at the time of inspection.

3.4 Damage mapping and causal chain reconstruction

Field findings were organised into a damage mapping framework correlating each anomaly with its location, probable cause, affected element and estimated extent. Causal chain reconstruction followed root cause analysis methodology, distinguishing between: primary causes executive deviations that initiated degradation; secondary causes conditions that amplified or accelerated it; and resulting manifestations observable symptoms constituting the physical evidence of failure.

3.5 Singular point analysis

Singular points where membrane continuity is interrupted by structural elements, penetrations or geometric transitions received specific investigative attention, as they represent the primary loci of waterproofing failure in elevated swimming pool systems (ABNT NBR 9575, 2010; Picchi, 1986). Points evaluated included: wall–slab interfaces; drain and sump penetrations; pipe penetrations; movement joints (three locations); and pool border transitions. Each was assessed for compliance with design detailing, localised reinforcement condition, membrane continuity quality and evidence of preferential infiltration paths since localised failures at these junctions are sufficient to cause generalised watertightness loss, even when the membrane field area remains intact.

3.6 Anomaly classification and diagnostic synthesis

The integrated analysis produced a structured diagnostic synthesis comprising three outputs: anomaly classification by type, location, extent and criticality; root cause hierarchy; and intervention recommendations grounded in the identified causal structure. All anomalies were classified as high criticality per ABNT NBR 16747 (2020) and IBI (2023), given their direct association with structural integrity risk, active moisture infiltration and evidence of reinforcement corrosion conditions that preclude continued use without immediate intervention

Figure 1: Methodology flowchart – Author

The proposed diagnostic framework has a replicable character for wet and damp areas of any buildings, being applicable to different types of waterproofing systems including membranes and sheets, in bonded or unbonded configurations.

4. Results and Discussion

The field investigation revealed progressive adhesion failure with visual evidence of exposed primer layers driven by interfacial overload from executive deviation, compounded by omission of the structural mesh reinforcement in the mechanical protection layer, inadequate singular point treatment and absence of system validation. The identified manifestations constitute sequential stages of a single progressive degradation mechanism, as demonstrated in the following subsections.

Figure 2: Detachment and efflorescence – Author

Figure 3: Efflorescence and hollow sound – Author

4.1 Correlation between design and execution

The comparative analysis between design specifications and field execution conditions identified four critical non-conformities, each with direct causal implication for system performance. The most significant deviation involved the mechanical protection layer thickness: the executed 5 cm exceeded the specified 3 cm by 67%, generating a direct gravitational overload of 42 kg/m² on horizontal surfaces calculated from the 2 cm additional thickness at a mortar unit weight of 2,100 kg/m³ (Neville, 2011; Souza & Ripper, 2009). On vertical surfaces, this additional mass generates shear and tensile stresses at the waterproofing-to-substrate interface that, in the absence of the reinforcing mesh specified in the design, are transferred directly and unevenly to the bonding interface, amplifying the effective overload to an estimated range of 80–130 kg/m². The structural reinforcing mesh specified at every 1.5 cm within the mechanical protection layer was entirely absent in the executed system, eliminating the stress redistribution mechanism and concentrating tensile forces at discrete interface points, accelerating adhesion loss under thermal and structural cycling. The singular points including wall–slab interfaces, poorly executed movement joints and drain penetrations were executed without the localised reinforcement and specific detailing required by the design, creating preferential infiltration paths that bypass the membrane field area entirely.

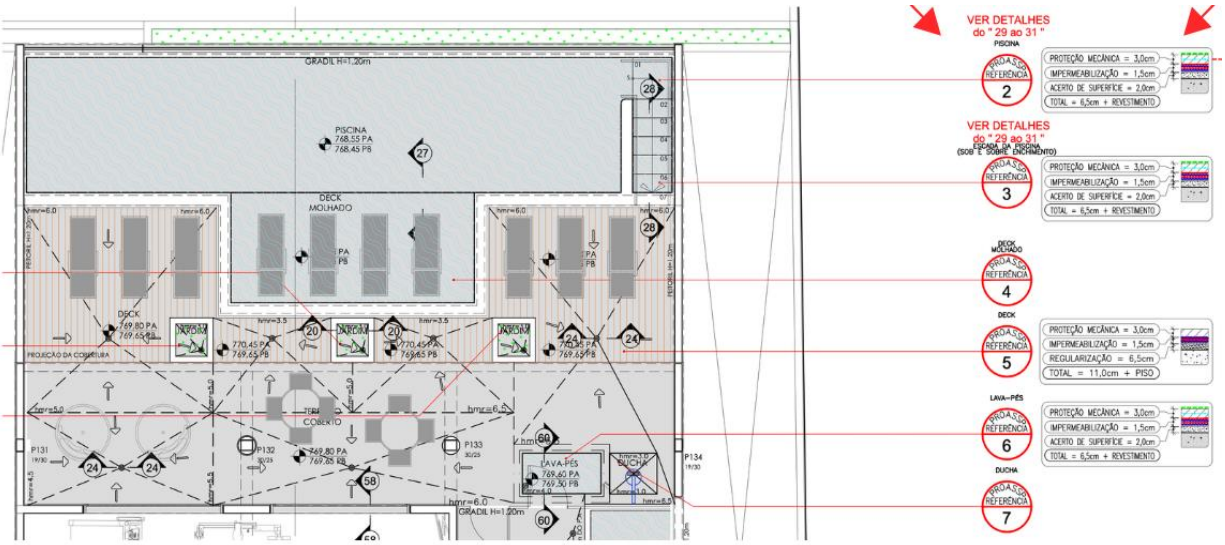

Figure 4: Analyzed waterproofing design – Swimming pool

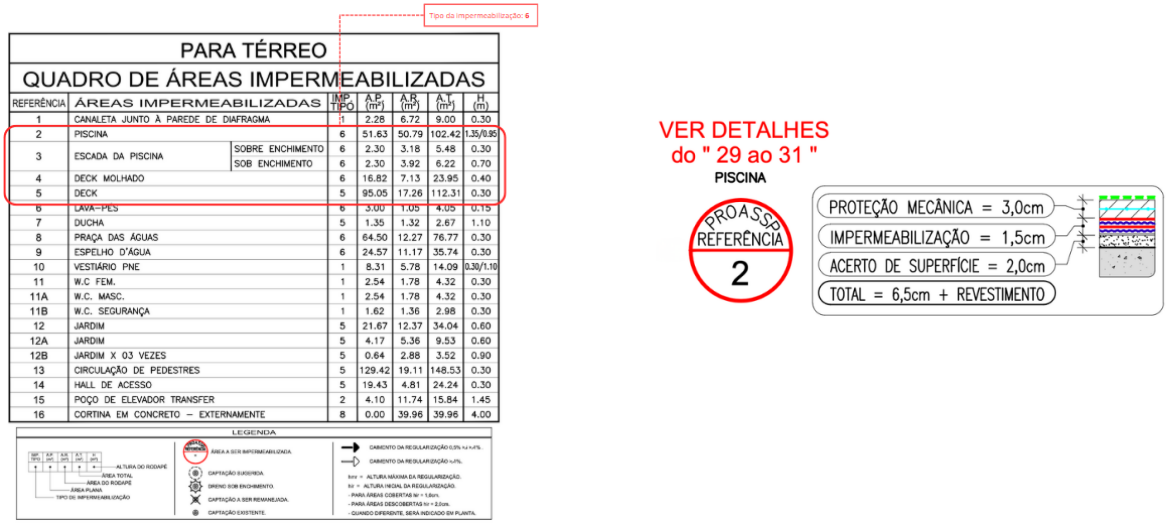

Figure 5: Area and waterproofing type chart

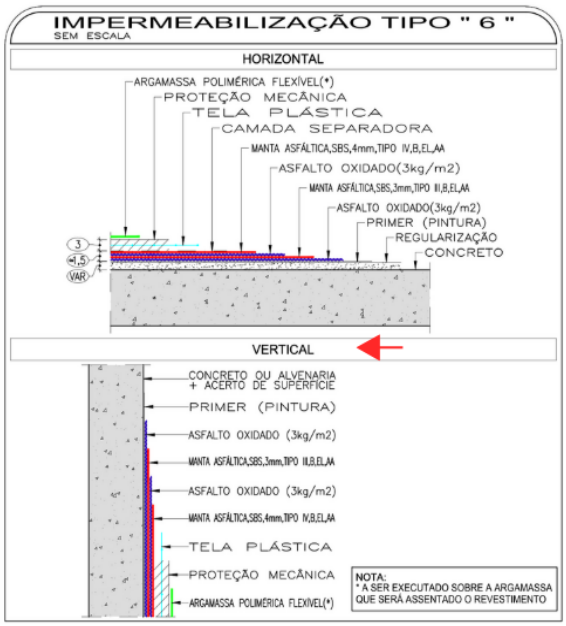

Figure 6: Thickness and layers – Author

Figure 7: Reinforcing plastic mesh – Author

Figure 8: Mechanical protection thickness – Author

Figure 9: Mesh and mechanical protection – Author

4.2 Degradation mechanism and progressive failure analysis

The degradation mechanism follows a four-stage progressive failure sequence initiated by the mechanical overload condition identified in section 4.1. This sequence is essential for distinguishing primary causes from secondary manifestations and for designing interventions that address root causes rather than symptoms.

Stage 1 — Interfacial stress initiation: the 67% thickness excess generated sustained interfacial stresses exceeding the adhesion capacity of the asphalt membrane-to-substrate bond, particularly on vertical surfaces where the additional layer mass acts as a sustained shear force. The absence of the reinforcing mesh eliminated the stress redistribution mechanism, concentrating stress at the weakest interface points. **Stage 2** — Microcracking and initial adhesion loss: sustained interfacial stress combined with thermal cycling and structural movement initiated microcracking at the membrane-to-substrate interface. This stage is typically invisible to visual inspection but produces the hollow sound response detected by percussion testing across more than 60% of the vertical wall area.

Stage 3 — Progressive detachment and membrane exposure: as microcracks coalesce, adhesion loss extends laterally; producing the macroscopic detachment visible in figures 2, 3, 8 and 9. The waterproofing membrane becomes directly exposed to mechanical stress and thermal variation, and at inadequately detailed singular points, to water penetration.

Stage 4 — Watertightness loss and structural propagation: water penetrating through singular points and exposed membrane areas migrates through the structural concrete, producing the efflorescence, moisture staining, horizontal cracking and reinforcement corrosion observed in basement elements (Figure 10). This stage represents the transition from waterproofing failure to structural durability risk, as chloride and sulphate ion transport in saturated concrete activates the reinforcement corrosion mechanism (Neville, 2011). The basement impacts were not the consequence of a single failure event but the terminal stage of a degradation process initiated by executive deviations that remained undetected due to the absence of conformity assessment and watertightness testing at the time of execution.

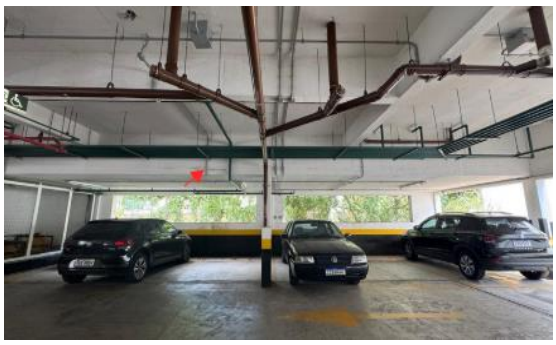

Figure 10: Horizontal crack and presence of moisture – Author

4.3 Design-to-execution synthesis

Tables 1 and 2 confirm that all identified anomalies are attributable exclusively to executive non-conformities, not to design inadequacy the specified double asphalt membrane system is technically appropriate for this typology.

Table 1: Planned vs. Executed Framework — Mechanical protection

Element	Design	Execution	Consequence
Mechanical protection	3 cm	5 cm	Overload
Reinforcement	As per design	Inadequate	Cracking and displacement
Singular points	Detailed	Poorly executed	Infiltration and displacement
Testing	Mandatory	No execution records	Watertightness failure

Table 2: Non-destructive inspection results — damage mapping and criticality classification

Localização / Element	Anomaly identified	Inspection method	Result	Criticality
Full pool perimeter wall–slab interface	Efflorescence along entire perimeter at slab level	Visual survey	Active moisture migration confirmed	High
Vertical walls — pool perimeter	Detachment and displacement of coating and mechanical protection	Visual survey + percussion	Displacement confirmed; 5 cm layer exceeds specified 3 cm; hollow sound across >60% of area	High
Mechanical protection layer — exposed section	Reinforcing mesh after 2 cm of protection	Direct measurement + visual inspection	Mesh at 2 cm; design deviation confirmed	High

Pool border strip	Mesh without galvanic coating in advanced corrosion	Visual survey + inspection window	Active corrosion identified	High
Movement joints — 3 locations	Inadequate execution of joint detailing	Visual survey	Singular points without specified detailing; preferential paths identified	High
Slab and walls — multiple locations	Efflorescence and hollow sound	Visual survey + percussion	Adhesion loss at 7 distinct locations	High

Note: Criticality classification follows ABNT NBR 16747 (2020) and IBI (2023) criteria. Percussion testing performed systematically across all accessible surfaces. Photo references correspond to field inspection records documented in the technical diagnostic report prepared for this building.

4.4 Technical Analysis and Critical Discussion

The results support a critical discussion of three technical dimensions with implications beyond the specific case. First, the interaction between mechanical protection layer overload and membrane adhesion loss. In elevated swimming pool systems, the mechanical protection layer serves a dual function: protecting the asphalt membrane from mechanical damage and distributing loads from the finishing layer. When its thickness exceeds design specification, it transitions from a protective element to a loading element, imposing stresses that the adhesion system was not designed to resist. The 67% thickness excess generated an estimated interfacial overload of 80–130 kg/m² substantially exceeding the adhesion capacity of asphalt membrane systems under sustained and cyclic loading. The progressive nature of the observed detachment is consistent with a mechanism of interfacial degradation by fatigue under cyclic thermal and structural loading. Movements of thermal origin differential expansion and contraction between system layers occur cyclically and introduce shear stresses at the interface between the impermeable layer and its substrate, which can result over time in fatigue of the bonds and, consequently, in progressive loss of adhesion (ASTM C1472, 2006; BS 5385-2, BSI, 2006). According to ASTM C1472 and DTU 44.1 (AFNOR, 2002), thermal movement is the predominant effect in dimensional variations of building components, being a determining factor for the dimensioning of movement accommodation systems. In the new study of the Brazilian normative plan, ABNT/CB-022 CE-22:0001.01 — Study Commission on Design and Execution of Waterproofing, currently under analysis for public consultation as Draft Standard ABNT NBR 9575-1 (2025), defines debonding of the impermeable layer as the loss of adhesion of the impermeable layer to the substrate in bonded systems (item 3.1.42), and establishes as a performance requirement that the impermeable layer must resist the effects caused by hygrothermal variations, such as cracking or crazing through excessive bending or rigidity (item 6.4), as well as debonding caused by total or partial adhesion loss (item 6.3.5). The same draft standard further defines degradation of the impermeable layer as the alteration of initial properties by physical and chemical aspects, caused by agents such as heat and UV rays, generating changes in flexibility, porosity and crazing (item 3.1.41). Experimental records demonstrate that concrete creep over 20 years can reach 1.5 to 3.0 times the value measured in the first two months of loading (Neville; Dilger; Brooks, 1983; ABNT NBR 6118, 2023; Sabbatini, 2005; Thomaz, 2002), evidencing the cumulative nature of this loading on non-structural systems. Second, the amplifying role of reinforcing mesh omission. The mesh serves not only as structural reinforcement but as a stress redistribution mechanism within the protection layer. Its omission transfers all tensile stresses generated by thermal contraction, structural movement and self-weight directly to the membrane interface. This concentration effect explains why adhesion loss was generalised exceeding 60% of the vertical wall area rather than localised, as would be expected if the failure had originated exclusively from singular point deficiencies. Third, the systemic nature of the failure. The convergence of three simultaneous non-conformities thickness excess, reinforcement omission and inadequate executive detailing of singular points suggests not isolated execution errors but a systemic absence of quality control, as recommended in Draft Standard ABNT/CB-022 CE-22:0001.01 — Study Commission on Design and Execution of Waterproofing. Corroborating

Madureira (2017), who proposes a systematic three-stage methodology detailed inspection, post-inspection actions and proactive planning precisely because the absence of formalised inspection procedures is the main gap identified in buildings.".

5. Rehabilitation Guidelines

The rehabilitation protocol prioritises root cause elimination. Given the generalised adhesion loss confirmed across more than 60% of the vertical surface area, palliative approaches are technically contraindicated, as they cannot restore watertightness capacity in a system with compromised membrane interface integrity (IBI, 2023). Complete removal of the existing waterproofing system is therefore required, including potentially affected adjacent areas, to allow full system exposure and identification of hidden failures, for the substrate treatment which, after removal of waterproofing layers, must be subjected to detailed inspection with identification and treatment of structural and non-structural cracks, removal of loose or deteriorated materials through high-pressure water jetting up to 250 bar, and surface regularisation with 1% slope towards the drain. Crack treatment must be performed according to its classification, which may involve resin injection or flexible sealing, in conformity with the criteria of ABNT NBR 6118 (2023). Subsequently, based on Draft Standard ABNT NBR 9575-1 — Waterproofing, Part 1 (ABNT/CB-022 CE-22:0001.01 — Study Commission. Rio de Janeiro: ABNT, 2023–2026. Draft Technical Standard under National Public Consultation), the waterproofing designer must present: preliminary report of waterproofing systems compatible with the structure; preliminary budget and technical-economic feasibility analysis; pre-executive design; detail booklet; descriptive specification; and quantitative material spreadsheet with estimated costs. Table 3 describes the deliverable documents established by Draft Standard ABNT/CB-022 CE-22:0001.01 — Study Commission on Design and Execution of Waterproofing.

Table 3: Deliverable documents of the Pre-Executive Design — Draft Standard ABNT/CB-022 CE-22:0001.01 — Study Commission on Design and Execution of Waterproofing

5.1 Quality control and acceptance plan

If Draft Standard ABNT/CB-022 CE-22:0001.01 — Study Commission on Design and Execution of Waterproofing is approved after public consultation, technical criteria for conformity assessment must be defined in advance (item 9.2.2, Draft Standard ABNT NBR 9575-1:2025): Technological Control Plan for Materials (TCPM_i): verification of classification, certification or qualification in PSQ/PBQPH of purchased products, Area Acceptance Plan for Service Release: substrate conditions (strength, moisture, temperature, flatness, absence of contaminants), Area Acceptance Plan for Waterproofed Areas with visual; dimensional and watertightness testing inspection by area; chronological photographic reports with identification of the person responsible for acceptance of each stage; construction diary with records of climatic conditions, team, materials used (brand, batch and consumption).

5.2 Technical responsibilities for conformity assessment

If Draft Standard ABNT/CB-022 CE-22:0001.01 — Study Commission on Design and Execution of Waterproofing is approved after public consultation: conformity assessment must be carried out by qualified professionals in architecture and civil engineering, qualified in waterproofing. For these technical services, an ART or RRT must be issued (item 9.3, Draft Standard ABNT NBR 9575-1:2025). Assessment must be performed by the designer or by an independent specialised company without conflict of interest, it cannot be performed by the applicator company, must be contracted by the owner/employer of the works and must be registered with an ART (CREA) or RRT (CAU).

Table 6: Mandatory delivery documents — Item 8.11, Table 22 of Draft Standard ABNT/CB-022 CE-22:0001.01 — Study Commission on Design and Execution of Waterproofing, after public consultation

Document	Mandatory content	Norm. basis
Service Delivery Certificate	· Date of inspection and area handover · Report of services executed and completed · Breakdown of areas with services · Notes on scope changes or impediments · List of products used (brand, batch and consumption) · Watertightness test report · Reference to technical responsibility ART or RRT · Acceptance signature by the employer	8.11 Table 22
Operation and Maintenance Manual	· Periodic_PLACEHOLDER with schedule · Preventive and corrective maintenance procedures · List of aggressive agents · Conduct prohibited by the user	8.11 · NBR 14037 · NBR 5674
Warranty Certificate	Warranty period by system and area · Conditions for warranty lapse · Conditions for possible interventions	8.11 ABNT · NBR 17170
ART / RRT of services	· ART (CREA) or RRT (CAU) for design, execution and conformity assessment · Must be issued for each phase contracted separately	Item 9.3

5.3 As-Built — As Constructed

If Draft Standard ABNT/CB-022 CE-22:0001.01 — Study Commission on Design and Execution of Waterproofing is approved after public consultation: this is a mandatory technical record prepared after execution, faithfully representing the waterproofing design as constructed, including all changes made on site (Draft Standard ABNT NBR 9575-1:2025, item 4.7). It must contain updated plans and details with the systems effectively executed, technical justifications and photographic records of changes, list of products used with technical data sheets, watertightness test results and chronological history of stages (Draft Standard ABNT NBR 9575-1:2025, item 4.7.2). Its preparation is the responsibility of the builder or employer and must be carried out by the designer or qualified professional who technically supervised the execution, with issuance of ART or RRT (Draft Standard ABNT NBR 9575-1:2025, item 4.7.3). The document must be delivered to the employer and filed together with the Building Operation and Maintenance Manual (Draft Standard ABNT NBR 9575-1:2025, item 4.7.4).

6. CONCLUSION

This study demonstrated that the progressive watertightness loss in the investigated elevated swimming pool originated from a systemic breakdown in execution quality control, not from material inadequacy or design failure. The forensic diagnostic investigation identified three simultaneous executive non-conformities 67% mechanical protection layer thickness excess (5 cm vs. 3 cm specified), complete absence of reinforcing plastic mesh and inadequate singular point detailing whose convergence triggered a progressive failure mechanism, culminating in generalised adhesion loss across more than 60% of the vertical wall surface area and structural impacts at basement level. The quantified causal analysis demonstrated that the 2 cm thickness excess generated an estimated interfacial overload of 80–130 kg/m² on vertical surfaces calculated from the mortar unit weight of 2,100 kg/m³ and amplified by the complete absence of the reinforcing mesh that would have redistributed tensile stresses across the bonding interface. Sustained under thermal cycling and structural movement typical of elevated swimming pool systems, this overload initiated an adhesion fatigue failure mechanism consistent with progressive detachment patterns documented in analogous bituminous membrane systems by Carretero-Ayuso & de Brito (2016). The six-stage forensic methodology technical anamnesis, design-to-execution comparison, systematic field inspection with non-destructive testing, damage mapping, singular point analysis and causal chain reconstruction produced three structured outputs: anomaly classification, root cause hierarchy and intervention protocol. This replicable diagnostic framework, applicable to any waterproofing system in wet areas, provides practitioners with a systematic methodology for distinguishing primary failure triggers from secondary manifestations and designing interventions that address root causes rather than symptoms. The Draft Standard ABNT NBR 9575-1 — Waterproofing, Part 1 (ABNT/CB-022 CE-22:0001.01 — Study Commission. Rio de Janeiro: ABNT, 2023–2026), referenced throughout this study, reinforces the importance of specialised design, conformity assessment and construction supervision as essential instruments for execution excellence and end-consumer protection. Diagnostic engineering combined with specialised waterproofing

methodology are essential tools for understanding progressive degradation mechanisms, supporting technically grounded decision-making in rehabilitation and contributing to the durability, safety and performance of buildings in critical systems such as elevated swimming pools.

Pathology of Ceramic Tile Systems in Brazil: Investigating Moisture Expansion in BIIb Tiles through a Multi-Analytical Case Study

Renato Freua SAHADE[1], Carlos Roberto Camello LIMA [2]

[1] Mackenzie Presbyterian University, São Paulo, Brazil, sahaderenato@gmail.com,
[2]Mackenzie Presbyterian University, São Paulo, Brazil carlos.lima@mackenzie.br

Abstract: The intensified occurrence of detachment failures in Brazilian indoor ceramic tile systems (CTS) is frequently associated with the moisture expansion (ME) of BIIb dry-pressed ceramic tiles. This study investigates the influence of ME on CTS durability through a comprehensive characterization of materials from a real-world failure case. The methodology involved a comparative analysis of detached ceramic tiles (CT-D) and unused reference tiles (CT-U) using integrated microstructural Scanning Electron Microscopy (SEM), chemical X-ray fluorescence (XRF), and mineralogical X-ray diffraction (XRD) with Rietveld refinement analysis. Forced expansion tests were conducted to comprehend the mechanisms driving interface failure. Results revealed a critical discrepancy between testing methods: while the standard boiling test yielded low ME values between 0.28 mm/m and 0.33 mm/m, falling below the 0.6 mm/m normative limit, the accelerated autoclave test exposed severe instability with values ranging from 0.84 mm/m to 0.99 mm/m. This represents an increase of over 200%. XRD quantification explained this behavior by revealing a microstructure dominated by a high amorphous phase (53.4%–58.3%) and residual quartz (37.7%–40.7%), with no detected mullite. Chemical analysis confirmed matrix vulnerability with low Al_2O_3/SiO_2 ratios (0.16–0.18) and total alkalis (K_2O + Na_2O ≈ 4.5%), confirming the presence of potentially expansive phases. The combination of autoclave testing with SEM imaging identified the root cause: unlike stable reference tiles which exhibited closed spherical porosity, detached tiles showed high interconnected porosity and phyllosilicates with preserved foliation, confirming incomplete sintering. It is concluded that the irreversible expansion creates shear stresses at the interface, acting as the primary mechanism for detachment. This study's primary contribution is to provide quantitative parameters for the diagnosis, prevention, and future standardization of CTS durability.

Keywords: Ceramic tile system; moisture expansion; detachment; microstructural analysis; durability.

1. Introduction

Ceramic Tile Systems (CTS) play a fundamental role in the Brazilian construction industry due to their durability, mechanical resistance, and aesthetic versatility. However, the sector has experienced significant technical and economic impacts associated with premature failures, particularly tile detachment (Silva *et al.* 2024). Since 2012, the occurrence of detachment in indoor applications has increased substantially, with forensic investigations indicating that up to 80% of BIIb dry-pressed ceramic tiles in surveyed developments exhibited failure within two years of completion (Barboza 2016; Klavdianos 2019).

BIIb ceramic tiles represent a significant portion of the Brazilian market, accounting for approximately 72% of national production due to their cost effectiveness and compatibility with large-scale housing demands (CCB 2024). These tiles are typically produced from a triaxial composition of clay, feldspar, and quartz, balancing plasticity, fluxing behavior, and dimensional stability. The manufacturing process involves three main stages: initial solid-state sintering below 1000 °C, characterized by particle rearrangement and the onset of mullite formation; partial melting between 1000 °C and 1100 °C, driven by feldspathic fluxes and resulting in progressive densification; and a final maturation stage, where optimal vitrification is achieved

without structural collapse (Conte *et al.* 2024; Cruz *et al.* 2022; Silva *et al.* 2018). The resulting microstructure is typically semi porous, composed of a glassy matrix with dispersed crystalline phases, including residual quartz and mullite, and water absorption values ranging from 6% to 10%.

This study is based on the hypothesis that moisture expansion (ME), defined as an irreversible dimensional increase caused by water adsorption into the ceramic body, is the primary mechanism driving these failures (Kayaci 2021; Sahade *et al.* 2025). This time-dependent expansion is understood to generate cumulative shear stresses at the tile adhesive interface (Nastri *et al.* 2015; Feldfogel and Rabinovitch 2021). Once these stresses exceed the adhesive bond strength, detachment occurs, often resulting in a clean separation between the ceramic tile and the adhesive mortar (Figure 1).

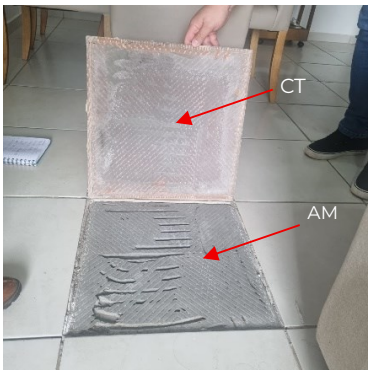

Figure 1 – Detail of the ceramic tile (CT) detached "clean" from the adhesive mortar (AM)

Accordingly, this study adopts an evidence-based approach, in which samples collected from areas exhibiting severe detachment were investigated through a multi-analytical framework. Detached tiles were compared with unused reference samples of similar classification to establish performance benchmarks and to reconstruct the failure mechanisms at the tile–adhesive interface.

Despite extensive research on ceramic tile systems, the limitations of standardized moisture expansion tests in predicting long-term performance remain insufficiently addressed. This study addresses this gap by integrating accelerated testing with microstructural, chemical, and mineralogical analyses, establishing a direct relationship between material characteristics and detachment behavior.

2. Methodology

This section describes the experimental program developed to investigate the relationship between moisture expansion and detachment in ceramic tile systems. The methodology integrates complementary analytical techniques to establish a direct link between material characteristics and failure mechanisms at the tile–adhesive interface.

2.1 Materials

The materials analyzed in this study were collected from a residential development completed in 2017, located in Jaraguá do Sul, southern Brazil. The project consists of eight residential towers, each with seven floors and a total of 448 housing units, comprising approximately 13,000 m² of ceramic tile coverings applied to indoor floors and walls. Shortly after occupancy, the building exhibited widespread and premature tile detachment affecting a significant portion of the system.

Technical data provided by the construction company indicated that the observed failures were independent of typical influencing factors, including solar orientation, floor level, unit location, adhesive mortar type, application method, substrate condition, and the presence of movement joints. Structural

assessments ruled out deformations in slabs and masonry. In addition, corrective actions such as workforce training and changes in application procedures did not mitigate the problem. Although pull-off tests performed according to NBR 13753 indicated adhesion values consistent with normative requirements in unaffected areas, the persistence and generalization of detachment suggest that the root cause is not related to execution or structural behavior, but rather to intrinsic material characteristics.

Two groups of ceramic tile samples were defined for comparative analysis:

- **Detached Ceramic Tiles (CT-D),** removed from areas affected by detachment, identified as samples D1 to D5;
- **Unused Ceramic Tiles (CT-U),** reference tiles of the same classification, sourced from different manufacturers and not installed, were used as a baseline for comparative analysis, comprising samples U1 to U5, including one sample from the same batch as the detached tiles (U2) and from four additional manufacturers (U1, U3, U4, and U5).

All adhesive mortars associated with the detached samples were classified according to NBR 14081 (ABNT 2012) as AC II and AC III (Brazilian classification), corresponding to types C1 and C2 according to EN 12004-1 (CEN 2017).

2.2 Experimental Program

A comprehensive characterization program was carried out to evaluate the physical, mechanical, chemical, mineralogical, and microstructural properties of the ceramic tiles. The objective was to establish a consistent relationship between material characteristics and detachment behavior at the tile-adhesive interface.

2.2.1 Physical and Mechanical Characterization

Water absorption and crazing resistance were determined in accordance with ISO 10545-3 (ISO 2018a) and ISO 10545-11 (ISO 2018b), respectively, for both detached and unused samples. In addition, in situ tensile adhesion tests were performed according to NBR 13753 (ABNT 1996) to evaluate the adhesion strength of the system prior to detachment. It is important to note that once hollow sound was detected by percussion, the test became no longer applicable due to the loss of adhesion.

2.2.2 Moisture Expansion (ME) Determination

Moisture expansion was determined using two procedures applied to both sample groups: the standard boiling method, in accordance with ISO 10545-10 (ISO 2021), and an accelerated procedure combining boiling followed by autoclave conditioning.

Prior to testing, all specimens were subjected to a refiring procedure to establish the reference length, as prescribed by ISO 10545-10 (ISO 2021). This procedure consists of heating the specimens to 550 ± 15 °C for 2 hours followed by controlled cooling. The initial length is then measured relative to a reference bar.

In the standard method, moisture expansion is determined after immersion in boiling water for 24 hours. In the accelerated procedure, the specimens are first subjected to the same boiling stage and subsequently exposed to autoclave conditions for 5 hours at 500 ± 20 kPa and 159 ± 1 °C.

The autoclave procedure was based on an internal method developed by the Materials Laboratory for Construction Products of IPT, established with reference to ISO 10545-3 (ISO 2018a) and ASTM C370 (ASTM 2012).

In both procedures, moisture expansion is calculated as the increase in specimen length relative to the reference length obtained after refiring.

2.2.3 Chemical and Mineralogical Analysis:

X-ray fluorescence (XRF) was used to determine the chemical composition of the ceramic tiles. X-ray diffraction (XRD) with Rietveld refinement was used to quantify the mineralogical composition, including both crystalline phases and amorphous content.

2.2.4 Microstructural Analysis:

Scanning electron microscopy (SEM) was performed on fracture surfaces to evaluate microstructural features, including porosity, morphology of the glassy phase, and the presence of residual mineral phases such as phyllosilicates. These features are directly related to moisture interaction and expansion behavior.

The tests executed, the number of samples tested and their identification are shown in Table 1.

Table 1 - Identification of the tested samples and the tests carried out

Group	Sample	Situation	Ev/ME/ CR	XRD	XRF	SEM
CT-D	1 to 5	Detached	X	X	X	X
CT-U	1 to 5	Unused	X	---	---	X

Key: Ev: Water Absorption. ME: Moisture Expansion. CR: Crazing Resistance. X: Carried out. ---: Not carried out.

The findings from this integrated experimental program are presented and discussed in the following section.

3. Results and Discussion

This section presents the integrated results of the experimental program, establishing a direct relationship between material characteristics, moisture expansion behavior, and the detachment mechanism at the tile-adhesive interface.

3.1 Tensile Adhesion Strength

Table 2 and Figure 2 show the results of in situ tensile adhesion tests performed on adhesive mortars classified as C1 and C2, according to NBR 13753 (ABNT 1996). All measured values exceeded the minimum requirement of 0.30 MPa (dashed red line), indicating adequate initial adhesion performance of the system.

Table 2 - Summary of tensile adhesion strength (pull-off) results by tower, floor level, sun exposure, and adhesive mortar classification (C1/C2), including coefficient of variation (C.V.)

Tower	Floor	Sun Path	Adesive Mortar	Adhesion Strength (MPa)	C.V. (%)
1	1	N	C1	0.50	28
1	6	S	C1	0.42	17
1	7	W	C1	0.36	14
2	1	W	C1	0.38	16
3	1	E	C2	0.54	13
4	1	S	C2	0.44	11
5	5	S	C2	0.55	20
6	6	E	C2	0.58	17

Sun Path refers to the facade orientation (N = North, S = South, E = East and W = West), adopted to represent different solar exposure conditions

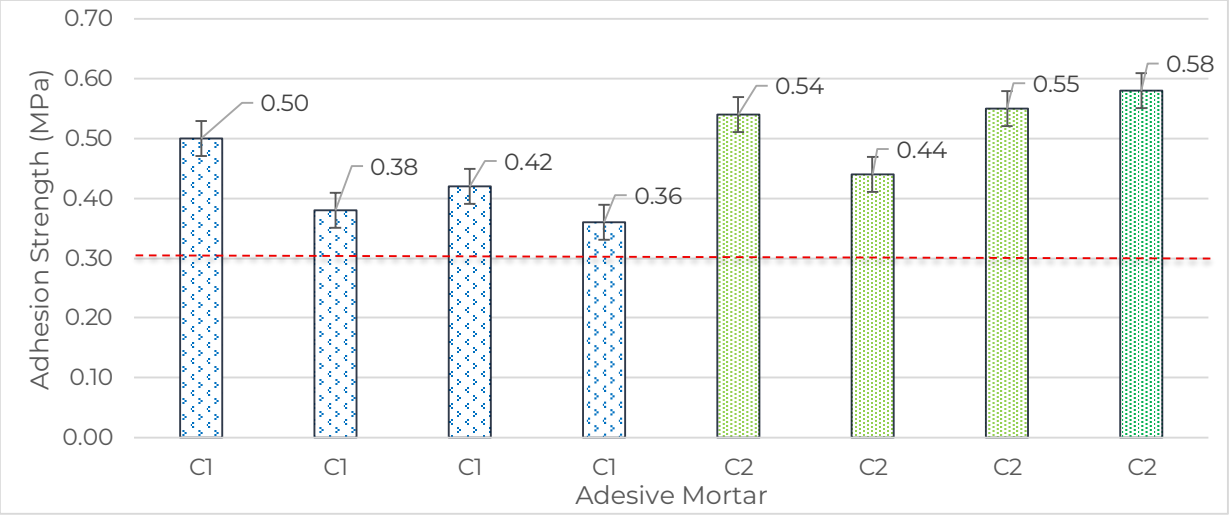

Figure 2 - Tensile adhesion strength (pull-off) results for adhesive mortars C1 and C2, including coefficients of variation

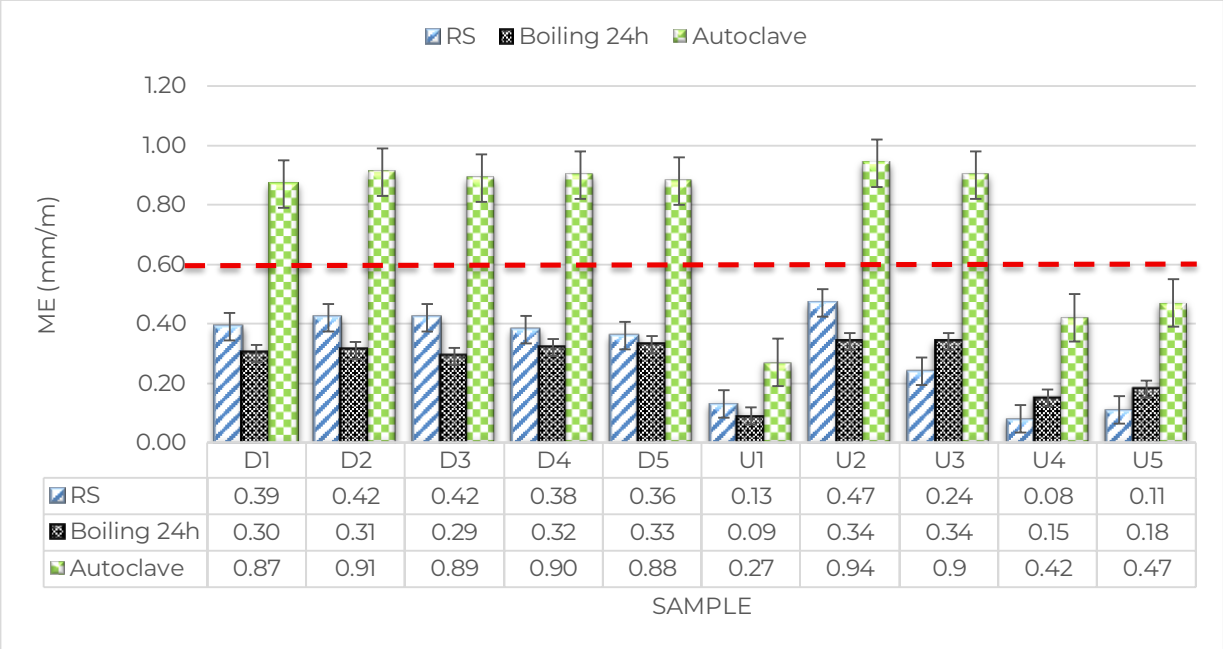
C1 mortars presented values ranging from 0.36 MPa to 0.50 MPa, while C2 mortars ranged from 0.44 MPa to 0.58 MPa. The coefficients of variation varied between 11% and 28%, reflecting typical execution variability without compromising compliance.

No significant influence of parameters such as tower, floor level, or solar orientation was observed, indicating homogeneous behavior across the evaluated conditions.

These results demonstrate that the tile system initially satisfied normative requirements. However, as the pull-off test represents a point-in-time assessment, it does not capture time-dependent degradation mechanisms. The subsequent widespread detachment therefore indicates the action of mechanisms not detectable by this test, particularly those associated with moisture expansion and stress development at the tile-adhesive interface.

3.2 Water Absorption Analysis



Water absorption values for detached samples ranged from 7.3% to 7.7%, with an average of 7.5%. Unused reference samples ranged from 6.6% to 8.2%, with an average of 7.4%.

All samples were classified as BIIb according to ISO 13006 (ISO 2018c), confirming that both detached and reference tiles belong to the same absorption group.

These results indicate that water absorption alone is not a distinguishing parameter for the observed detachment, reinforcing the need to investigate other mechanisms, particularly moisture expansion.

3.3 Moisture Expansion Analysis

Figure 3 presents the moisture expansion results obtained by refiring, standard boiling, and autoclave testing for both detached and reference samples. The dashed red line in Figure 3 refers to the limit suggested by the ISO 10545-10 (ISO 2021) standard of 0.06% or 0.6 mm/m.

	D1	D2	D3	D4	D5	U1	U2	U3	U4	U5
RS	0.39	0.42	0.42	0.38	0.36	0.13	0.47	0.24	0.08	0.11
Boiling 24h	0.30	0.31	0.29	0.32	0.33	0.09	0.34	0.34	0.15	0.18
Autoclave	0.87	0.91	0.89	0.90	0.88	0.27	0.94	0.9	0.42	0.47

Figure 3 - Graph of the moisture expansion test results for the detached (D) and unused (U) ceramic tile samples

A consistent increase in expansion was observed with increasing test severity. The lowest values were obtained by the boiling method, ranging from 0.28 mm/m to 0.33 mm/m, while autoclave results ranged from 0.87 mm/m to 0.91 mm/m for detached samples. Refiring results were intermediate, between 0.36 mm/m and 0.42 mm/m.

This behavior is consistent with the thermomechanical assumptions of each method and with previous studies (Menezes 2001; Antunes 2019). The boiling method, although standardized, presents well documented limitations in capturing the full expansion potential of partially sintered materials (Menezes 2001; Antunes 2019). In contrast, the autoclave method revealed significantly higher expansion values, exceeding boiling results by more than 200%, as also discussed by Martin (2019).

The low dispersion of autoclave results indicates a consistent and systemic behavior among detached samples, suggesting a common origin related to material formulation and firing conditions. X ray diffraction results confirmed similar phase assemblages among samples, reinforcing this interpretation.

Among the reference samples, three distinct behaviors were identified. Samples U1, U4, and U5 exhibited stable behavior, with autoclave expansion below 0.50 mm/m. In contrast, samples U2 and U3 showed high expansion, reaching values up to 0.94 mm/m, despite complying with normative limits under the boiling method.

Sample U2, representative of the detached tiles, confirms the causal relationship between high moisture expansion and in service detachment. Although compliant under standard testing, the material exhibited critical expansion when subjected to more severe conditions.

These findings reinforce that moisture expansion must be evaluated using accelerated methods to reveal latent instability, as also supported by ASTM C370 (ASTM 2012).

Furthermore, as shown in Figure 3, sample U3 presents behavior comparable to the detached tiles. This relationship is reinforced by the microstructural features illustrated in Figure 4, where both D1 and U3 exhibit preserved phyllosilicates within a porous matrix, indicative of incomplete sintering. Among the reference samples, U3 is the one that most closely resembles the detached tiles in morphological terms, as discussed in the Section 3.6.

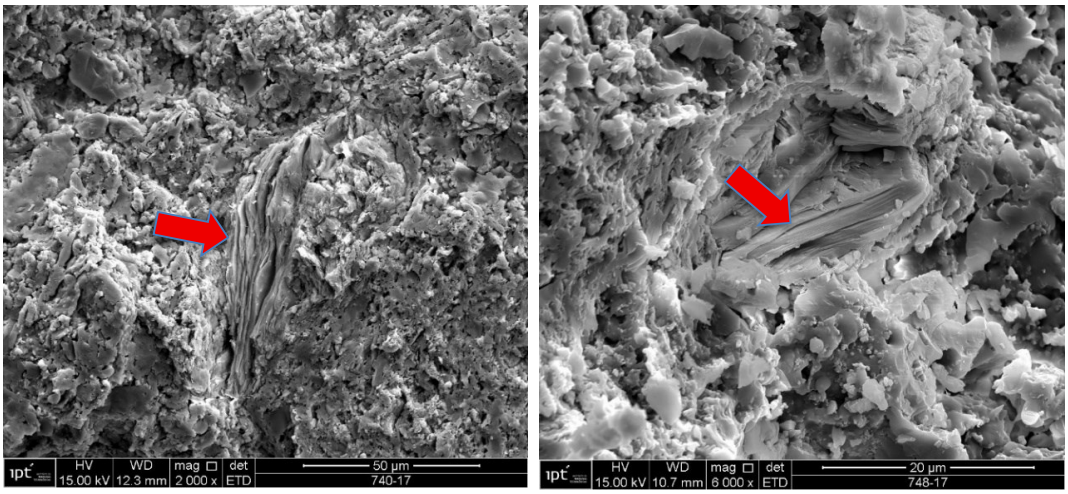


Figure 4 - Fracture surfaces of samples D1 (left) and U3 (right). SEM micrographs obtained using secondary electrons, indicating the presence of preserved phyllosilicates within a porous matrix in both samples

3.4Crazing Resistance

The crazing resistance results, summarized in Table 3, indicate that glaze cracking is not governed solely by moisture expansion (ME), but rather by a combination of factors related to the ceramic body–glaze system.

Table 3 - Summary of Crazing Occurrence vs. EPU and Sample Condition

Sample	Condition	Crazing (Before)	Crazing (Autoclave)	ME Autoclave (mm/m)	Interpretation
D1–D5	Detached	Partial/No	Yes (all)	0.87–0.91	Critical behavior
U2	Reference	No	Yes	0.94	Similar to detached
U3	Reference	No	No	0.90	High ME no crazing
U1, U4, U5	Reference	No	No	0.27–0.47	Stable behavior

All detached samples exhibited crazing after autoclave testing, consistent with their high expansion values and in agreement with observations reported by Kayaci (2021). However, sample U3 did not show crazing despite exhibiting similar expansion levels. This behavior indicates that moisture expansion acts as an aggravating factor rather than a direct cause of crazing. Other parameters, such as thermal compatibility and microstructural characteristics, play a determining role, as discussed by Dvořáková *et al.* (2021).

3.5 Chemical and Mineralogical Analysis

The XRF and XRD analyses provided a detailed understanding of the tile composition, which is fundamental to its susceptibility to ME. The chemical analysis reveals critical molar ratios when compared to the correlations established by Young and Brownell (1959), as illustrated in the graphs of Figures 5 and 6. The Al_2O_3/SiO_2 ratio ranged from 0.164 to 0.185 for samples D1 to D5, with values significantly below the trend line. In parallel, the $(Na_2O + K_2O)/Al_2O_3$ ratio for all samples lies above the historical trend line, varying from 0.328 to 0.429.

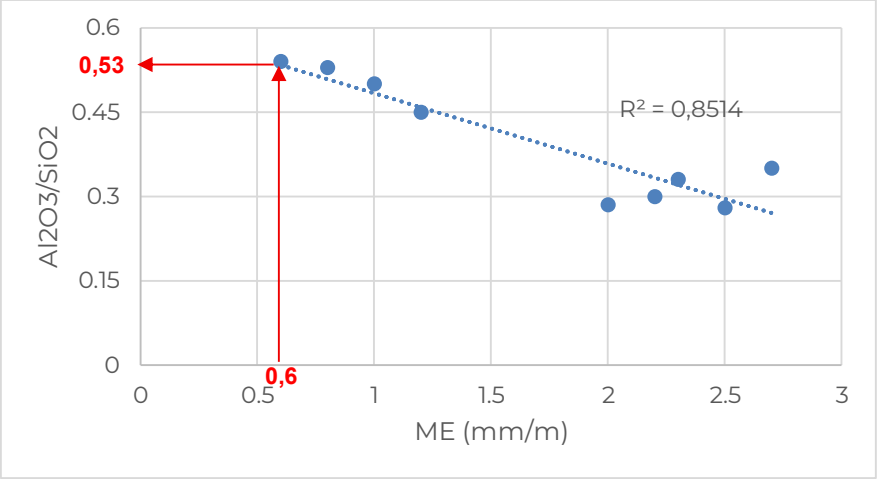

Figure 5 - Al_2O_3/SiO_2 ratio versus ME (8% water absorption). The red-highlighted region indicates the minimum ratio of 0.53 recommended for ceramic tiles with the maximum moisture expansion (ME) suggested by standards (0.6 mm/m)

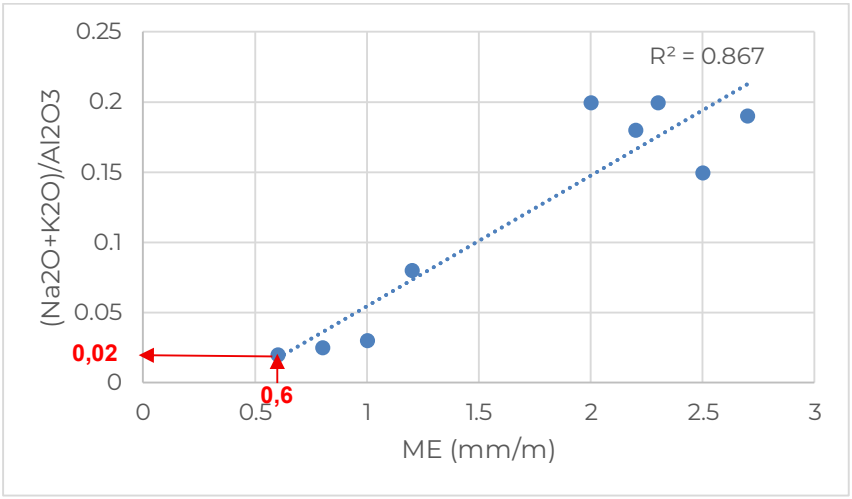

Figure 6 - $(Na_2O + K_2O)/Al_2O_3$ ratio versus ME (8% water absorption). The red-highlighted region indicates the maximum limit recommended by standards for ceramic tiles (0.6 mm/m)

The high quartz content (SiO_2) tends to modify the pore structure of the material (amorphous silica), allowing moisture to penetrate more easily and thereby increasing moisture expansion (ME), as shown in Figure 5 (Cole 1962; Mendonça *et al.* 2012).

Moisture expansion increases with the presence of an alkaline glassy phase, particularly Na and K, and an amorphous phase containing alkaline oxides (Na_2O and K_2O) in the fired ceramic body, as illustrated in Figure 6 (Kayaci 2021). Conversely, it generally decreases with increasing crystalline phases and with higher alkaline-earth content (Ca and Mg) in the structure (Dvořáková *et al.* 2021; Hosseiny *et al.* 2023).

According to Sahade *et al.* (2025), when combined with pressure and temperature determination tests (autoclave), these parameters may represent a more accessible and cost-effective alternative for predicting future expansion.

The mineralogical findings from the XRD analysis with Rietveld refinement confirmed this (Figure 7). The most significant finding was the predominance of a high amorphous phase content, consistently greater than 50% across the samples. The primary crystalline phase was residual quartz (≈37–41%), with minor phases

including hematite-proto and goethite. This highly amorphous microstructure (≈53–58%) is a key contributing factor to the tiles' dimensional instability, as the disordered glassy network provides numerous reactive sites for chemical bonding with water molecules over time (Hosseiny *et al.* 2023).

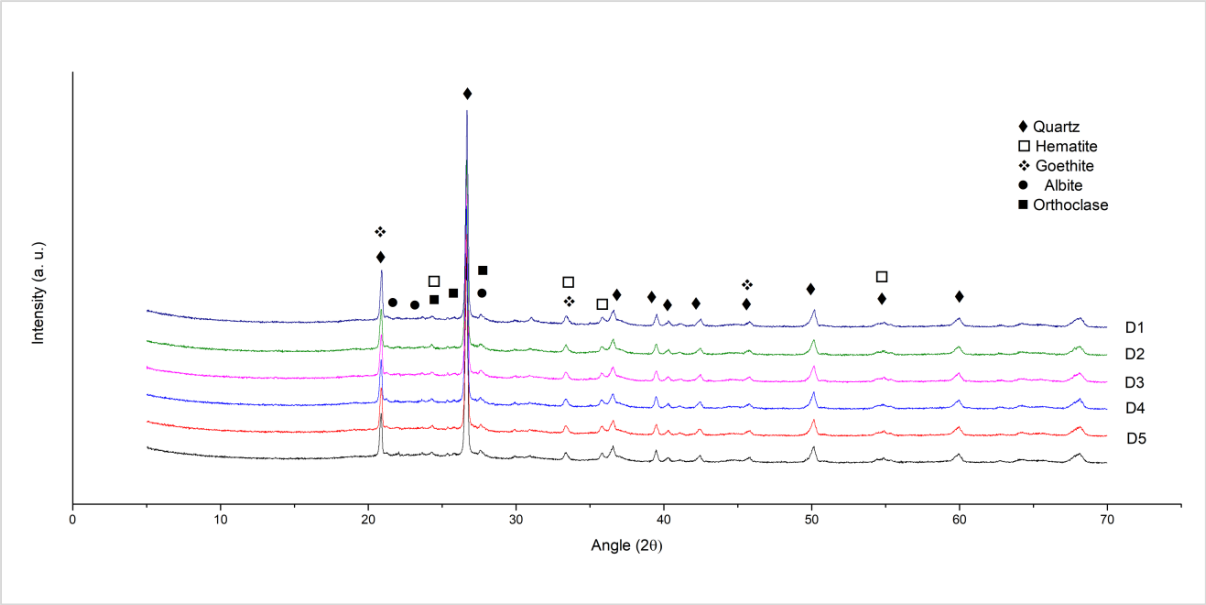

Figure 7 - X-ray diffraction (XRD) patterns of the CT-D samples. The amorphous content was quantified from the halo in the 18°–29° 2θ region

3.6 Microstructural Characteristics

Scanning electron microscopy (SEM) analysis, performed on fracture surfaces, revealed significant differences between detached and reference samples.

Detached samples exhibit a heterogeneous microstructure, characterized by a predominantly porous matrix (Figure 8a), the presence of phyllosilicates with partially preserved foliation, and isolated glassy phase clusters (Figure 8b). This arrangement indicates incomplete and non-uniform sintering, resulting in high open porosity and increased susceptibility to moisture adsorption, which contributes to higher ME values.

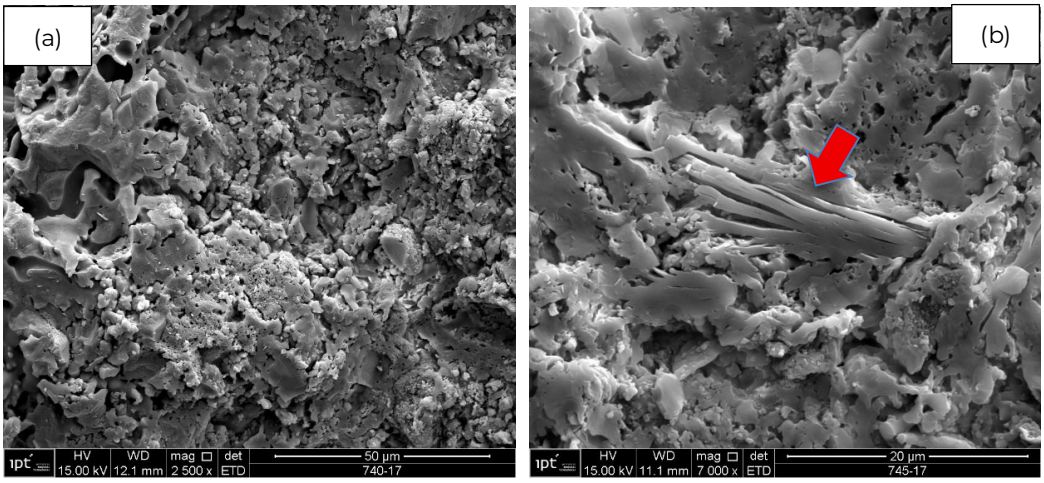

Figure 8 - (a) Porous mass arranging itself as a matrix - mag. 2,500×. (b) Fragments of phyllosilicates with preserved foliation in the middle of the porous mass and isolated glassy clusters - mag. 7000×

In contrast, the unused reference samples present a more homogeneous microstructure, with predominantly closed, sub-spherical pores (Figure 9a) and a continuous glassy matrix (Figure 9b), typical of more effective sintering. This configuration reduces permeability and limits water interaction, being consistent with greater dimensional stability.

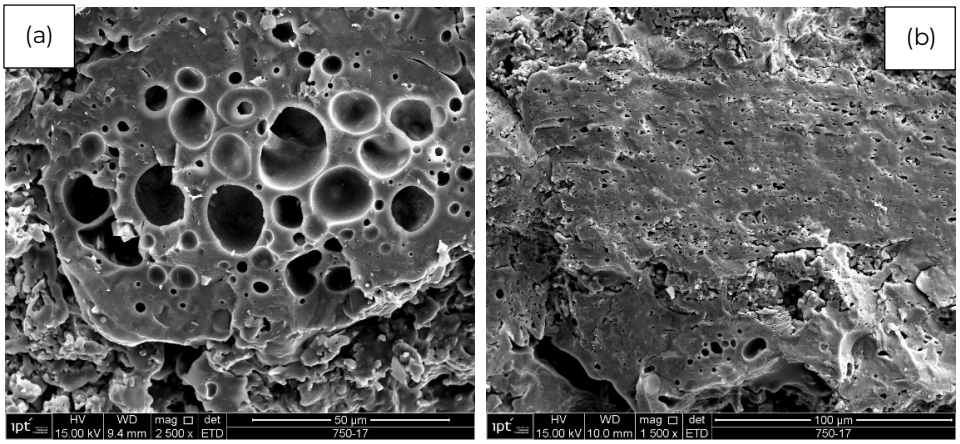

Figure 9 – (a) Closed and sub-spherical pores - mag. 2,500×. (b) Continuous glassy matrix - mag. 1,500×

4. Conclusions

This study demonstrated that the premature detachment of indoor ceramic tile systems is primarily governed by the intrinsic dimensional instability of BIIb ceramic tiles subjected to moisture expansion.

The results establish a direct relationship between material characteristics, moisture expansion, and failure at the tile-adhesive interface. Tiles with high amorphous content, unfavorable chemical ratios, residual quartz, and porous microstructures resulting from incomplete sintering exhibit increased susceptibility to moisture interaction. This leads to progressive and irreversible expansion, generating cumulative shear stresses that ultimately exceed the adhesive bond strength and cause detachment.

From a diagnostic perspective, the findings confirm that moisture expansion must be treated as a primary durability parameter. The observed failures were not associated with execution deficiencies or insufficient initial adhesion, as confirmed by pull-off results in accordance with NBR 13753 (ABNT 1996), but rather with a time-dependent degradation process driven by the ceramic material itself.

A central contribution of this study is the critical assessment of current standardized testing methods. The boiling method defined in ISO 10545-10 (ISO 2021) proved insufficient to represent the actual expansion potential of the tiles, consistently underestimating their behavior. In contrast, the autoclave-based procedure demonstrated higher sensitivity, revealing expansion levels more than twice those obtained by the standard method and identifying latent instability not detectable under conventional testing conditions.

The results further indicate that expansion levels around 0.40 mm/m, below the current normative threshold, are sufficient to induce detachment. This finding highlights the need for a critical reassessment of both limit values and testing methodologies currently adopted in international standards.

Finally, the integration of microstructural, chemical, mineralogical, and accelerated expansion analyses provides a robust framework for understanding detachment mechanisms and improving diagnostic practices. The proposed approach contributes to more reliable material specification and supports future revisions of technical standards aimed at ensuring the durability and long-term performance of ceramic tile systems.

Abstract: The rehabilitation of waterproofing systems in large-scale buildings, especially those with precast systems and hollow-core slabs, is critical due to the complex differential structural and thermal movements exhibited by these structures. This behavior is inherent to the structural concept, characterized by a large number of joints and semi-rigid connections. The slenderness of hollow-core slabs, designed for large spans and significant flexural demands, amplifies vertical displacements, differential movements between elements, and thermal expansion, requiring more rigorous expansion-joint and waterproofing designs than those typically used in reinforced concrete structures. Failure of the waterproofing system to accommodate this structural behavior leads to pathological manifestations such as infiltrations, leaks, and efflorescence, classified as critical risk, with serious implications for structural durability, maintenance costs, and the healthfulness of indoor environments. This article presents a case study of the 1,560 m² slab at the Brumadinho/MG Administrative Center, where severe pathological manifestations appeared after one year of use. The methodology, based on standards and guidelines, employed on-site diagnostic investigations with systematic visual inspections, thermography for moisture mapping, and pull-off tests. The failures were attributed to the incompatibility of the original system with structural movement, the absence of a detailed waterproofing design, and inadequate joint execution, resulting in cracks of up to 1.3 mm. The rehabilitation proposal involves flexible thermoplastic polyolefin waterproofing membranes (PO-F). This system was selected for its exceptional structural flexibility, weather resistance, and suitability for application during the rainy season, sealing cracks of up to 3.6 mm without prior treatment and optimizing the intervention. The study contributes to building pathology by demonstrating the technical feasibility and effectiveness of advanced solutions for the rehabilitation of complex waterproofing systems. It aims to improve diagnosis, decision-making, and the application of technologies that enhance the longevity and safety of large roof slabs, mitigating risks. The study concludes that the use of high-performance, flexible systems, with specific bond-breaker detailing over the joints, offers a robust and durable solution, mitigating the risks associated with material fatigue and adhesion failures.

Resumo: A reabilitação de sistemas de impermeabilização em edificações de grande porte, especialmente aquelas com sistemas pré-fabricados e lajes alveolares, é crítica devido às complexas movimentações estruturais e térmicas diferenciais que estas estruturas apresentam. Este comportamento é inerente ao conceito estrutural, caracterizado pelo grande número de juntas e ligações semirrígidas. A esbeltez das lajes alveolares, projetadas para grandes vãos e forte flexão, amplifica deslocamentos verticais, movimentações diferenciais entre elementos e dilatação térmica, exigindo projetos de juntas de dilatação e de

impermeabilização mais rigorosos que em estruturas de concreto armado. A falha do sistema de impermeabilização em atender a essa dinâmica estrutural acarreta manifestações de patologia como infiltrações, vazamentos e eflorescência, classificadas como risco crítico, com sérias implicações para a durabilidade da estrutura, custos de manutenção e a salubridade dos ambientes. Este artigo apresenta um estudo de caso da laje de 1560m² do Centro Administrativo de Brumadinho/MG, com manifestações de patologia severas após um ano de uso. A metodologia, pautada em normas e diretrizes, empregou investigações diagnósticas *in loco* com inspeções visuais sistemáticas, termografia para mapeamento de umidade e ensaios de arrancamento. As falhas foram atribuídas à incompatibilidade do sistema original com a movimentação estrutural, à ausência de projeto detalhado de impermeabilização e à execução inadequada de juntas, resultando em trincas de até 1,3 mm. A reabilitação propõe lâminas de impermeabilização flexível de poliolefinas termoplásticas (PO-F). Este sistema foi escolhido pela excepcional flexibilidade estrutural, resistência a intempéries e aplicabilidade em período chuvoso, estancando trincas de até 3,6mm sem prévio tratamento, otimizando a intervenção. O estudo contribui para a patologia das construções, demonstrando a viabilidade técnica e a eficácia de soluções avançadas na reabilitação de impermeabilizações complexas. Visa aprimorar diagnóstico, decisão e aplicação de tecnologias para longevidade e segurança de grandes lajes de cobertura, mitigando riscos. O estudo conclui que a utilização de sistemas de alto desempenho, flexíveis, com detalhamento específico de "bond-breakers" sobre as juntas, oferece uma solução robusta e durável, mitigando os riscos associados à fadiga do material e falhas de aderência.
Palavras-chave: Impermeabilização, Patologia da Construção, Estrutura Pré-fabricada, Termografia, Poliolefinas Termoplásticas.

1. Introdução

A degradação de sistemas de impermeabilização em coberturas de grande porte representa um problema recorrente na construção civil, com impactos diretos na durabilidade, no desempenho em serviço e na salubridade das edificações (ABNT, 9575; ABNT, 15575). Em estruturas pré-fabricadas, especialmente aquelas compostas por lajes alveolares de grandes vãos, esse problema é agravado pela ocorrência de movimentações estruturais diferenciais, variações térmicas significativas e elevada incidência de juntas e interfaces construtivas (PCA, 1992; PEREIRA; HELENE, 2007). Esses fatores, quando não devidamente considerados em projeto e execução, favorecem o surgimento de manifestações patológicas como infiltrações, fissuração, eflorescência e perda de aderência dos sistemas impermeabilizantes (ABNT. NBR 9574, HELENE, 1992).

Para garantir o desempenho e a integridade desses sistemas, torna-se essencial a realização de diagnósticos precoces e tecnicamente fundamentados. Nesse contexto, a engenharia diagnóstica se destaca como ferramenta fundamental, integrando inspeções visuais, análise documental e métodos complementares de investigação (ABNT. 16747). Dentre esses métodos, a termografia infravermelha apresenta papel relevante por possibilitar a identificação não destrutiva de variações térmicas associadas à presença de umidade e falhas no sistema de impermeabilização, contribuindo para uma leitura mais abrangente do comportamento da cobertura (TOMITA; CHEW, 2022 MALHOTRA; CARINO, 2004).

A termografia infravermelha baseia-se na detecção da radiação térmica emitida pelos materiais, permitindo mapear anomalias que não são visíveis a olho nu (TOMITA; CHEW, 2022) Quando associada a ensaios mecânicos, como o ensaio de arrancamento (pull-off), e à inspeção visual sistemática, essa técnica amplia significativamente a confiabilidade do diagnóstico, possibilitando a distinção entre sintomas aparentes e mecanismos de degradação subjacentes (ASTM, 2020; MALHOTRA; CARINO, 2004). No estudo em questão, essa abordagem integrada foi aplicada para investigar uma laje alveolar pré-fabricada de grande extensão, onde manifestações patológicas severas foram identificadas em curto período de uso.

Apesar dos avanços nas técnicas de inspeção e diagnóstico, ainda existem desafios importantes relacionados à interpretação dos dados obtidos e à definição de soluções compatíveis com o comportamento estrutural das edificações. Em muitos casos, intervenções inadequadas decorrem da ausência de uma análise sistêmica, que considere simultaneamente projeto, execução, materiais e condições de exposição (ABNT. 15575, HELENE, 1992). Essa lacuna evidencia a necessidade de metodologias mais robustas, capazes de correlacionar causas, mecanismos e manifestações patológicas de forma integrada.

Diante desse cenário, o presente trabalho tem como objetivo analisar as causas das falhas no sistema de impermeabilização de uma cobertura em laje alveolar pré-fabricada e propor uma metodologia de reabilitação tecnicamente compatível com sua dinâmica estrutural. A solução adotada baseia-se na aplicação de lâminas flexíveis de poliolefinas termoplásticas (PO-F), selecionadas por sua elevada capacidade de acomodação de deformações, resistência a intempéries e adequação a condições adversas de execução, conforme discutido na literatura técnica (ABNT. 9574, PERIOTTO, PINHEIRO, FERREIRA. 2014).

2. Revisão Bibliográfica

A literatura técnica sobre impermeabilização evidencia que esse sistema ocupa posição central na proteção das edificações contra a ação da água, sobretudo em elementos expostos de forma contínua à umidade e a variações de temperatura. As normas ABNT NBR 9575 e ABNT NBR 9574 estabelecem, respectivamente, diretrizes para seleção, projeto e execução dos sistemas impermeabilizantes, reforçando que o desempenho da solução depende da articulação entre material, substrato, condições de exposição e detalhamento construtivo (ABNT, 2010; ABNT, 2008). Nesse contexto, Helene (1992; 2003) destaca que a durabilidade do concreto está intrinsecamente associada ao controle da penetração de agentes agressivos e à adoção de medidas preventivas desde a concepção do sistema construtivo.

A relação entre impermeabilização e desempenho em serviço é reforçada pela ABNT NBR 15575, ao estabelecer requisitos mínimos de estanqueidade, manutenção e vida útil de projeto para as edificações habitacionais (ABNT, 2013). Mehta e Monteiro (2014) demonstram que a presença de água em elementos de concreto intensifica mecanismos de degradação, favorecendo processos como fissuração, destacamento, perda de aderência e comprometimento da integridade física do sistema. Assim, a impermeabilização deixa de ser entendida como um recurso acessório e passa a integrar o conjunto de estratégias essenciais à preservação do desempenho global da edificação.

No caso das estruturas pré-fabricadas, a literatura aponta que a eficiência do sistema depende não apenas da resistência dos elementos isolados, mas da qualidade da concepção global, da montagem e do tratamento das interfaces. O PCA (1992) assinala que sistemas pré-fabricados, embora apresentem vantagens de racionalização construtiva e agilidade executiva, exigem projeto rigoroso e detalhamento preciso para assegurar o comportamento esperado em serviço. Periotto, Pinheiro e Ferreira (2014) demonstram que o desempenho das lajes alveolares está condicionado à interação entre os elementos estruturais, capeamentos, apoios e regiões de transferência de esforços. Em complementação, Pereira e Helene (2007) observam que a incompatibilização entre componentes estruturais e sistemas complementares figura entre as principais origens de manifestações patológicas em coberturas de grande área.

A literatura de patologia das construções descreve que sistemas de impermeabilização mal concebidos ou mal executados tendem a manifestar infiltrações, manchas de umidade, eflorescências, bolhas, destacamentos e degradação localizada de revestimentos. Contudo, a interpretação desses sinais requer cautela, uma vez que o sintoma visível pode decorrer da combinação de múltiplos fatores, incluindo insuficiências de projeto, falhas de execução, envelhecimento dos materiais e incompatibilidades entre camadas. A ABNT NBR 16747 orienta a inspeção predial como procedimento técnico estruturado de levantamento, análise e diagnóstico, fundamentado em evidências observáveis e documentação

apropriada (ABNT, 2020). Nessa perspectiva, a engenharia diagnóstica consolida-se como ferramenta indispensável para a distinção entre manifestação aparente e mecanismo de degradação subjacente.

Entre os métodos complementares de investigação, a termografia infravermelha consolidou-se como recurso relevante para a identificação de descontinuidades, variações térmicas anômalas e áreas potencialmente associadas à presença de umidade ou perda de aderência. Tomita e Chew (2022) demonstram que a técnica apresenta elevado potencial para a detecção não destrutiva de delaminações em infraestruturas e edificações, particularmente em superfícies extensas e de acesso restrito. De modo complementar, o ensaio de arrancamento (pull-off) é amplamente empregado para a avaliação da resistência de aderência entre camadas e substratos, permitindo verificar a integridade de interfaces e a compatibilidade entre sistemas aplicados sobre concreto (ASTM, 2020; MALHOTRA; CARINO, 2004). A associação entre inspeção visual, termografia e ensaios mecânicos tem sido amplamente reconhecida como estratégia capaz de ampliar a confiabilidade diagnóstica e reduzir a subjetividade associada às avaliações exclusivamente perceptivas.

No âmbito das soluções de reabilitação, a literatura técnica indica que sistemas flexíveis apresentam maior compatibilidade com estruturas submetidas a deformações, deslocamentos diferenciais e variações dimensionais. Em coberturas de grande extensão, a capacidade de acomodar movimentações sem perda de estanqueidade é frequentemente apontada como um dos critérios decisivos para a seleção da tecnologia de impermeabilização. Nesse cenário, as membranas de poliolefinas termoplásticas (PO-F) surgem na literatura como alternativa de interesse técnico por reunirem flexibilidade, resistência e boa adaptação ao substrato, sobretudo em situações nas quais a solução precisa responder simultaneamente a exigências de continuidade, deformabilidade e desempenho durável em serviço.

Dessa forma, o conjunto de estudos consultados evidência que falhas em sistemas de impermeabilização de lajes pré-fabricadas de grande extensão decorrem, em grande parte, da interação entre insuficiências de projeto, incompatibilidades entre sistemas e comportamento estrutural, além de deficiências executivas em pontos singulares. A literatura também demonstra que a investigação dessas anomalias é fortalecida pela combinação entre inspeção visual e métodos complementares, em especial termografia e ensaios de aderência, como apoio à formulação de diagnósticos tecnicamente mais consistentes. Nesse contexto, soluções flexíveis como as membranas de PO-F representam uma possibilidade tecnológica promissora para coberturas extensas sujeitas a movimentações relevantes, sem que isso configure uma conclusão generalizável, mas sim uma tendência identificada na literatura especializada.

3. Metodologia

A pesquisa adotou abordagem de estudo de caso com finalidade diagnóstica e prescritiva, conforme as diretrizes aplicáveis à inspeção predial e às perícias de engenharia. O objetivo metodológico foi identificar as causas das manifestações patológicas observadas na cobertura, avaliar a extensão dos danos e fundamentar tecnicamente a solução de reabilitação mais compatível com o comportamento da estrutura.

Inicialmente, foi realizado levantamento documental com análise dos projetos disponíveis, registros fotográficos, informações de manutenção e dados do empreendimento. Essa etapa permitiu compreender o sistema construtivo, identificar limitações de informação técnica e reconhecer a ausência de projeto específico de impermeabilização, aspecto relevante para a interpretação das falhas observadas.

Na sequência, procedeu-se à inspeção visual sistemática in loco, com registro das manifestações patológicas por meio de documentação fotográfica e mapeamento das áreas afetadas. Foram observadas infiltrações, umidade localizada, eflorescências, fissuras e descontinuidades em regiões críticas, com maior incidência em juntas, encontros com elementos verticais e pontos de drenagem. A inspeção foi conduzida de modo a relacionar os sintomas visíveis às possíveis causas estruturais, executivas e funcionais.

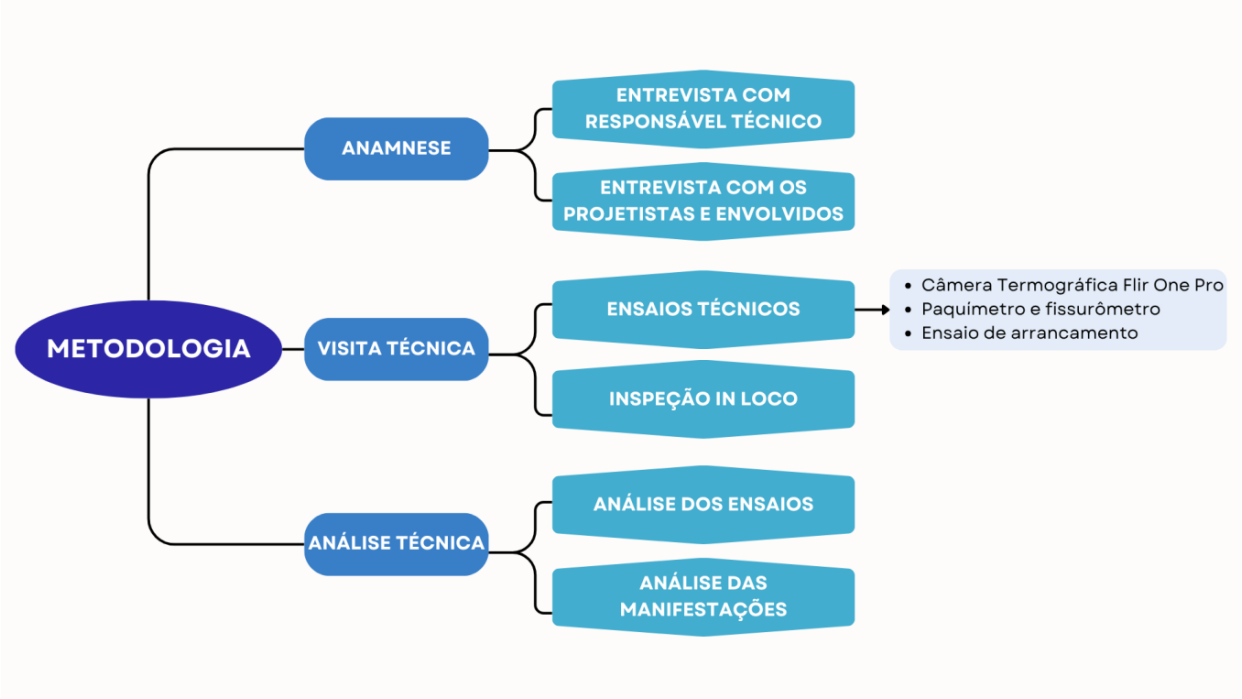

Figura 1 - Fluxograma de metodologia

Como complemento à análise visual, foram empregados ensaios não destrutivos, com destaque para a termografia infravermelha, utilizada para identificar variações térmicas compatíveis com acúmulo de umidade e possíveis falhas no sistema impermeabilizante. Também foram realizados ensaios de arrancamento em pontos estratégicos, com o objetivo de avaliar a aderência do sistema existente e sua compatibilidade com eventual reabilitação por sobreposição.

A interpretação dos resultados foi orientada por uma lógica de causalidade técnica, buscando distinguir sintomas, mecanismos de degradação e agentes agravantes. Em vez de restringir a análise à constatação das manifestações aparentes, a metodologia priorizou a compreensão do comportamento do sistema como um todo, considerando a interação entre estrutura, substrato, movimentação diferencial e desempenho da camada impermeabilizante. A partir dessa leitura, foi possível formular a proposta de intervenção mais adequada ao caso.

4. Resultados e Discussões

As inspeções realizadas na cobertura evidenciaram um quadro patológico expressivo, com infiltrações recorrentes, pontos de umidade persistente, eflorescências e fissuração em áreas variadas da laje. A manifestação dos danos em curto intervalo de uso indicou que o problema não se limitava ao desgaste natural dos materiais, mas resultava de incompatibilidade entre o sistema de impermeabilização adotado e as solicitações reais impostas pela estrutura.

A análise técnica mostrou que o comportamento da laje alveolar pré-fabricada, caracterizado por movimentações diferenciais e deformações associadas à esbeltez do elemento, exigia um sistema impermeabilizante com maior capacidade de adaptação. O desempenho insuficiente do sistema original sugere que a solução empregada apresentava limitação frente às deformações do suporte, especialmente em pontos singulares, como juntas estruturais, transições de plano, encontros com elementos verticais e regiões de drenagem.

Outro fator determinante foi a ausência de projeto detalhado de impermeabilização. Sem diretrizes específicas para regularização de base, tratamento de juntas, caimentos, reforços e pontos singulares, a

execução tende a reproduzir soluções genéricas, pouco adequadas à complexidade do sistema. Em coberturas de grande extensão, essa lacuna pode gerar falhas localizadas que evoluem rapidamente para danos generalizados.

A leitura crítica das anomalias observadas indica que a degradação não decorre apenas da presença de água, mas da combinação entre falhas de concepção, falhas de execução e insuficiente compatibilização entre material e suporte. Em termos técnicos, trata-se de um caso em que a patologia não é apenas sintoma de desgaste, mas resultado da inadequação sistêmica da solução originalmente adotada. Essa interpretação é essencial para evitar diagnósticos simplificados e intervenções meramente corretivas, sem enfrentamento das causas raiz.

A ausência de um projeto detalhado de impermeabilização, a execução inadequada da regularização da base sem o caimento de 2% e pontos de empossamento provocaram a degradação precoce da membrana acrílica, assim como a aplicação com pontos de falhas como falta de aderência e enrugamento da tela de poliéster que apodreceu devido aos intemperes, as viradas de rodapés, tubulações e ralos fora de padrões normativos.

Figura 2: Empossamento

Figura 3: Tela de poliéster sem cobrimento da membrana acrílica

Figura 4: Acabamento em tubo fora de norma

A execução inadequada das juntas estruturais agravou o problema. As juntas de dilatação e as interfaces entre os painéis pré-fabricados, que são pontos críticos de concentração de tensões, não foram tratadas com o devido rigor técnico. A falta de limitadores e de elementos flexíveis nessas regiões permitiu que as movimentações estruturais se transmitissem diretamente ao sistema de impermeabilização, o que permitu

o surgimento de trincas e fissuras na estrutura e no sistema de impermeabilização, causando sua falha prematura.

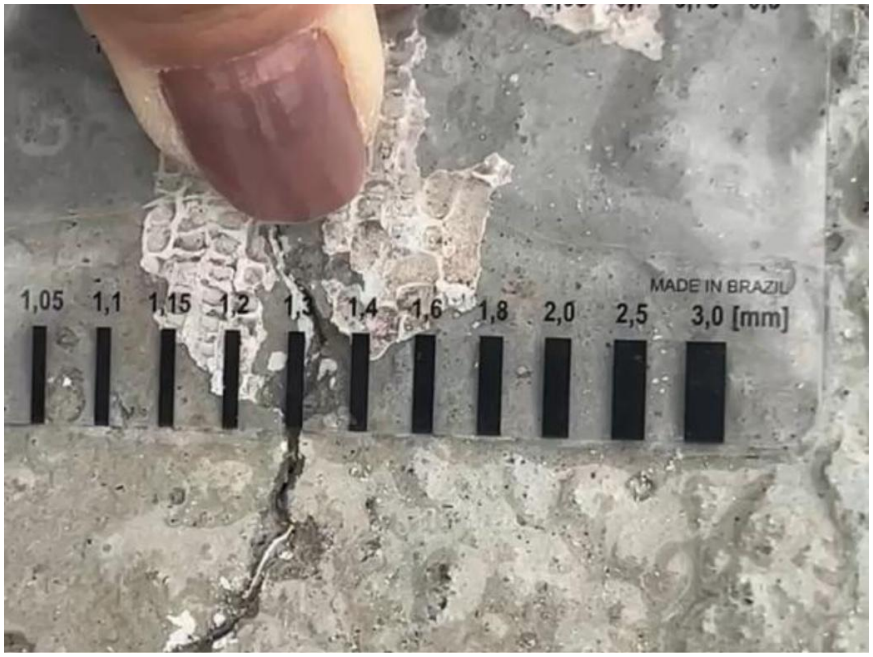

Figura 5: Fissura na laje de 1,3mm

Figura 6: fissura na laje de 1,1mm

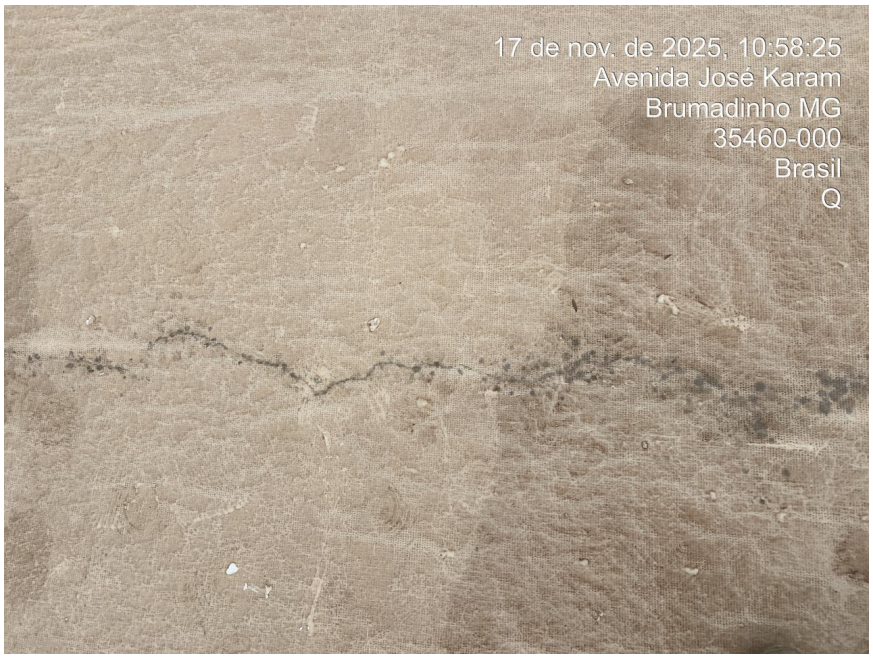

Figura 7: Fissura no sistema de impermeabilização

A termografia confirmou a presença de umidade e infiltrações em áreas extensas da laje, muitas delas não visíveis a olho nu. Os padrões térmicos anômalos indicavam a presença de água na laje alveolar, contribuindo para a degradação do sistema e do substrato. Os ensaios de arrancamento revelaram que, embora a aderência em algumas áreas fosse aceitável, a integridade geral do sistema estava comprometida pelas trincas e pela fadiga do material.

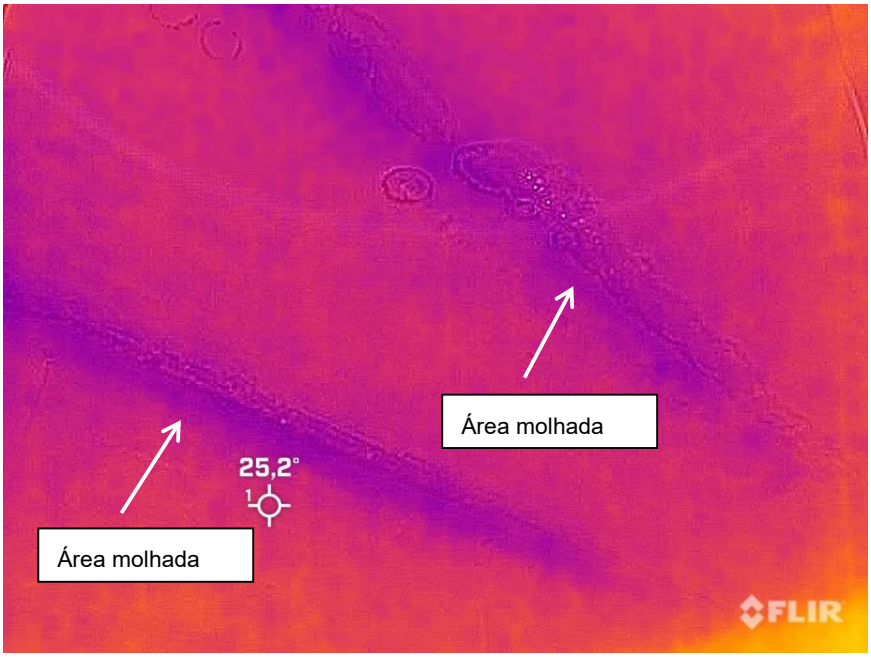

Figura 8: Umidade nos encontros da laje alveolar

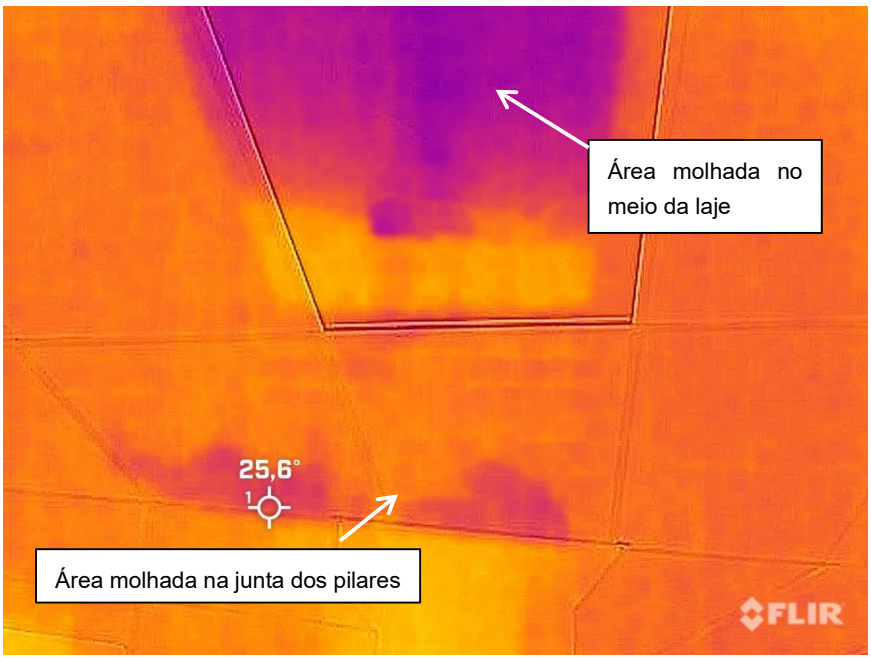

Figura 9: Áreas com umidade

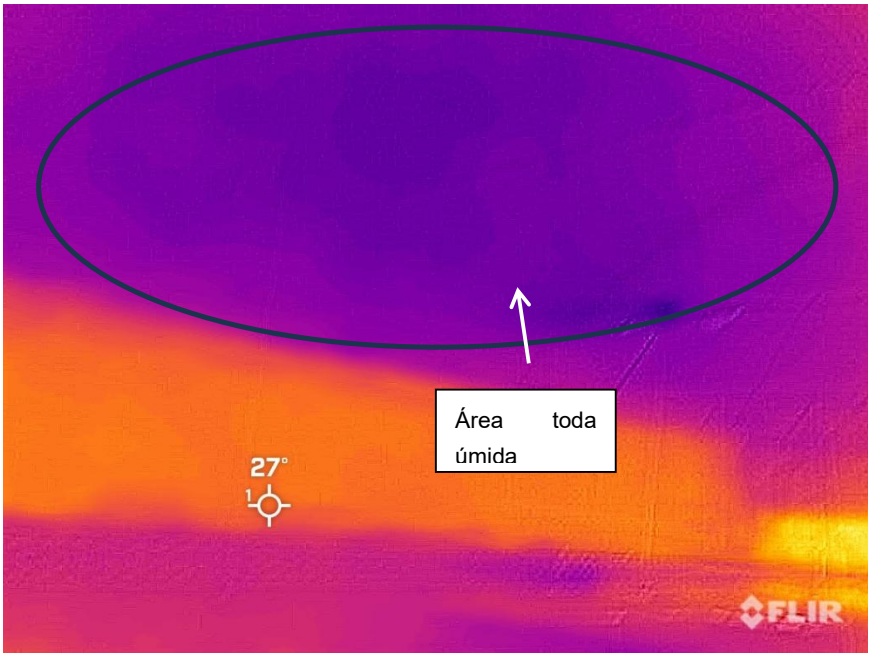

Figura 10 : Áreas com umidade

Diante desse cenário, a discussão se concentrou na busca por uma solução de reabilitação que não apenas corrigisse as manifestações patológicas existentes, mas que também fosse capaz de se adaptar à dinâmica estrutural da laje a longo prazo. A escolha de lâminas de impermeabilização flexível de poliolefinas termoplásticas (PO-F) foi fundamentada em suas propriedades intrínsecas, que se alinham perfeitamente às necessidades do caso.

Diante desse cenário, a comparação entre sistemas mostrou que soluções de natureza mais flexível apresentam vantagens claras em coberturas sujeitas a movimentação estrutural. Nesse contexto, o PO-F se diferencia por oferecer maior capacidade de acomodação deformacional e melhor resposta às fissuras e juntas quando comparado a sistemas mais rígidos ou menos tolerantes ao movimento. Essa característica justifica tecnicamente sua seleção para o caso estudado, especialmente diante da necessidade de durabilidade, estanqueidade e compatibilidade com a estrutura.

Em comparação com membranas acrílicas, o PO-F apresenta vantagem significativa em situações de maior movimentação estrutural, uma vez que sistemas acrílicos tendem a depender de substrato mais estável e apresentam limitação em pontes de fissura mais críticas. Em relação às mantas asfálticas, o PO-F oferece melhor desempenho em detalhes complexos e menor sensibilidade a determinadas condições de aplicação, embora ambas possam ser tecnicamente adequadas em cenários distintos. Já em comparação com poliuretanos, o PO-F se destaca pela combinação entre flexibilidade, estabilidade dimensional e capacidade de execução em condições adversas, desde que o detalhamento das juntas e da superfície seja corretamente executado.

Assim, a escolha do PO-F não se justifica por superioridade absoluta em todos os contextos, mas por sua maior compatibilidade com o mecanismo de falha identificado no presente caso. Esse ponto é importante porque demonstra critério técnico na seleção do sistema, e não preferência aleatória por um produto de mercado.

Tabela 1 – Comparativo de desempenho entre o sistema de impermeabilização original e o sistema PO-F proposto.

Critério de Desempenho	**Sistema de Impermeabilização Original**	**Sistema PO-F Proposto**
Flexibilidade Estrutural	Baixa (não acomoda movimentações)	Excepcional (acomoda grandes deformações)
Capacidade de Ponte de Trincas	Limitada (falha em trincas 0,5mm)	Alta (estanca trincas de até 3,6mm sem pré-tratamento)
Resistência a Intempéries	Moderada (degradação precoce)	Alta (resistência a UV, ozônio, variações térmicas)
Aplicabilidade em Condições Adversas	Restrita (exige tempo seco)	Permite aplicação em período chuvoso
Vantagem Principal	Não há vantagem	Compatibilidade com a dinâmica estrutural da laje

Fonte: Elaborado pelas autoras (2026).

5. Justificativa Econômica da Solução Adotada

Para justificar a escolha da metodologia de reabilitação, procedeu-se a uma análise comparativa de custos diretos e ciclo de vida entre o sistema proposto (Lâminas PO-F) e três alternativas de mercado: manta asfáltica dupla, membrana de poliureia e manta de PVC (Tabela 2).

A análise demonstra que, embora o custo de aquisição dos materiais do sistema PO-F seja superior ao da manta asfáltica dupla, a dispensa das etapas de proteção mecânica e a não exigência de tratamento prévio

para trincas de até 3,6 mm otimizam o escopo da obra. O custo total de intervenção da manta asfáltica dupla apresentou-se inicialmente inferior (R$ 265,80/m² contra R$ 255,00/m² da PO-F). Contudo, a avaliação puramente baseada no custo de implantação é insuficiente para obras de grande magnitude e complexidade estrutural.

Ao incorporar a Vida Útil de Projeto (VUP) na matriz de decisão, o sistema PO-F evidencia sua superioridade financeira. O Custo Anualizado da Lâmina PO-F (R$ 8.292,96/ano) representa uma redução de aproximadamente 38,70% em relação à manta asfáltica dupla (R$ 13.531,44/ano), justificada pela sua longevidade estimada de 50 anos. Conclui-se que a capacidade do material de acomodar as severas movimentações térmicas e estruturais das lajes alveolares mitiga os riscos de falhas precoces, traduzindo-se na alternativa mais econômica e segura ao longo do ciclo de vida da edificação.

Tabela 2 – Análise Comparativa de Custos e Vida Útil dos Sistemas de Impermeabilização Viáveis

Etapas / Parâmetros de Custo	**Lâmina PO-F (CPE)**	**Manta Asfáltica Dupla**	**Membrana Poliureia**	**Manta PVC**
Custo de Material (R$/m²)	R$ 110,00	R$ 17,12	R$ 120,00	R$ 130,00
Custo de materiais de aplicação	R$ 45,00	R$ 15,93	R$ 80,00	R$ 45,00
Custo de Mão de Obra (R$/m²)	R$ 80,00	R$ 40,00	R$ 300,00	R$ 168,00
Regularização / Contrapiso (R$/m²)	R$ 20,00	R$ 80,00	R$ 106,20	45
Proteção Mecânica / Acabamento(R$/m²)	R$ 10,80	R$ 60,00	R$ 40,00	Não se aplica
Tratamento de Trincas de até 3,6mm (R$/m²)	Não se aplica	R$ 3,80	R$ 3,80	Não se aplica
Custo Total de Intervenção (R$/m²)	R$ 265,80	R$ 216,85	R$ 650,00	R$ 388,00
Custo Total de Intervenção Área Total	R$ 414.648,00	R$ 338.286,00	R$ 1.014.000,00	R$ 605.280,00
Vida Útil de Projeto - VUP (anos)	50	25	25	30
Custo Ano (R$/ano)	**R$ 8.292,96**	**R$ 13.531,44**	**R$ 40.560,00**	**R$ 20.176,00**

6. Proposta de Intervenção / Prescrição Técnica

A reabilitação do sistema de impermeabilização da laje do Centro Administrativo de Brumadinho/MG foi concebida para superar as deficiências do sistema original, garantindo estanqueidade duradoura e compatibilidade com as movimentações estruturais da laje alveolar pré-fabricada. A solução proposta baseia-se na aplicação de lâminas de impermeabilização flexível de poliolefinas termoplásticas (PO-F), por ser um material que oferece características superiores para este tipo de desafio devido a sua maior capacidade de acomodar movimentações diferenciais e manter o desempenho de estanqueidade em coberturas de grande extensão.

A metodologia de intervenção compreendeu as seguintes etapas:

1. Preparação da Base: Limpeza rigorosa da superfície da laje, remoção de detritos, regularização de pequenas imperfeições e tratamento de pontos de umidade remanescentes. A aderência do novo sistema depende criticamente de uma base limpa e coesa.

Figura 11: Limpeza da laje

Figura 12: Laje limpa para assentamento da lâmina

2. Tratamento de Trincas e Fissuras: Embora o sistema PO-F tenha alta capacidade de ponte de fissuras (até 3,6mm sem pré-tratamento), as trincas existentes foram avaliadas para garantir a máxima eficácia. Em casos de trincas ativas ou de maior dimensão, foram considerados tratamentos localizados antes da aplicação da manta.

3. Aplicação de Limitadores e Reforço de Juntas: Nas regiões das juntas de dilatação e de encontro entre os painéis pré-fabricados, foram aplicados "bond-breakers" (elementos que impedem a aderência da manta diretamente sobre a junta, permitindo sua movimentação livre) e reforços específicos com a própria manta PO-F. Este detalhe é crucial para absorver as movimentações diferenciais sem comprometer a estanqueidade.

Figura 13: Tratamento de junta de dilatação

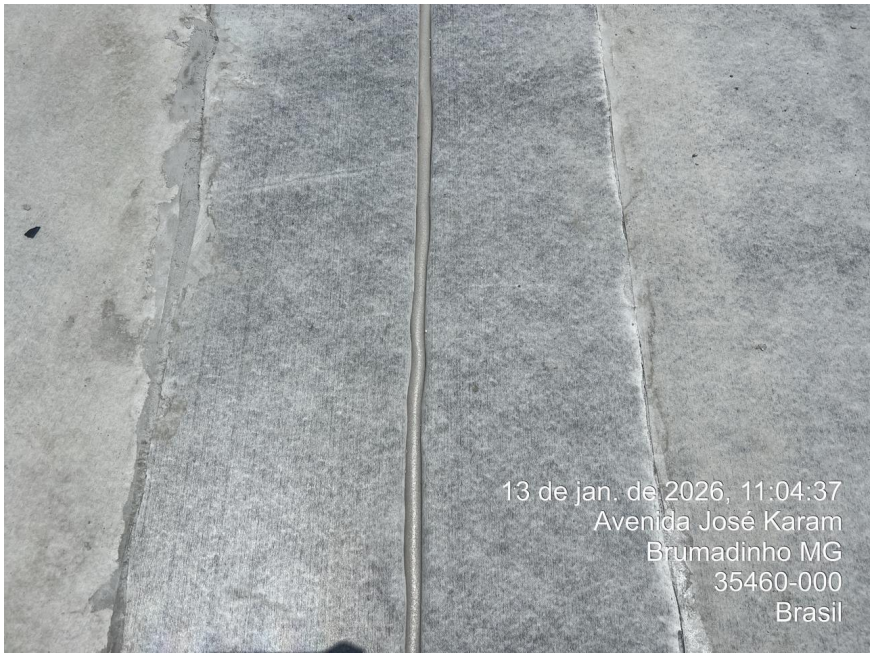

Figura 14: Execução da junta estrutural

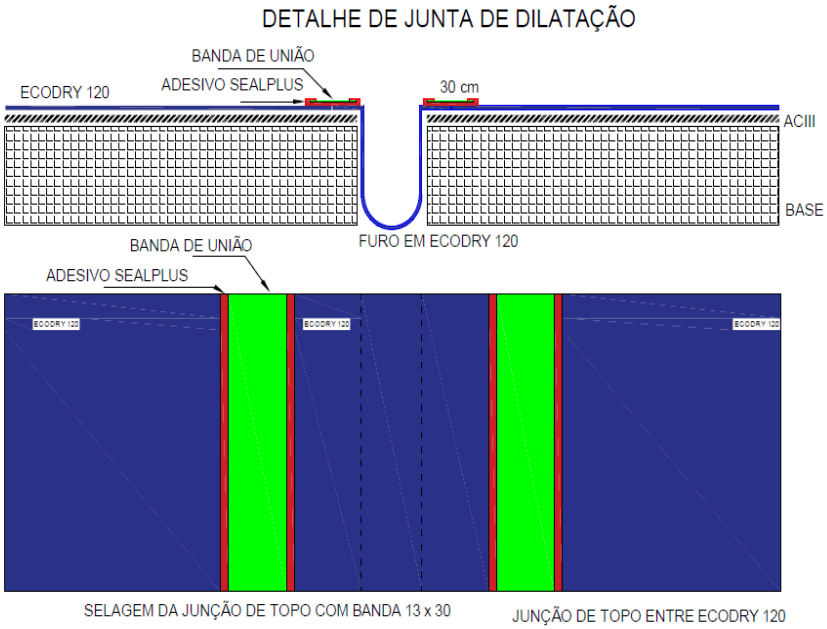

Figura 15: Detalhe da junta estrutural

4. Aplicação das Lâminas PO-F: As lâminas de poliolefinas termoplásticas foram aplicadas com ACIII de alta performance, suas emendas foram realizadas com uma banda do mesmo material de PO-F aderidas com selante fornecido pelo próprio fabricante formando uma membrana contínua e flexível sobre toda a superfície da laje. A técnica de aplicação permite a formação de soldas homogêneas e resistentes, garantindo a integridade do sistema.

Figura 16: Aplicação da lâmina

Figura 17: Lâmina aplicada

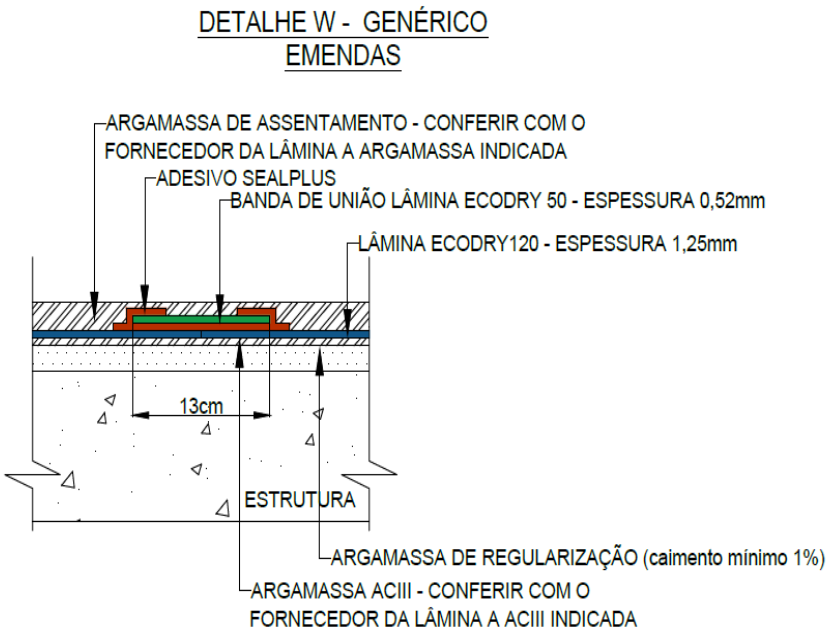

Figura 18: Detalhe da emenda da lâmina

5. Detalhes Construtivos: Cuidados especiais foram dedicados aos detalhes construtivos, como ralos, calhas, encontros com paredes e elementos emergentes. Nestes pontos, foram utilizados reforços e peças moldadas para garantir a continuidade da impermeabilização e evitar pontos de falha.

Figura 19: Acessório pré fabricado para ralo

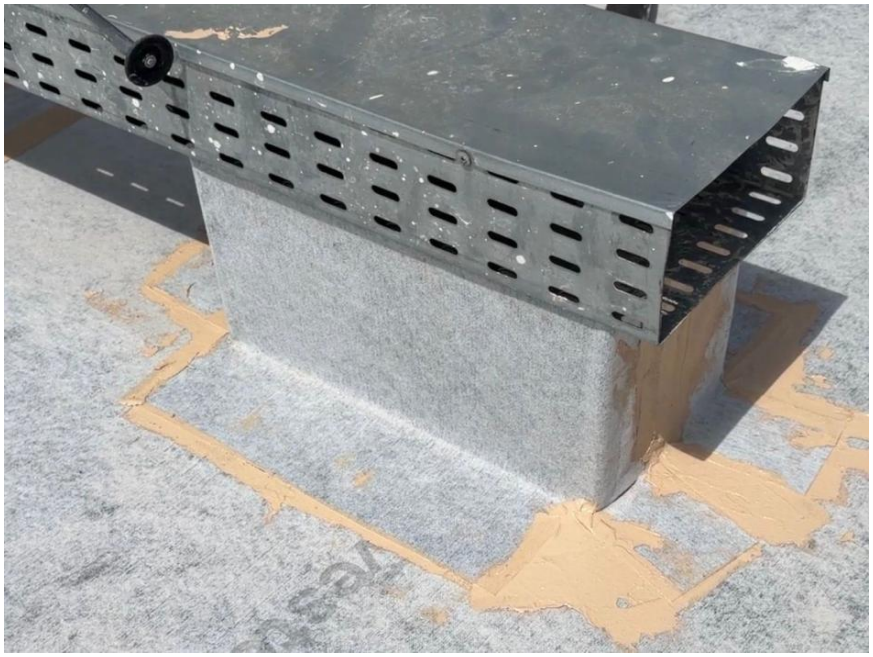

Figura 20: Acabamento dos apoios de acessórios

6. Teste de Holiday: Após a instalação da membrana, foi realizado o Holiday Test (teste de faísca elétrica). Este ensaio não destrutivo utiliza uma sonda de alta voltagem para detectar microfuros, falhas ou descontinuidades na membrana, garantindo que a superfície esteja 100% estanque antes da liberação da área. Este rigoroso controle de qualidade é fundamental para a eficácia a longo prazo do sistema reabilitado.

7. Testes de Estanqueidade: Após a conclusão das emendas realizadas após a identificação de falhas com o aparelho de Holiday Teste, foram realizados testes de estanqueidade por lâmina d'água para verificar a eficácia do novo sistema.

Figura 21: Lâmina de água para teste de estanqueidade

8. Aplicação de membrana acrílica: Antes da liberação da área, para garantir a eficácia e prolongar a vida útil das lâminas de PO-F foi aplicada uma camada de membrana acrílica, para promover uma blindagem superficial e proteger da ação dos raios UV no material impermeabilizante.

Figura 22: Menbrana acrilica aplicada para proteção UV

A escolha do sistema PO-F foi estratégica devido à sua excepcional flexibilidade estrutural, resistência a intempéries (incluindo raios UV e ozônio) e a possibilidade de aplicação em período chuvoso, o que otimizou o cronograma da intervenção em um ambiente de condições adversas. A capacidade de estancar trincas de até 3,6mm sem prévio tratamento simplificou o processo e reduziu os custos de mão de obra e materiais.

7. Conclusão

O estudo de caso evidencia que o desempenho de sistemas de impermeabilização em coberturas pré-fabricadas de grande extensão depende de maneira decisiva da compatibilidade entre a solução adotada e o comportamento estrutural da edificação. No caso analisado, a ocorrência precoce de infiltrações, umidade persistente, fissuração e eflorescência demonstrou que o sistema original não possuía capacidade suficiente para acomodar as movimentações diferenciais da laje alveolar, especialmente em regiões de junta e pontos singulares.

A investigação reforça que a falha da impermeabilização não pode ser interpretada apenas como defeito do material, mas como resultado de uma cadeia de incompatibilidades entre projeto, execução e comportamento estrutural. Esse entendimento é relevante porque desloca a discussão de uma abordagem meramente corretiva para uma visão sistêmica da patologia, na qual a solução precisa ser coerente com a causa raiz do problema.

A proposta de reabilitação com lâminas flexíveis de poliolefinas termoplásticas (PO-F) mostrou-se tecnicamente adequada ao caso por reunir flexibilidade, resistência às intempéries e capacidade de acomodação deformacional superior a sistemas menos adaptáveis. A comparação com outras soluções reforça que a seleção do sistema impermeabilizante deve considerar o mecanismo de falha, o grau de movimentação da estrutura e as condições reais de exposição, e não apenas critérios genéricos de aplicabilidade.

Do ponto de vista científico e prático, o artigo contribui para a engenharia diagnóstica ao demonstrar a importância da associação entre inspeção visual, termografia, ensaios de aderência e análise documental na formulação de um diagnóstico consistente. Contribui também para a engenharia de reabilitação ao mostrar que soluções flexíveis, quando corretamente detalhadas, podem oferecer desempenho mais robusto em coberturas de grande porte submetidas a movimentação estrutural. Assim, o trabalho reforça a necessidade de projetos de impermeabilização específicos, compatibilizados com a estrutura e orientados por critérios de desempenho, durabilidade e manutenção.

Abstract: Structural Health Monitoring (SHM) has evolved significantly over recent decades, driven by the need for more accurate, objective, and continuous methods for assessing the integrity of concrete structures. In this context, computer vision has emerged as a promising tool by enabling the automated detection and quantitative characterization of cracks from images, reducing reliance on subjective visual inspections and complex instrumented systems. This paper presents a systematic literature review aimed at analyzing how computer vision techniques have been applied to structural health monitoring, with emphasis on the detection and characterization of cracks in concrete structures. The bibliographic survey covers methods based on digital image processing, machine learning, and deep learning, discussing their capabilities, limitations, and accuracy levels reported in recent studies. The review was conducted through searches in the Scopus (Elsevier) and Web of Science (Clarivate Analytics) databases, selected for their relevance and comprehensive coverage in the fields of civil engineering and computational sciences. The search strategies involved combinations of keywords related to structural monitoring, computer vision, and concrete cracking. Inclusion and exclusion criteria were established considering thematic scope, type of structural application, publication period, and methodological clarity of the studies. The selected works were analyzed with respect to the techniques employed, computational approaches adopted, and parameters extracted for crack characterization. Comparative analysis allowed the identification of trends, recent advances, and limitations of existing approaches. The reviewed studies indicate that the integration of computer vision and SHM results in innovative, non-invasive, and potentially scalable techniques capable of supporting decision-making in structural inspection and maintenance programs. Thus, this work contributes to the systematization of the state of the art and to the consolidation of image-based structural monitoring as a viable and complementary alternative to traditional structural diagnostic techniques.

Keywords: Structural health monitoring; Computer vision; Concrete cracks; Artificial intelligence; Mobile devices; Systematic Review

1. Introduction

The durability and safety of reinforced concrete structures have become central concerns in contemporary civil engineering, particularly in light of aging infrastructure and increasing performance demands throughout the lifecycle of buildings. Although widely used, concrete exhibits heterogeneous behavior and low tensile strength, which favors the development of cracks under mechanical loading and environmental actions. These cracks not only compromise structural durability but also serve as relevant indicators of structural integrity, being widely used as parameters for structural assessment (Narayanan and Subramaniam, 2017).

The evolution of cracks is directly associated with damage mechanisms in concrete, ranging from the nucleation of microcracks to their propagation and coalescence at macroscopic levels (Shahin et al., 2024). Geometric parameters such as width, length, and orientation are fundamental for damage characterization and structural behavior analysis, enabling inferences regarding loading conditions, degradation processes,

and potential failures (Qingguo et al., 2019; Wei, Makhloof and Ren, 2022). In this context, accurate crack detection and quantification become essential steps for effective monitoring and maintenance strategies.

Traditionally, crack identification has been performed through visual inspections and conventional methods, which are highly dependent on the evaluator's experience. Despite their widespread use, these approaches present significant limitations, including subjectivity, low repeatability, and difficulty in large-scale application (Wan et al., 2023). These constraints have driven the development of more advanced approaches capable of providing quantitative and continuous diagnostics of structural conditions (Jayaraju et al., 2022).

In this scenario, Structural Health Monitoring (SHM) emerges as a promising approach for the continuous assessment of structural integrity. SHM integrates sensors, data acquisition systems, and analytical techniques to detect, locate, and quantify damage over time, supporting data-driven decision-making (Xu et al., 2024). With advancements in sensor networks and embedded systems, SHM has evolved significantly, expanding its applicability across different structural contexts (Yao et al., 2024).

More recently, the incorporation of artificial intelligence techniques has transformed the SHM field, particularly regarding automated damage detection (Reis et al., 2025). Machine learning and deep learning methods have been widely explored for processing large volumes of data, with particular emphasis on computer vision-based applications (Sofi et al., 2022). Convolutional neural networks (CNNs), such as U-Net and Mask R-CNN, have demonstrated high performance in crack detection and segmentation on concrete surface images, enabling more robust and automated analyses (Meng et al., 2023).

Semantic segmentation represents a significant advancement in this context, as it allows detailed crack identification at the pixel level, enabling the extraction of essential geometric parameters for structural assessment (Zeng et al., 2024; Wu et al., 2024). This approach contributes to transforming visual inspection into a quantitative process aligned with the demands of modern monitoring systems.

At the same time, there has been a growing use of mobile devices as platforms for structural data acquisition and processing. Smartphones, equipped with high-resolution cameras and embedded sensors, have been explored as low-cost alternatives for SHM applications, expanding access to monitoring technologies (Sarmadi et al., 2023; Kromanis, 2020). This trend reinforces the potential for scalable and accessible solutions, particularly in resource-constrained environments.

Despite these advances, the literature remains fragmented regarding the integration of artificial intelligence, computer vision, mobile devices, and SHM applications. Studies often address these elements in isolation, making it difficult to identify trends, gaps, and research opportunities. Furthermore, there is a lack of systematic analyses that consolidate the main advances, methodologies, datasets, and limitations of the proposed models (Wu et al., 2025).

Given this context, a structured and comprehensive analysis of the literature is required to synthesize the state of the art and identify future research directions. Systematic literature reviews play a fundamental role in this process by applying rigorous methods for the selection, analysis, and interpretation of scientific studies, ensuring greater reliability and reproducibility of results.

Thus, the present study aims to conduct a systematic literature review on the use of artificial intelligence and computer vision for crack detection in concrete structures, with emphasis on integration with structural health monitoring systems and the use of mobile devices. The objective is to identify the main scientific advances, technological trends, adopted methodologies, and existing gaps, contributing to the direction of future research and the development of more efficient and accessible solutions in the field of civil engineering.

2. Methodology

2.1 Search Strategy and Review Design

This study adopts a Systematic Literature Review (SLR) approach with the objective of identifying, analyzing, and synthesizing the most recent contributions related to the use of computer vision and artificial intelligence for crack detection and characterization in concrete structures. The choice of an SLR is justified by the need to ensure a structured, transparent, and reproducible process, enabling the consolidation of the state of the art within the context of SHM.

The review was conducted based on four main axes: (i) computational methods and algorithms employed, (ii) image acquisition techniques, (iii) performance evaluation metrics, and (iv) emerging technological trends. In this way, the study aims not only to map existing approaches but also to understand the evolution of techniques over time and their inherent limitations. Figure 1 schematically illustrates the intersection between the main thematic criteria adopted in the systematic review.

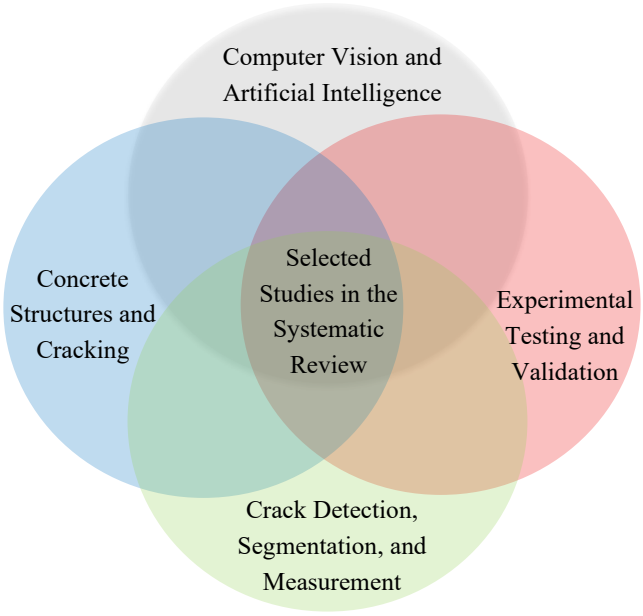

Figure 1 – Venn diagram of search strategies applied in the Scopus and Web of Science databases.

The literature search was carried out in the Scopus (Elsevier) and Web of Science (Clarivate Analytics) databases, selected due to their broad coverage and relevance in the fields of civil engineering, materials science, and applied computing. Articles indexed in Scopus were accessed in full through the ScienceDirect platform. In addition, the adopted time frame spans from 2015 to 2025, justified by the significant growth of deep learning techniques and the consolidation of architectures such as convolutional neural networks (CNNs), as well as the emergence of widely used frameworks such as TensorFlow and PyTorch. This period represents a phase of technological transformation in the field of computer vision applied to engineering.

2.2 Search Strategy and Study Selection Criteria

The search strategy was structured based on the combination of technical keywords and Boolean operators, with specific adaptations for each database according to their indexing characteristics. The objective was to retrieve studies addressing, simultaneously: (i) crack detection, segmentation, and measurement in concrete; (ii) the application of machine learning and deep learning techniques; (iii) the use of computer vision in experimental contexts; and (iv) image acquisition using digital cameras or mobile devices.

The search strings were organized into three main thematic groups: crack detection, segmentation, and measurement, also incorporating terms related to the use of mobile devices. Table 1 presents the main search strings applied across the selected databases.

Table 1 – Search strategies adopted in the systematic review, including identification codes, databases, and corresponding search strings.

Code	Database	Search String
SD-1	ScienceDirect	("concrete" AND "crack detection" AND ("crack width" OR "crack length") AND "deep learning")
SD-2	ScienceDirect	("concrete specimen" AND "crack" AND ("image segmentation" OR "computer vision") AND "laboratory")
SD-3	ScienceDirect	("smartphone" AND "crack" AND "concrete" AND ("measurement" OR "image analysis"))
SC-1	Scopus	TITLE-ABS-KEY("crack detection" AND concrete AND "deep learning")
SC-2	Scopus	TITLE-ABS-KEY("crack segmentation" AND concrete AND "machine learning")
SC-3	Scopus	TITLE-ABS-KEY("crack measurement" AND concrete AND "computer vision")
WOS-1	Web of Science	TS=("crack detection" AND concrete AND ("machine learning" OR "deep learning"))
WOS-2	Web of Science	TS=("crack segmentation" AND concrete AND ("computer vision" OR CNN))
WOS-3	Web of Science	TS=("crack measurement" AND concrete AND ("smartphone" OR "mobile imaging"))

After executing the searches, all retrieved records were exported in .ris format and imported into the Rayyan platform, a tool widely used in systematic reviews (Ouzzani et al., 2016). This step enabled the organization of the dataset and the identification of duplicate records. The study selection process followed the guidelines of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) protocol, ensuring transparency and reproducibility throughout the review process (Page et al., 2021).

As illustrated in Figure 2, a total of 1,931 records were initially identified from the selected databases. After the removal of 413 duplicate records, 1,518 unique studies remained for title and abstract screening. The potentially relevant articles were subsequently assessed through full-text reading according to the predefined eligibility criteria, resulting in a final corpus of 95 studies included in the qualitative analysis.

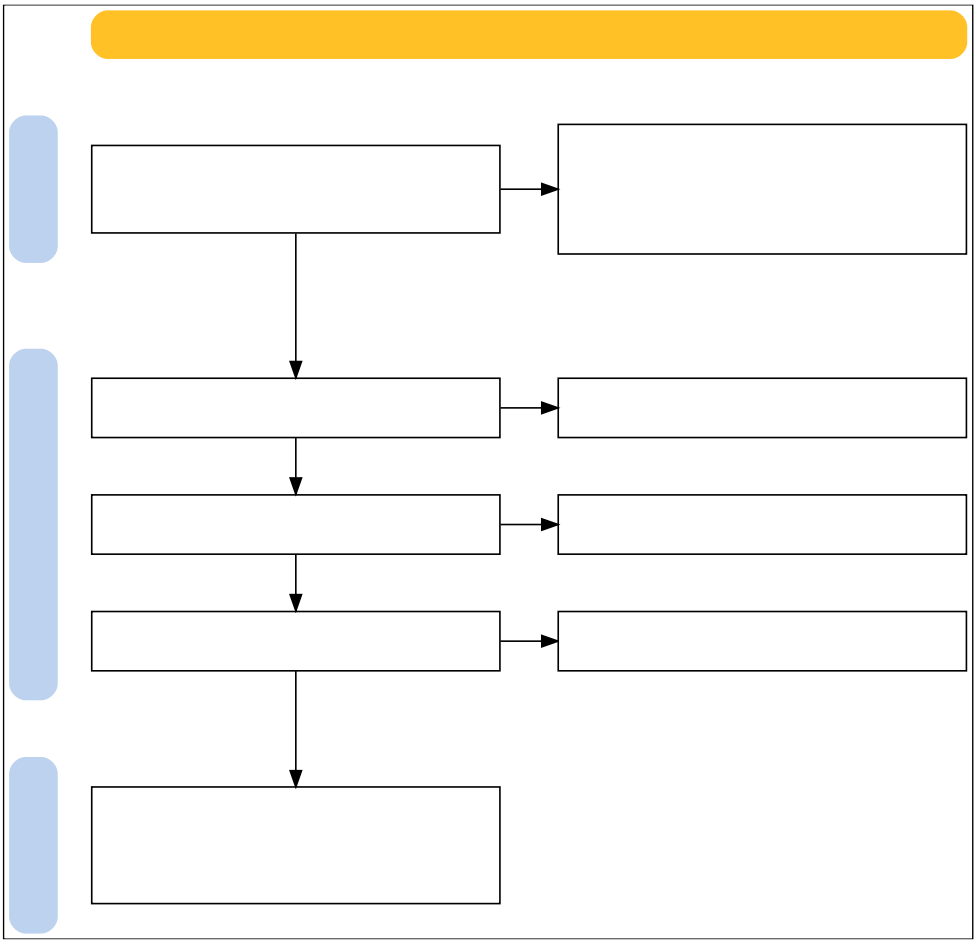

Figure 2 – Flowchart of the identification, screening, eligibility, and inclusion process of studies in the systematic review, developed according to PRISMA guidelines. Source: Authors.

To ensure consistency, transparency, and reproducibility, clear inclusion and exclusion criteria were established. Eligible studies were those addressing crack detection, segmentation, or measurement in concrete, applying computer vision, machine learning, or deep learning techniques, published in peer-reviewed journals between 2015 and 2025, and presenting clear methodological descriptions.

Conversely, studies were excluded if they were not related to structural engineering, lacked adequate methodological description, consisted only of abstracts without full-text availability, were duplicated across databases, or did not involve image-based analysis. This process ensured the selection of a robust set of studies aligned with the research objectives.

2.3 Data Extraction and Analysis

After defining the final set of studies, a systematic data extraction process was conducted to standardize the information and enable comparative analyses among the selected works. For each article, the following information was collected: (i) type of computational approach (image processing, machine learning, or deep learning); (ii) architecture or algorithm used (e.g., CNN, U-Net, YOLO); (iii) application context (laboratory or field); (iv) data acquisition method (cameras, smartphones, sensors); (v) crack-related parameters analyzed (width, length, area); and (vi) performance metrics (accuracy, precision, recall, IoU).

The extracted data were organized and comparatively analyzed, allowing the identification of: (i) prevailing technological trends; (ii) the evolution of algorithms over time; (iii) key methodological limitations; and (iv) existing research gaps.

This analysis provides the foundation for the next section of the paper, in which the results of the systematic review are presented and discussed, focusing on the evolution of techniques, performance of methods, and opportunities for advancement in computer vision-based SHM.

3. Results and Discussion

3.1 Overview of Publications and Evolution of the Field

The analysis of the selected studies reveals a well-defined technological evolution in crack detection in concrete structures, strongly driven by advances in artificial intelligence and computer vision over the past decade. In general, a transition is observed from methods based on digital image processing and classical machine learning to approaches grounded in deep learning, particularly convolutional neural networks.

As these techniques matured, the field evolved from classification and object detection strategies toward pixel-level semantic segmentation approaches, enabling higher accuracy in crack representation and allowing for precise geometric quantification. More recently, the incorporation of attention mechanisms, transformer-based architectures, and generative artificial intelligence has emerged, indicating a new technological frontier focused on automation, robustness, and advanced data interpretation. Table 2 summarizes this evolution, highlighting the main technological phases, seminal works, and their contributions to the advancement of the field.

Table 2 –Summary of the main studies and the temporal evolution of crack detection techniques in concrete.

Period	Technological Phase	Key Studies	Main Contribution
Pre-2015	Image Processing and Classical ML	Yamaguchi & Hashimoto (2010); Jahanshahi & Masri (2012)	Use of edge detection filters, thresholding, and morphological operations; low robustness
2015–2017	Deep Learning (Classification)	Ronneberger et al. (2015); Cha et al. (2017)	Introduction of CNNs and U-Net; crack classification
2017–2018	Object Detection	Cha et al. (2018); Zhang et al. (2018)	Use of Faster R-CNN; detection of multiple types of damage
2018–2020	Semantic Segmentation	Dung & Anh (2019); Liu et al. (2019)	Pixel-level classification; crack measurement
2021–2022	Attention Mechanisms and Transformers	Liu et al. (2021); Wang & Su (2022)	Improved detection of fine and complex cracks
2023–2025	Generative AI and Foundation Models	Li et al. (2025); Duan et al. (2025)	Use of GANs, SAM, and LLMs; data generation and automated reporting

Although the systematic search was restricted to publications between 2015 and 2025, seminal studies published before 2015 were included exclusively for historical contextualization of the technological evolution of crack detection methods.

Recent publications (2023–2025) indicate an advanced stage of maturity in the field, characterized by the adoption of more complex, efficient, and hybrid models. There is a notable increase in the use of architectures based on attention mechanisms, such as Vision Transformers and Swin Transformers, which aim to overcome the limitations of CNNs in capturing global context (Xiong et al., 2024). In parallel, emerging approaches based on generative artificial intelligence, diffusion models, and large language models (LLMs) point to a new frontier focused on data synthesis, mitigation of sample scarcity, and support for automated decision-making (Duan et al., 2025; Farahzadi et al., 2025).

From a quantitative perspective, the scientific production in this field has grown steadily over the last decade, with a marked increase after 2020, reflecting the rapid advancement of deep learning techniques and the increasing availability of computational resources. Although recent publications have accumulated fewer citations due to their recency, studies published between 2017 and 2020 remain highly influential and played a key role in establishing the foundations of AI-based crack detection.

The geographical distribution of publications, shown in Figure 3, reveals a strong concentration of research activity in Asia. China clearly dominates the field, accounting for 280 publications, which represents nearly half of the scientific production identified in this review. India (88 publications), the United States (60 publications), and South Korea (50 publications) also demonstrate significant contributions. This distribution highlights the leading role of these countries in the development of artificial intelligence, computer vision, and structural health monitoring technologies. Furthermore, the concentration of publications in a limited number of countries suggests the existence of well-established research hubs, while indicating opportunities for broader international collaboration and technology transfer to regions with lower scientific output.

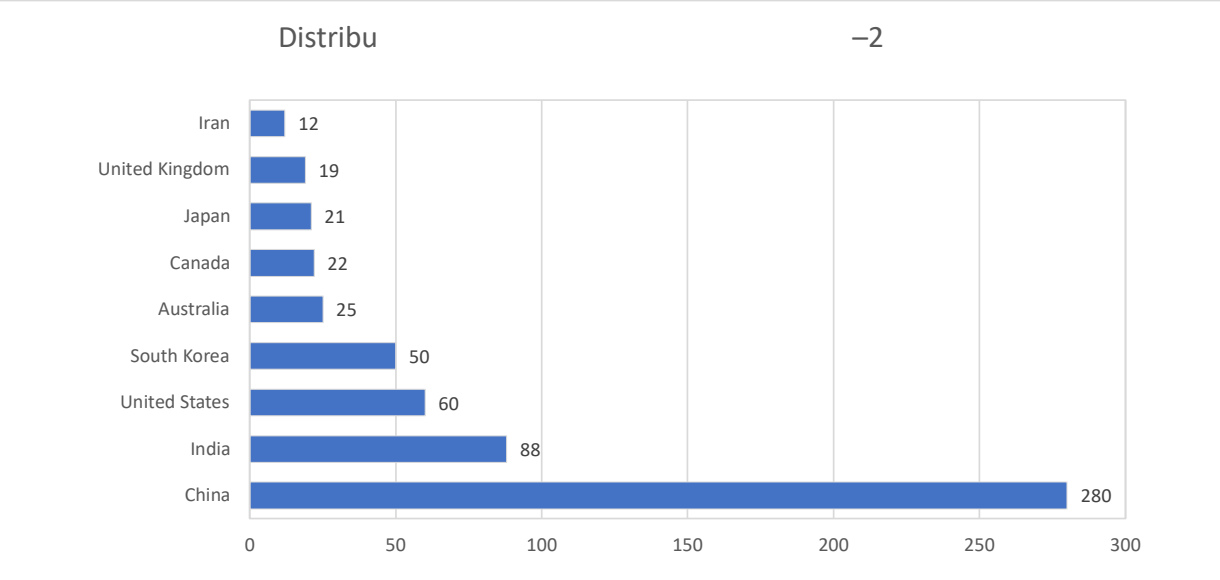

Figure 3 – Distribution of publications by country identified in the systematic review. Source: Authors' elaboration based on Scopus and Web of Science databases.

The predominance of Asian countries in the publication landscape is consistent with their substantial investments in artificial intelligence research, smart infrastructure, and digital transformation. This trend suggests that future advances in AI-based structural inspection are likely to continue being driven by research groups from these regions, particularly in the development of scalable and real-time monitoring solutions.

3.2 Methods, Approaches, and Evaluation Metrics

The analysis of the selected studies reveals a consistent evolution of computational approaches applied to crack detection and quantification in concrete structures. Initially, methods based on digital image

processing and classical machine learning predominated, in which feature extraction was manually designed through edge detection, thresholding, and texture analysis techniques. Although widely used in early applications, these approaches presented limited robustness to noise, illumination variations, and complex surface conditions.

From 2015 onwards, the consolidation of convolutional neural networks (CNNs) marked a significant methodological shift, enabling automatic feature extraction directly from image data. Early applications focused primarily on crack classification tasks and subsequently evolved toward object detection frameworks based on bounding boxes, improving the localization of structural damage. As the field matured, semantic segmentation emerged as the dominant paradigm, allowing pixel-level crack identification and the extraction of geometric parameters such as crack width, length, and affected area.

A quantitative assessment of the 65 studies included in this review highlights the predominance of deep learning-based approaches. Approximately 95% of the analyzed studies employed CNN-based architectures as their primary computational framework. Among them, U-Net and its variants—including Attention U-Net, R2U-Net, CrackUnet, and TransUNet—were identified in approximately 35% of the publications, confirming their widespread adoption for crack segmentation tasks. More recently, hybrid CNN–Transformer architectures have gained prominence, representing nearly 15% of the reviewed studies. These models combine the efficient local feature extraction capability of CNNs with the global contextual representation provided by attention mechanisms, resulting in improved performance for thin, discontinuous, and complex crack patterns.

A critical comparison of the reviewed methods indicates that Fully Convolutional Networks (FCNs) played a pioneering role in semantic segmentation but often suffered from loss of fine crack details and discontinuities. U-Net-based architectures significantly improved segmentation accuracy and robustness, becoming the most widely adopted framework in the literature. Attention-enhanced models further increased performance by selectively emphasizing crack regions and suppressing background noise. More recently, Transformer-based and hybrid architectures have demonstrated superior capability in capturing long-range spatial dependencies and global contextual information, particularly in challenging inspection scenarios. However, these gains are generally accompanied by increased computational complexity, higher training costs, and greater hardware requirements, which may limit their deployment in real-time applications and embedded systems.

Regarding model evaluation, Accuracy, Precision, Recall, F1-score, and Intersection over Union (IoU) were the most frequently reported performance metrics. Although these indicators provide a robust assessment of image-based detection performance, relatively few studies investigated metrics directly associated with structural assessment or maintenance decision-making. Furthermore, most validation procedures were conducted using laboratory datasets or controlled image collections, while a smaller number of studies evaluated model performance under real inspection conditions. This limitation highlights the persistent challenge of domain shift, where variations in lighting conditions, surface textures, environmental noise, shadows, and image acquisition procedures can significantly reduce model generalization and practical applicability in structural health monitoring programs.

From an engineering perspective, the transition from crack classification to pixel-level segmentation represents an important advancement for structural inspection practice. Detailed crack characterization enables more reliable condition assessment, supports maintenance planning, and provides valuable information for structural health monitoring systems. Nevertheless, the limited number of studies validated under real field conditions indicates that further efforts are still required to bridge the gap between laboratory performance and practical implementation in infrastructure inspection and maintenance. The table 3 presents a comparative summary of the main architectures used for crack segmentation, highlighting their characteristics, performance, and applicability.

Table 3 –Comparison of segmentation architectures applied to crack detection in concrete.

Architecture	Segmentation Accuracy	Efficiency / Speed	Key Characteristics
FCN	Moderate	High	Pioneering architecture, with loss of fine details and crack connectivity
U-Net	High	Moderate	Good edge and detail capture; robust with limited datasets
Attention U-Net	Very high	Moderate to low	Improved focus on cracks and better noise suppression
Lightweight U-Net (MobileNet)	High	Very high	High performance with low computational cost; suitable for mobile devices
CNN + Transformer	Very high	Variable	Captures both global and local context; effective for complex crack patterns

3.3 Gaps and Trends in the Application of AI for Crack Detection

The integrated analysis of the literature, combined with the bibliometric mapping performed using VOSviewer (Van Eck & Waltman, 2010), provides insights into the current maturity level of AI-based crack detection research in concrete structures. Figure 4 presents the keyword co-occurrence network, revealing four major thematic clusters that characterize the field. The green cluster is centered on semantic segmentation and crack quantification, emphasizing pixel-level analysis for the extraction of geometric parameters relevant to structural assessment. The yellow cluster is associated with UAV-based inspection and remote sensing technologies, highlighting the growing use of automated data acquisition systems for large-scale infrastructure monitoring. The red cluster connects BIM, Digital Twins, durability assessment, and non-destructive testing, reflecting the integration of crack detection results into digital asset management and predictive maintenance frameworks. Finally, the blue cluster encompasses attention mechanisms and transformer-based architectures, representing recent advances in feature extraction and segmentation performance. Together, these clusters demonstrate the evolution of crack detection from isolated computer vision tasks toward integrated Structural Health Monitoring (SHM) ecosystems.

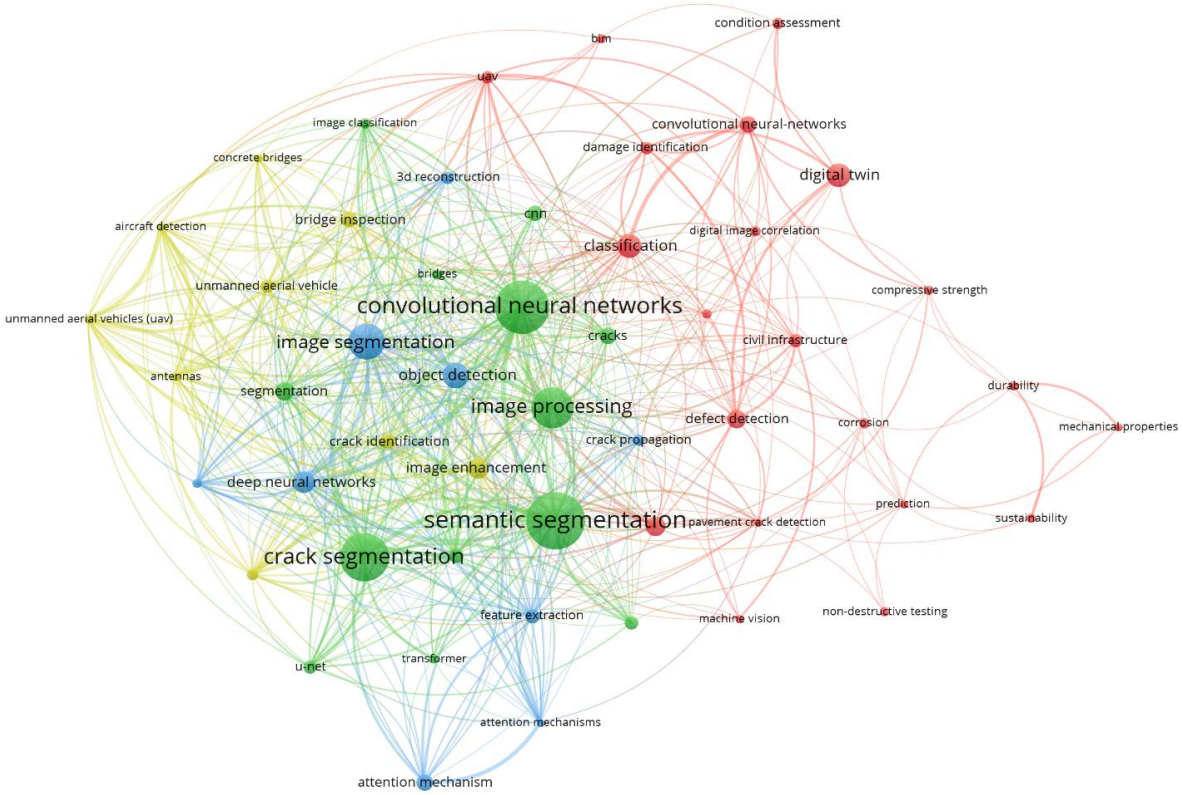

Figure 4 – Keyword co-occurrence map, illustrating the thematic organization of the analyzed literature.

Despite the significant progress achieved during the last decade, several research gaps remain. The most recurrent challenge is the scarcity of large-scale annotated datasets, as most publicly available databases are acquired under controlled laboratory conditions. Consequently, models that achieve excellent results on benchmark datasets often exhibit reduced performance in real inspection environments affected by lighting variations, shadows, surface contamination, weathering effects, and heterogeneous concrete textures.

Another important limitation concerns the restricted validation of proposed methods under practical operating conditions. Although approximately 95% of the reviewed studies employed deep learning-based approaches, only a limited number evaluated their models in real infrastructure inspection scenarios. Furthermore, the increasing computational complexity of state-of-the-art architectures, particularly Transformer-based and hybrid CNN–Transformer models, may restrict their deployment on mobile devices, drones, and edge-computing platforms commonly used in structural inspections.

To address these limitations, several emerging trends can be identified. Generative artificial intelligence, including Generative Adversarial Networks (GANs) and diffusion models, has been increasingly explored to generate synthetic crack images and mitigate data scarcity. At the same time, transformer-based architectures continue to gain prominence due to their ability to model long-range spatial dependencies and improve segmentation accuracy in complex crack patterns.

Recent studies also point toward multimodal and integrated SHM frameworks, combining image data with information obtained from sensors, laser scanners, and unmanned aerial vehicles (UAVs). Advances in edge computing, lightweight neural networks, foundation models, and large language models indicate a future in which crack detection systems become more autonomous, interpretable, and suitable for field deployment. The integration of these technologies with BIM, Digital Twins, and predictive maintenance strategies represents a promising pathway toward intelligent infrastructure management.

4. Conclusions

This study, conducted through a Systematic Literature Review, provided a comprehensive and up-to-date overview of the application of artificial intelligence to crack detection in concrete structures. The findings reveal a clear technological evolution from traditional digital image processing techniques to deep learning-based approaches, particularly convolutional neural networks applied to semantic segmentation. The bibliometric analysis further confirms this trend, highlighting the central role of deep learning and the consolidation of the field within the broader context of Structural Health Monitoring (SHM), characterized by strong interactions between computer vision, artificial intelligence, and engineering applications.

From a methodological perspective, the reviewed studies demonstrate a continuous progression toward more accurate, robust, and automated solutions, especially through the incorporation of attention mechanisms and transformer-based architectures capable of modeling complex spatial relationships. Despite these advances, important challenges remain, including the scarcity of annotated datasets, limited model generalization under real inspection conditions, and the high computational requirements associated with state-of-the-art architectures, all of which restrict their large-scale implementation in engineering practice.

The identified research trends indicate a new phase of development driven by generative AI, multimodal sensing, edge computing, and intelligent decision-support systems. The integration of these technologies with digital environments such as BIM and Digital Twins creates new opportunities for automated inspection, condition assessment, and predictive maintenance of infrastructure assets. Future research should therefore prioritize field validation, computational optimization, and model interpretability, contributing to the transition from laboratory-oriented research toward robust and scalable solutions suitable for real-world structural inspection and maintenance programs.

Abstract: In small-scale residential construction, inadequate soil preparation is still frequent, despite the fact that it constitutes the main support element of the building and one of the most recurrent causes of pathological manifestations, such as differential settlement. In this context, this study focuses on the diagnostic analysis of active differential settlement and the discussion of the applicability of foundation reinforcement through Mega Piles in existing buildings. This article presents a case study of a single-family residence located in Goiânia, GO, built ten years ago, which exhibited recurrent cracks and fissures associated with active differential settlement. The diagnosis was based on a technical inspection and the application of Berberian's Perpendicular Bisector Theorem to the observed fissures, enabling the identification of three critical settlement points related to soil heterogeneity and the loss of its load-bearing capacity. The crack openings ranged from 0.30 mm to 1.8 mm, with a predominance of diagonal patterns, characteristic of differential ground movements. The study highlights the ineffectiveness of previous superficial corrective interventions, such as metallic stitching, as they did not address the primary cause of the problem. As a solution, foundation reinforcement using Mega Piles was proposed as the recommended intervention, consisting of pressed reaction piles whose application is suitable for existing buildings and sites with restricted access. This technique uses the structure itself as a reaction element, allowing immediate wedging and controlled load transfer. The work presents the diagnostic methodology, the recommended intervention methodology, and concludes that geotechnical stabilization is an indispensable condition for subsequent structural rehabilitation.

Keywords: Differential settlement, Berberian Method, Mega Piles, Fissure.

1. Introduction

The construction industry plays a fundamental role in the socioeconomic development of any country. It is responsible not only for job creation and economic growth, but also for producing the built environment in which people live [1]. Within this sector, single-family residential buildings represent one of the most significant building typologies in terms of construction volume, reflecting a continuous and widespread demand worldwide [2]. For these buildings to perform their function safely and durably, it is essential that their structural elements, including columns, beams, slabs, and walls, be properly designed and executed in order to ensure the integrity of the system over time [3]. However, none of these elements can perform adequately without a solid base to support them. In this context, the foundation stands out as the most critical element of a building, since it is responsible for safely transferring structural loads to the ground and directly conditioning the performance and stability of the entire construction throughout its service life [4].

The selection of an appropriate foundation system depends on geotechnical and structural investigations, taking into account factors such as soil type, groundwater level, and climatic conditions, while also

complying with local building regulations to ensure structural safety and stability [5]. Although these criteria are well established in technical literature and standards, negligence during the preliminary stages, particularly in geotechnical investigation and in the proper preparation of the foundation soil, remains a recurring problem. From this perspective, soil, although it is the primary supporting element of any structure, is often treated inadequately in construction practice due to the involvement of professionals who are not specialized in foundations, the presence of unusual unidentified materials, and the lack of accurate information on local conditions [4]. This compromises the load-bearing capacity of the foundation and creates conditions for the development of structural pathologies.

Among the most critical anomalies observed in the superstructures of residential buildings, differential settlement stands out because of its diagnostic complexity and its potential to cause progressive damage. Since most buildings undergo settlements of only a few tens of millimeters, which are generally imperceptible to the naked eye, estimating these deformations should be part of routine foundation design practice, so that the predicted values remain below admissible limits [6]. According to ABNT NBR 6122:2022, Sections 6.1 and 6.2, foundation design must account for soil deformations, since heterogeneity in the underlying layers and construction failures may lead to non-uniform settlements [7]. These movements may become visually apparent through fissures and cracks, which, when properly interpreted using appropriate diagnostic methods, provide evidence capable of revealing both the location and the nature of the ongoing settlement, as observed in the case study presented herein.

In 1970, the Brazilian professor Dickran Berberian proposed a technique known as the Perpendicular Bisector Rule to determine the causative factor of a crack. According to this method, when the perpendicular bisectors of the cracks observed in the walls of a building are traced, the point at which these lines converge indicates the region of greatest foundation subsidence. This makes the method a diagnostic tool of considerable practical value for identifying points of differential settlement in residential buildings [8] [9]. In the present study, this procedure was applied as an auxiliary tool in the diagnostic investigation of a single-family dwelling in Goiânia, state of Goiás, Brazil, making it possible to map the zones of subsoil instability on the basis of the recorded pathological manifestations and to support the definition of the structural intervention adopted.

Given that differential settlement was identified as the cause of the fissures and cracks in the building located in Goiânia, foundation underpinning using mega piles, also known as reaction piles or jacked piles, emerges as a high-performance technological solution for existing buildings, as it is a non-destructive and low-impact technique. Among its main advantages is the immediate transfer of load by using the structure's own weight as the reaction force. This makes it possible to stabilize the settlement without requiring extensive demolition and without interrupting the use of the building, which is especially relevant in situations involving restricted access [10].

Therefore, considering that the safety of the built environment depends directly on the integrity of the foundations that support it, the relevance of investigating and disseminating effective methodologies for structural diagnosis and rehabilitation becomes evident. In view of the limited consolidated technical and scientific literature on both the Perpendicular Bisector Rule and mega piles, this article presents a diagnostic analysis of a real case of active differential settlement in a single-family residence and discusses the technical effectiveness of mega piles as a solution for definitive structural stabilization.

2. Methodology

This study was characterized as an applied case study, with a qualitative approach and descriptive objectives, focused on diagnostic investigation and on proposing a solution for structural pathological manifestations.

The object of study was a single-family residence with a floor area of 226.77 m², approximately ten years old, located in Condomínio do Lago, in Goiânia, GO, Brazil (Figures 1 and 2).

Figure 1 - Front View (on site).

Figure 2 - Location (Google Maps, 2025).

As described in the technical report supporting this case study, the investigation was divided into three main stages: document review and anamnesis, on-site technical inspection, and definition of the geotechnical rehabilitation methodology. In the initial stage, a technical anamnesis was conducted through interviews with the owner in order to reconstruct the history of the building and previous interventions. It was found that the structure had already undergone superficial repairs, such as the "Z-shaped metal stitching" technique, which had not been successful in remediating the cracks. At the same time, the available architectural drawings were analyzed, and the absence of structural, foundation, and soil investigation documents was confirmed, reinforcing the need for a diagnosis based on the observed damage patterns. For anomaly mapping, the supporting tools included a millimeter-graduated steel measuring tape for measuring crack openings and a Bosch GMS 120 wall scanner, used to identify the presence of embedded metallic elements and piping in the affected areas. The field procedure consisted of a detailed inspection of all areas of the residence, with photographic documentation and classification of the cracks according to their morphology, including direction, width, and extent, as well as their location, ranging from the perimeter wall to interior spaces such as the suite and living room.

During the inspection, atypical structural behavior was identified with respect to the building's position on the site. As illustrated in the cross section (Figure 3), part of the structure was founded directly on natural ground at the higher elevation, whereas other areas, including the living room, bedrooms, and part of the

sanitary installations, were built over partially filled zones in order to level the internal platforms. According to Milititsky et al. (2015), the lack of quality control in fill placement creates zones of heterogeneity that are classic sources of differential settlement, since such materials may be poorly compacted and may settle unevenly relative to the adjacent natural ground. Thus, although conventional engineering judgment would normally indicate the fill area as the zone of greatest risk, the inspection revealed that the most severe damage manifestations, characterized by diagonal cracks and clear signs of differential settlement, were predominantly concentrated in the upper part of the site, affecting the main suite, the kitchen, the area near the swimming pool, and the side wall adjoining these spaces.

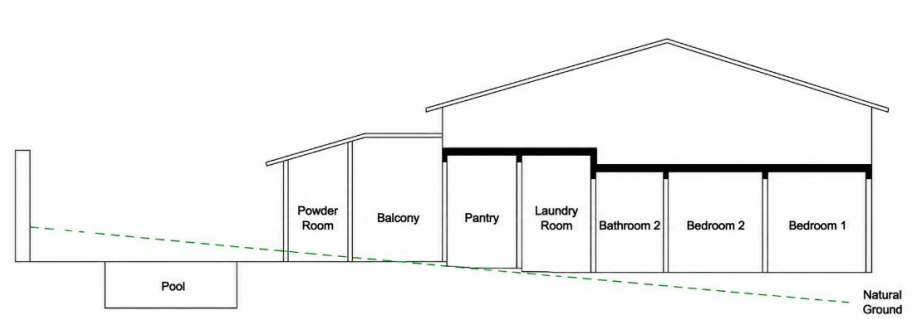

Figure 3 - Cross Section of the Building.

This spatial distribution of the cracks suggests that the instability mechanism is not limited to the densification of the fill material, but rather involves differential movements within the natural ground itself. Visual analysis indicates that the foundation at the higher elevation may not have a bearing capacity compatible with moisture variations and the local stresses imposed by the wall, resulting in loss of support that is expressed as vertical displacements, that is, differential settlement, and in the development of the observed pathological manifestations from the side wall to the interior of the residence.

The mapping of the cracks identified in the plan shown in Figure 4 made it possible to correlate the location of the anomalies with the different ground levels and structural elements. This analysis is essential for identifying the compartments most susceptible to stress variations and differential settlement.

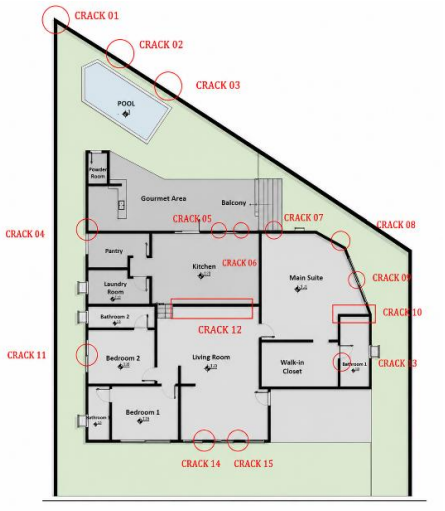

Figure 4 - Mapping of the Identified Cracks

2.1. Perpendicular Bisector Method

For data analysis and confirmation of active differential settlement, Berberian's Perpendicular Bisector Rule was applied to the mapping of the identified diagonal and horizontal cracks. This method consists of a widely used technique for identifying the agent or mechanism responsible for the appearance of cracks in building elements. The technique consists of drawing lines perpendicular to the axis of the diagonal cracks identified during the inspection. Since these openings occur perpendicular to tensile stresses, the convergence of the traced lines directly indicates the support point that underwent the greatest vertical displacement, as shown in Figure 5 (Quirino, 2023; Silva, 2019).

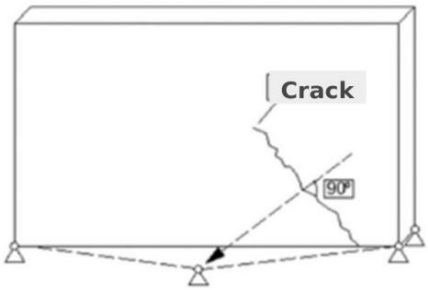

Figure 5 - Perpendicular Bisector Method (Source: Silva & Rodrigues, 2019).

To illustrate the application of Berberian's Perpendicular Bisector Rule to the present case study, Figure 6 shows the projection of the perpendicular bisector from a representative diagonal crack identified during the inspection. The same procedure was subsequently applied to all representative diagonal cracks, and the convergence of the projected lines enabled the identification of the three differential settlement zones presented in Figure 7.

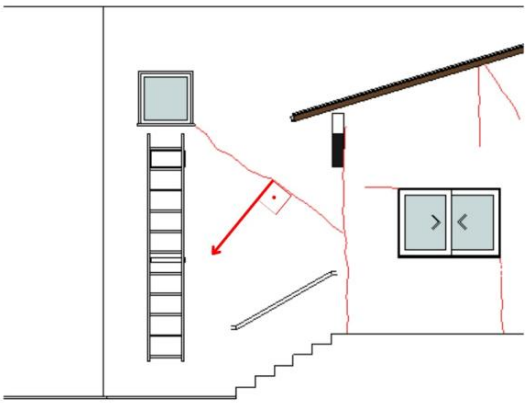

Figure 6 - Application of Berberian's Perpendicular Bisector Rule

3. Diagnostic Analysis and Proposed Rehabilitation Strategy

The application of the Perpendicular Bisector Rule (Silva, 2019) to the mapped cracks made it possible to isolate the geotechnical origin of the structural movements. By projecting orthogonal lines perpendicular to the axis of each diagonal crack, a convergence of vectors was obtained, pointing to three critical points of vertical displacement: the external corner of the kitchen, the end of the suite, and the angular section of the perimeter wall. This geometric triangulation confirms that the differential settlement is not widespread, but

rather concentrated at specific foundation points where there is a transition in levels or a variation in the bearing capacity of the natural ground, as shown in Figure 7.

Figure 7 - Mapping of the Observed Differential Settlements.

During the inspection, the measured crack openings ranged from 0.3 mm to 1.80 mm, with the largest openings observed in the kitchen corner and in the main suite. Most of the observed cracks exhibited a diagonal orientation, which is consistent with differential settlement mechanisms. Representative examples are presented in Figures 8, 9 and 10.

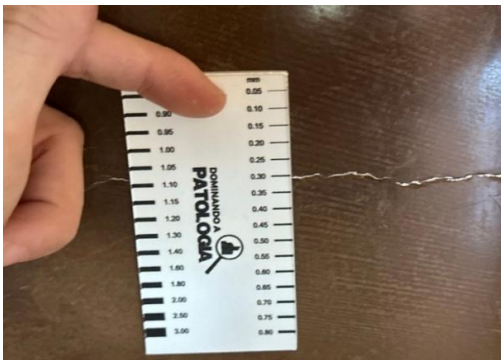

Figure 8 - Crack (opening = 0.30 mm)

Figure 9 – Diagonal crack (opening = 1.80 mm)

Figure 10 - Diagonal crack observed in the kitchen corner

3.1. Proposed Therapy – Mega Piles

Given the diagnosis of differential settlement concentrated in transition zones and in the elevated portion founded on natural ground, foundation underpinning using the Mega Pile technique was proposed. Mega piles, also known as reaction piles or jacked piles, differ from other driven piles because they are installed statically through the reaction force generated by a hydraulic jack acting against a reaction frame or against the existing structure itself, provided that the structure can withstand the applied loads (Teixeira et al., 2020). The selection of this intervention is justified by the nature of the identified problem, since the technique allows direct control of the applied load through manometric readings and can be executed in confined spaces. This is essential for the rapid stabilization of structures at risk, without the need for additional deformations for the underpinning system to begin carrying load effectively.

According to ABNT NBR 6122:2022, reaction piles, referred to as mega piles or jacked piles, consist of concrete or steel elements introduced into the ground by means of a hydraulic jack reacting against a pre-existing structure or against a structure specifically created for that purpose. The installation of each segment proceeds until one of the following limits is reached: the reaction capacity of the structure itself, when it begins to show signs of uplift, cracking, or deformation; the structural limit of the pile, corresponding to the maximum resistance of the steel or concrete element; or the resistance of the soil, when the element reaches a sufficiently stiff layer capable of preventing further penetration.

According to ABNT NBR 6122:2022, Annex Q (normative), item Q.4, the jacking and wedging loads for reaction piles must be specified in design and shall be at least 1.5 times the working load. In the context of underpinning existing structures, the working load at each intervention point is not predetermined by theoretical calculation, but is defined during execution by the actual reaction capacity of the building, monitored continuously through manometric readings until structural response signs such as uplift, cracking, or deformation are observed. The wedging load is subsequently applied in accordance with item Q.4, respecting the structural limits identified during jacking. This empirical load control procedure is inherent to the mega pile technique when applied to existing buildings and does not exempt the intervention from compliance with the normative requirements of ABNT NBR 6122:2022.

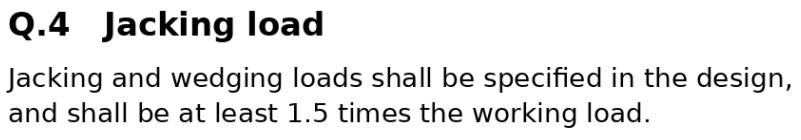

Figure 11 - Jacking Load (ABNT, adapted by the author).

The use of mega piles is therefore intended to stabilize the settlement observed in the existing foundation, redistribute stresses to levels compatible with the bearing capacity of both the soil and the structure, provide additional and immediate support, mitigate differential displacements, and eliminate or reduce the progression of cracks and deformations, thereby restoring the load-bearing capacity of the foundation and extending the building's service life. Prior to any intervention, SPT or CPTu soundings are strongly recommended in the vicinity of the affected areas in order to determine the depth required for pile support and to characterize the competent bearing strata of the subsoil. In the case study presented herein, such geotechnical investigations were not carried out, which constitutes a limitation of the present study. Their execution prior to the proposed intervention is considered essential for the accurate design and safe implementation of the mega pile underpinning.

Should the proposed intervention be carried out, the execution procedure is recommended to follow the stages described below, based on established practice for mega pile underpinning:

3.1.1. Area preparation and excavation of the working pit

Initially, the pile installation point is defined according to the structural analysis. Next, a pit approximately 1.0 m × 1.0 m is manually excavated to a depth of about 1.0 m below the support base of the structure, thereby ensuring safe shoring conditions and adequate access for the crew. Finally, the bearing surface is cleaned and leveled to allow the proper positioning of the hydraulic jack.

3.1.2. Installation of the reaction system

The hydraulic jack is positioned against the grade beam, footing block, or previously assessed structural element. The hydraulic power unit, equipped with a calibrated pressure gauge, is then installed, allowing accurate pressure readings during the operation. Before jacking begins, the vertical alignment of the equipment is adjusted in order to ensure the proper insertion of the segments into the ground.

3.1.3. Installation of the segments (repetitive procedure)

Segment installation consists of a repetitive procedure in which the initial segment, whether a concrete pipe or a threaded steel tube, is first positioned, after which the hydraulic jack is activated, thereby driving the segment into the ground by reaction. The maximum pressure recorded on the gauge is immediately converted into the corresponding applied load (tf), while the structural response is continuously monitored by observing any local uplift, opening or closing of cracks, audible structural responses, and deformations in the supporting beams. Once the maximum stroke is reached, the equipment is retracted and a new segment is coupled, either by direct bearing in the case of concrete, or by threading in the case of the steel tube, and the process is repeated until one of the termination criteria is met: unacceptable structural reaction, maximum system capacity, or refusal due to soil resistance.

For determining the loads involved in the process, it is necessary to understand the operating principle of mega piles, which is based on the interaction of three main components: the hydraulic jack, whose piston has a given area (A) and is responsible for applying the force (F); the hydraulic power unit, which functions as a pump that delivers pressurized oil to the jack; and the pressure gauge, which measures the oil pressure (p) and, consequently, allows the determination of the force applied to the system.

The force applied during installation is obtained from Equation (1) below, in which F represents the force, p the pressure measured by the gauge, and A the internal area of the hydraulic jack piston.

$$F = p \times A \tag{1}$$

This equation allows the load applied to the pile at each stage of installation to be accurately determined. Each segment is jacked into the ground until a predefined pressure limit is reached, at which point the jack is retracted and a new segment is added, with the cycle repeated as many times as necessary. In this way, the pile is progressively built from the bottom up, using the existing structure itself as the reaction system.

3.1.4. Determination of the final pile load

The final pile load corresponds to the value recorded during the last jacking cycle prior to reaching the limit imposed by the structure, the soil, or the pile itself. This value represents the actual and effective capacity of the element at that specific intervention point and is used as the basis for determining the total number of piles required for foundation underpinning.

3.1.5. Wedging and preloading

Wedging is the stage that ensures the effective transfer of load from the structure to the mega pile after jacking. It is the process that brings the pile into an active load-bearing condition, allowing it to contribute

immediately to structural support. Proper execution of wedging is essential because it distinguishes the behavior of mega piles from that of other foundation strengthening techniques that depend on additional settlement to mobilize their bearing capacity.

3.1.5.1. Load transfer and level adjustment

After jacking, the hydraulic jack may be used to apply a controlled preload in order to ensure firm contact between the structure and the pile and to correct minor level differences, whenever technically feasible and safe, thereby promoting partial crack closure and stabilization of the structural condition. This adjustment must always be limited and carefully monitored in order to avoid overloading the existing structure.

3.1.5.2. Installation of the head block

Once the final load achieved during jacking has been established, the head block is installed. It may be precast or cast in place using concrete with strength compatible with the applied demands, serving as the intermediate element between the pile and the structural support point.

3.1.5.3. Repositioning of the jack and application of the preload

With the head block in place, the hydraulic jack is positioned once again between the top of the pile and the underside of the head block, making it possible to apply the preload required for final locking. This load, which is lower than the maximum jacking load, is intended to ensure continuous and firm contact between the pile and the structure, guarantee that the pile enters an active load-bearing condition without depending on subsequent settlements, stabilize residual deformations prior to locking, and allow fine level adjustment whenever applicable. The value of this load must be compatible with the local structural capacity and with the behavior observed during jacking.

3.1.5.4. Locking with wedges

With the load applied, locking is carried out by means of steel wedges placed on either side of the jack or between the top of the pile and the head block, depending on the system adopted. The wedges prevent load release after the jack is removed, ensure the immediate transfer of forces to the pile, and maintain the stability of the assembly until the infill materials have fully cured.

3.1.5.5. Final wedging and completion of the head block

After the initial locking, final wedging of the space between the top of the pile and the original foundation or intermediate structural element is carried out. The most commonly used methods include constructing the head block in high-strength reinforced concrete, using bearing pieces, steel wedges, and final concreting to ensure composite action, which is the traditional procedure widely adopted in underpinning with mega piles, or injecting microconcrete, structural mortar, or high-strength grout in order to ensure full bonding and continuity of load transfer. Finally, the jack is removed under controlled gradual release, the load remains active in the system, and the pile immediately begins to act as a load-bearing element, thereby confirming the effectiveness of the wedging process and the stability of the assembly.

3.1.6. Injection, when applicable:

When applicable to steel mega piles or concrete mega piles using injection techniques, cement grout is introduced through the interior of the pile after jacking, ensuring that the grout exits through the tip and is distributed along the shaft. During the process, the injected volume, pressure, and return behavior are recorded, and curing is then allowed in accordance with the technical specification.

3.1.7. Structural reconditioning and monitoring

Once the installation of all piles has been completed, settlement stabilization should be verified and cracks and levels monitored for a minimum period of 30 days after underpinning. The necessary structural repairs should then be carried out, including masonry, beams, and finishes, concluding with the issuance of a technical compliance report after stabilization has been confirmed. It is noted that the execution of this intervention and the subsequent monitoring fall outside the scope of the present study, and their documentation is recommended as the subject of future work.

Figures 12 to 15 below illustrate the execution process of the mega pile system:

Figure 12 - Installation of the Hydraulic Jack. Source: Reproduced from the Geotecnia Brasil YouTube channel (2022).

Figure 13 - Hydraulic Jack Head Block.Source: Reproduced from the Geotecnia Brasil YouTube channel (2022).

Figure 14 - Locking of the Wedging System Using Steel Wedges. Source: Reproduced from the Geotecnia Brasil YouTube channel (2022).

Figure 15 - Structural Reconditioning and Post-Intervention Monitoring. Source: Reproduced from the Geotecnia Brasil YouTube channel (2022).

The mega pile solution is technically well suited to settlement-related problems, as it acts directly beneath the existing structure and provides immediate load-bearing capacity after wedging, with a level of load control that is distinctive among foundation methods. In addition, it eliminates the need for deep excavations, extensive drilling, or vibration, and can be executed even under extremely restricted access conditions, making it a safe and effective solution for emergency stabilization and structural rehabilitation.

4. Conclusions

The present study demonstrated that the application of Berberian's Perpendicular Bisector Rule to a real case of active differential settlement was considered an effective and practical diagnostic tool. By mapping the observed fissures and projecting orthogonal lines to their axes, it was possible to precisely identify three critical points of vertical displacement, located at the external corner of the kitchen, the end of the suite, and the angular section of the perimeter wall, all concentrated in the highest portion of the site over natural ground. This geometric method allowed the diagnosis to be grounded in the observed pattern of structural distress rather than in assumptions, which is particularly relevant in contexts where geotechnical investigation documents and structural drawings are unavailable, as was the case in this study.

The case also revealed important lessons regarding the conditions that led to the pathological manifestations. The absence of prior geotechnical investigation, the presence of fill placed without adequate quality control, and the heterogeneity of the natural ground were identified as the primary factors responsible for the differential settlement. Furthermore, the ineffectiveness of the superficial corrective measures previously adopted, such as metallic stitching, reinforces that surface-level interventions are insufficient when the root cause lies in foundation instability. These findings serve as a practical warning for professionals involved in small-scale residential construction, where geotechnical investigation is frequently omitted.

Based on the diagnosis, foundation underpinning with Mega Piles was proposed as the recommended intervention. This technique presents itself as technically suitable for the case studied, given its capacity for direct load control through manometric readings, its compatibility with restricted-access conditions, and its ability to provide immediate load-bearing capacity after wedging without requiring additional settlements. The proposed approach is based on the guidelines of ABNT NBR 6122:2022 and geotechnical stabilization is identified as an indispensable prerequisite for any subsequent structural rehabilitation. The execution of the proposed intervention and its monitoring fall outside the scope of the present study, and their documentation is recommended as the subject of future work.

Summary: The preservation and management of built cultural heritage require documentation strategies that integrate construction data, historical information, and essential data for preventive conservation and continuous monitoring. In this context, Heritage Building Information Modeling (HBIM) emerges, aiming to transpose the Building Information Modeling methodology to the context of historical assets, allowing the creation of digital representations that unify geometry with its semantic database. However, it is common for digital models to still emphasize only geometric information while dissociating technical information, resulting in visually accurate but semantically empty models. In this context, this study focuses on the Church of Our Lady of the Conception of Almofala, a historical heritage site in Ceará state listed by IPHAN (National Institute of Historic and Artistic Heritage), which, despite its relevance, lacks systematized technical records capable of supporting future restoration interventions. Therefore, this work aims to collect, identify, and categorize historical and constructive information necessary for the semantic enrichment of the future HBIM model of the building, using forms developed within the Documenta-CE project, specifically designed for cataloging heritage attributes. To this end, a bibliographic review of vernacular techniques applied in the region and the mechanical properties of the materials used was conducted. Following this, a technical visit to the church was carried out to collect visual and material information, which was then used to complete the technical form. As a result, a hierarchical and categorized database was created according to BIM standards, to be applied in future HBIM models of the church. Finally, this work attests to the applicability of the developed form in the collection and cataloging of heritage information, while contributing to the preservation and management of Ceará's built heritage.

1. Introduction

The safeguarding of historical built heritage demands, in contemporary engineering and architecture, a methodological transition from purely reactive interventions to preventive conservation strategies. For the diagnosis of structural vulnerabilities and the mitigation of pathological processes to be effective, the consolidation of geometric, historical, and physicochemical data in a centralized, auditable, and continuously updatable technical repository is imperative (Lourenço 2006; ICOMOS 2017).

In this context, Heritage Building Information Modeling (HBIM) has established itself as the main technological response in the sector, proposing the adaptation of Building Information Modeling (BIM) principles to the complexities of pre-existing structures (Murphy, McGovern, and Pavia 2009). However, the specialized literature points to a recurring methodological mismatch in the practice of heritage digitization: driven by advances in reality capture sensors (such as laser scanning and aerial photogrammetry), projects often restrict themselves to geometric hyper-representation. This methodological asymmetry generates three-dimensional models with high visual precision, but which are

"semantically empty," lacking essential non-geometric parameters—such as the stratigraphy of materials, the mapping of degradations, and the mechanical properties of the substrate. This deficiency makes it impossible to fully utilize these tools for structural simulations and for managing the life cycle of buildings (Bruno et al. 2018; Pocobelli et al. 2018).

Overcoming this informational gap proves particularly critical in the context of vernacular architecture, whose construction systems are highly susceptible to harsh microclimates. The Church of Our Lady of the Conception of Almofala, a heritage site listed by the National Institute of Historic and Artistic Heritage (IPHAN) on the coast of Ceará, is a paradigmatic case. Subjected to a prolonged historical process of burial by shifting dunes, the building embodies a complex pathological condition (marked by intense salt crystallization and capillary rise) that requires much more than visual records to support future rehabilitation projects.

Given this analytical and documentary gap, this research aims to propose and apply a methodological protocol for the systematic collection and categorization of constructive and pathological attributes aimed at semantic enrichment in HBIM (Historical Building Information Modeling). Through the implementation of Characterization Sheets developed within the Documenta-CE project, the study establishes a workflow that converts field technical inspection into a relational and parameterizable database. By structuring this information under an object-oriented architecture (compatible with BIM platforms), this work aims to demonstrate the feasibility of providing digital models with the informational rigor required by diagnostic engineering, directly contributing to the safeguarding of Ceará's historical heritage.

2. The Role of HBIM in Structural Conservation

2.1. Semantic enrichment and pathology management:

The BIM model, by definition, transcends traditional graphic representation by integrating parametric information into each of its virtual elements. In the context of built heritage (HBIM), the process of inserting non-geometric data is known as semantic enrichment. This procedure consists of linking specific metadata—such as the physical-chemical properties of materials, history of interventions, state of conservation, and levels of degradation—to the three-dimensional components of the model (Brumana et al. 2018).

For rehabilitation engineering and restoration architecture, this parameterization is a determining factor for the success of structural damage diagnosis. Traditionally, the mapping of pathologies (such as cracks, mortar disintegration, and rising damp) is carried out in a two-dimensional way or in decentralized textual reports, which hinders spatial visualization and systemic understanding of degradation (Bruno et al. 2018). By incorporating this data directly into the HBIM model, professionals have a unified and three-dimensional environment for pathology management.

Semantic enrichment allows, for example, a finite element model (FEM) for structural simulation to be fed with the real properties of degraded materials, extracted directly from the BIM database (Oreni et al. 2014). Furthermore, the systematic categorization of pathological manifestations in the virtual environment enables advanced spatial analyses, such as the identification of fault propagation patterns and the correlation between structural damage and external agents.

In this way, the insertion of non-geometric data transforms HBIM from a simple static repository into an active management tool. It begins to act as a digital twin (digital twin) focused on preventive conservation, allowing technical teams to perform scenario simulations, plan interventions with greater precision, and monitor the behavior of the structure throughout its life cycle (Pocobelli et al. 2018).

2.2. Vernacular techniques and regional materials:

Colonial and vernacular-influenced architecture is often characterized by the use of self-supporting mixed masonry and historical lime and sand-based mortars. Understanding the mix and mechanical behavior of these traditional mortars is the first step for any compatible intervention. The introduction of Portland cement in historical masonry restorations, for example, can accelerate degradation processes due to the incompatibility of stiffness and permeability (Veiga 2017).

For diagnostic engineering, the analysis of monuments located in coastal microclimates requires an understanding of aggressive vulnerabilities, which combine high salinity, abrasion, and humidity. Established conservation literature demonstrates that capillary rise combined with contamination by marine chlorides and sulfates is one of the main causes of collapse in historical masonry (Goudie and Viles 1997). The crystallization and hydration cycles of these salts within the pores (cryptoflorescence) generate expansive mechanical stresses that exceed the tensile strength of mortars and bricks, resulting in powdery disintegration and severe loss of resistant section over time (Scherer 2004; Binda, Saisi and Tiraboschi 2000).

In the context of advanced digital documentation, historical buildings present additional technical and methodological challenges. Traditional surfaces, such as those coated with whitewash, exhibit high albedo and high reflectance. Studies indicate that excessively light or reflective surfaces can scatter the light beam.*Laser Scanner*(TLS), generating noise in the point cloud or data gaps (*data voids*) that require hybrid capture strategies integrated with photogrammetry (Hichri et al. 2013).

In this sense, the semantic enrichment of HBIM models transcends the aesthetic register. By parameterizing physical properties (such as porosity and compressive strength) and mapping weathering damage directly onto BIM objects, a vital information model is created for seismic or gravitational vulnerability assessments. The insertion of this non-geometric data into the virtual environment is what allows the transition from a simple 3D model to a digital twin capable of feeding finite element (FEM) simulations and guiding precise structural reinforcement designs (Angelini et al. 2017).

3. Acquisition and Cataloging Methodology

3.1. Methodological Protocol for On-Site Data Acquisition

To ensure that the three-dimensional model (HBIM) transcends mere aesthetic representation and is effectively applicable to diagnostic engineering, it was necessary to establish a rigorous reality capture protocol. The methodology developed by the Documenta-CE project team aims to standardize the pre-field, multisensor acquisition, and information organization stages, ensuring the technical reliability and traceability of the collected data for subsequent geometric and semantic modeling.

The core of this protocol is based on a hybrid digitization strategy, combining active and passive surveying techniques to overcome the individual operational limitations of each piece of equipment. Laser Scanning (Terrestrial - TLS and Mobile - SLAM) is employed as the primary method for obtaining millimeter-precision point clouds of internal surfaces and facades accessible at ground level. Simultaneously, Digital Photogrammetry, performed with the support of Unmanned Aerial Vehicles (UAVs), is applied for mapping roofs, inaccessible vertical elements, and for capturing high-resolution photorealistic textures. Data fusion is essential in structural diagnosis, as it eliminates traditional shadow zones and spatial gaps (data voids), resulting in a continuous and metrically reliable digital skeleton of the building.

Beyond spatial capture, the protocol innovates by requiring the simultaneous structuring of non-geometric documentation directly on the construction site. During laser scanning, the technical team performs a rigorous visual and tactile inspection, based on standardized survey forms. At this stage, the construction typologies are identified, cracking patterns are mapped, the level of degradation of historical mortars is recorded, and pathological manifestations are noted, such as areas affected by moisture or salt crystallization.

Finally, the methodology establishes the mandatory registration of metadata and paradata (detailed information about the data acquisition and processing process). The developed protocol requires the systematic recording of specifications and calibrations of the equipment used, environmental lighting conditions, and grid density profiles at the time of on-site operation. For conservation engineering, this archival rigor ensures that the generated point cloud and the future HBIM model are not interpreted as mere static visual products, but rather as traceable, scientifically reproducible databases capable of supporting structural analyses with perfectly known and documented margins of error..

3.2. Structuring and systematic approach to the attribute characterization form

The digitization of built heritage has historically faced the structural challenge of the "semantic void": the generation of highly precise three-dimensional geometric models that, however, lack data on the materiality, history, and structural degradation embedded in their components. Assuming the mitigation of this semantic void as the fundamental element for defining our protocol, the on-site inspection stage was implemented through the application of HBIMPath (Magalhães et al. 2025). This is a characterization form specifically designed to address the ontology of Ceará's built heritage.

The logical structure of this tool transcends purely descriptive functionality, being based on an object-oriented data architecture designed to fill informational gaps. This premise ensures direct compatibility with the hierarchy of classes and families inherent in parametric modeling platforms (such as Revit and Archicad).

The documentary protocol organizes data acquisition into constructive macro-categories (masonry, window and door frames, and structural elements, among others), as illustrated in Figure 2, proceeding to the decomposition of each architectural component into three systematic informational dimensions created to address the shortcomings of the digital model:

1. Stratigraphic Decomposition: In contrast to traditional two-dimensional documentation—which often conceives of sealing elements in a monolithic way—this instrument requires detailed discrimination of the constituent layers (structural core, successive mortar substrates, and finishing coatings). By feeding the geometric model with this stratification, the internal data gap is filled, which proves imperative for rehabilitation engineering, as it enables the association of mechanical properties and specific degradation states to each stratum. Consequently, the detection of physical-chemical incompatibilities between vernacular materials and subsequent contemporary interventions is optimized.
2. Morphological and Aesthetic Parameterization: To combat the absence of computable properties, the form promotes the conversion of qualitative attributes into classificatory and quantifiable data. This processing encompasses the detailing of articulation mechanisms, sealing typologies, and the exhaustive cataloging of finishes (textures, reflectance indices, and standardized colorimetry systems, such as Pantone and RGB). The insertion of this metadata ensures that the HBIM model achieves a high Level of Information (LOI), an indispensable criterion for scientific restoration projects that require rigor in chromatic and textural reintegration.
3. Traceability and Metadata Anchoring: The definitive mitigation of the semantic void requires that textual information be intrinsically tied to spatial geometry. The document establishes the "Final Modeling Code," functionally operating as a globally unique identifier (GUID). This code establishes a one-to-one relationship between the inspected physical element and its respective digital representative in the model. Additionally, the form includes variables for the insertion of paradata, encompassing correlation with historical documentary sources, geometric detail sketches, and the mandatory verification of the associated photographic collection.

Figure 1– Systematic approach to in-situ data collection via the HBIMPath protocol: parameterization of morphological, stratigraphic, and structured degradation attributes for integration into parametric models (HBIM).

In summary, HBIMPath structures its informational dimensions in such a way that combating the "semantic void," which represents the greatest methodological challenge in digital preservation—since models limited to geometric hyper-representation act as inert visual shells that induce diagnostic paralysis—acts as the generating principle of the entire survey, converting the subjectivity inherent in empirical visual inspections into a relational and structured database. Thus, the characterization form is consolidated as the exact translation protocol between the materiality of historical buildings and the digital interface, providing the necessary data infrastructure for future structural behavior simulations and for the optimized lifecycle management of built heritage.

4. Results

4.1. On-site survey and data collection

The practical application of the methodological protocol at the Almofala Church occurred through a field campaign that integrated high-precision geometric capture with systematic technical inspection. Documenting this monument required specific strategies due to its unique material and environmental conditions: the building bears the physical marks of its history of being buried by mobile dunes (between 1897 and the 1940s) and features facades entirely covered in whitewash, whose high albedo effect challenges the reading of laser and photogrammetric sensors (Figure 1). To overcome this complexity, the acquisition process was subdivided into two simultaneous and complementary fronts: three-dimensional digital reconstruction and semantic cataloging of constructive attributes.

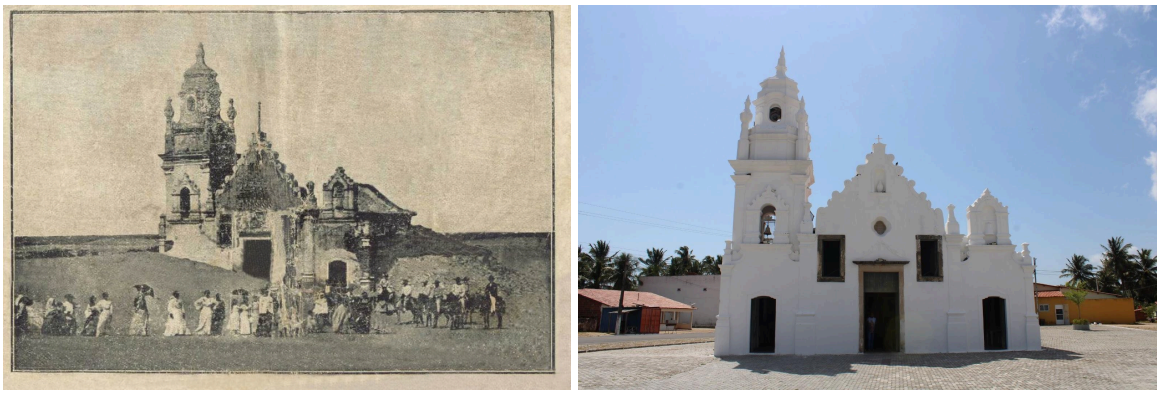

Figure 2– Church of Our Lady of the Conception of Almofala: (a) Historical record of burial by shifting dunes; (b) Current view highlighting the high-albedo whitewash.

4.1.1. Three-Dimensional Geometric Survey

The geometry capture followed a data fusion strategy. For mapping the internal surfaces and facades at ground level, Terrestrial Laser Scanning (TLS) and SLAM (Simultaneous Localization and Mapping) technology were used. The use of the Leica BLK2GO sensor allowed for agile navigation through the interior of the nave and sacristy in journeys of approximately 15 minutes, ensuring the continuity of the point cloud in spaces with complex geometry. Complementarily, the Leica BLK360 static sensor was positioned at 26 strategic stations to ensure maximum density in areas with a high level of ornamental detail, such as the main altar.

PFor the documentation of the roof and upper areas of the bell tower—historically inaccessible areas prone to data voids—aerial photogrammetry was employed using the DJI Mavic 3T Enterprise model. The flight plan (with approximate durations of 30 minutes) followed an 80% overlap pattern and generated a total of 470 images from converging nadir and orbital trajectories. These images were essential for generating high-resolution orthophotos that supported texture mapping and the visual identification of cracks and pathologies in the ceramic tile and the tower's crowning.

Processing the ground scans (26 TLS stations and 2 SLAM paths) in Leica Cyclone REGISTER 360 software resulted in a unified point cloud with an average overlap of 69%. This consolidated model is composed of approximately 430 million points and has a maximum registration error of 0.003 m (3 mm). Subsequently, global alignment between the laser base and the 288 million vertices generated by photogrammetric processing was performed in the CloudCompare environment, resulting in a single, gap-free geometric product (Figure 3).

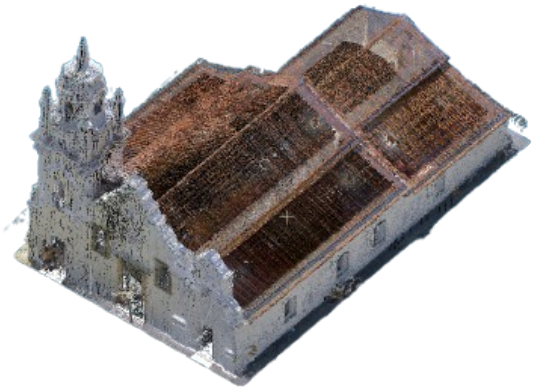

Figure 3 -Unified point cloud resulting from multisensor integration (UAV and TLS), demonstrating the suppression of spatial gaps in global volumetry.

4.1.2. Semantic Inspection and Cataloging

In parallel with geometric digitization, non-geometric data was collected using the HBIMPath protocol (Magalhães et al. 2025), developed within the scope of the Documenta-CE project.The inspection focused on identifying the constituent layers of the masonry and window and door frames, as well as identifying the main pathologies manifested in these elements (Figure 4), translating physical reality into the logic of BIM objects. Each inspected element received a "Final Modeling Code," ensuring traceability between the real item and its future digital representation.

Figure 4 -Semantic survey of pathological manifestations associated with the marine microclimate: (a) Salt crystallization in mixed masonry; (b) Degradation by wood-boring insects/humidity; (c) Severe oxidation in metallic components.

Semantic data collection prioritized the stratigraphy of materials, identifying lime mortar substrates and different levels of finish. Aesthetic characterization included color measurement using standardized systems (RGB and Pantone), fundamental for recording the whitewash of the church, whose high albedo represents a technical challenge for the calibration of optical sensors. Additionally, the state of conservation of each component was recorded, documenting the presence of saline efflorescence and material disintegration; this data was linked to the record through mandatory photographic records and detailed sketches. This approach ensured that the survey resulted not only in a geometric "shell," but in a structured technical inventory, ready to feed the semantic enrichment of the HBIM model.

4.2. Structuring the semantic database in the HBIM environment

Structuring the collected information*in loco*This constitutes the critical preparatory phase for the future semantic enrichment of the virtual environment. Although three-dimensional geometric modeling (HBIM) has not been completed at the time of publication of this work, the data consolidated in the Characterization Sheets — generated from the processing of more than one hundred high-resolution photographic records and visual inspections — are already fully tabulated to be transposed to parametric software in the form of customized metadata.

Figure 5 -Isometric perspective of the three-dimensional model (HBIM) of the Church of Our Lady of the Conception of Almofala, Ceará.

To ensure interoperability and traceability of information in this pre-modeling stage, the "Final Modeling Code" (e.g., ALV_INT_NAVE_01 for masonry or ESQ_POR_PRINCIPAL_01 for window and door frames) was adopted as the primary key (GUID -*Globally Unique Identifier*This code acts as a one-to-one link, connecting the cataloged physical evidence to its future three-dimensional representation, establishing a rigorous relational data flow, as illustrated in the figure.Figure6.

The semantic cataloging of the masonry of the Almofala Church illustrates the effectiveness of this method. Instead of predicting the modeling of the walls as mere homogeneous solids, the data scope dictates that the future HBIM model be parameterized to reflect the actual stratigraphic decomposition: a core structure of mixed masonry (stone and brick), covered with historical lime-rich mortars and finished with whitewash. From a diagnostic engineering perspective, the pathologies identified in the photographs were organized as future instance attributes of the elements. The schematic record of "rising damp by capillarity" and "saline efflorescence" at the bases of the internal walls unequivocally documents the impact of the history of burial by dunes. Once inserted into the BIM environment, this parameterization will cease to be a textual report, enabling the automatic extraction of quantities (e.g., exact calculation of the area of plaster to be replaced) and the generation of thematic degradation maps.

A similar procedure was applied to the inventory of architectural elements and joinery. The main door of the temple, for example, had its materials (solid wood and wrought iron hardware) and its state of conservation rigorously documented. The planned inclusion of parameters regarding "severe oxidation of the hardware by salt spray" and "mechanical abrasion" by wind agents will computationally translate the material's behavior in the face of the coastal microclimate. Additionally, the preliminary tabulation of aesthetic attributes, such as the color system (e.g., RGB: 242, 240, 235 for whitewash with dirt), already ensures a high Level of Information (LOI), an essential methodological requirement for future studies of chromatic reintegration.

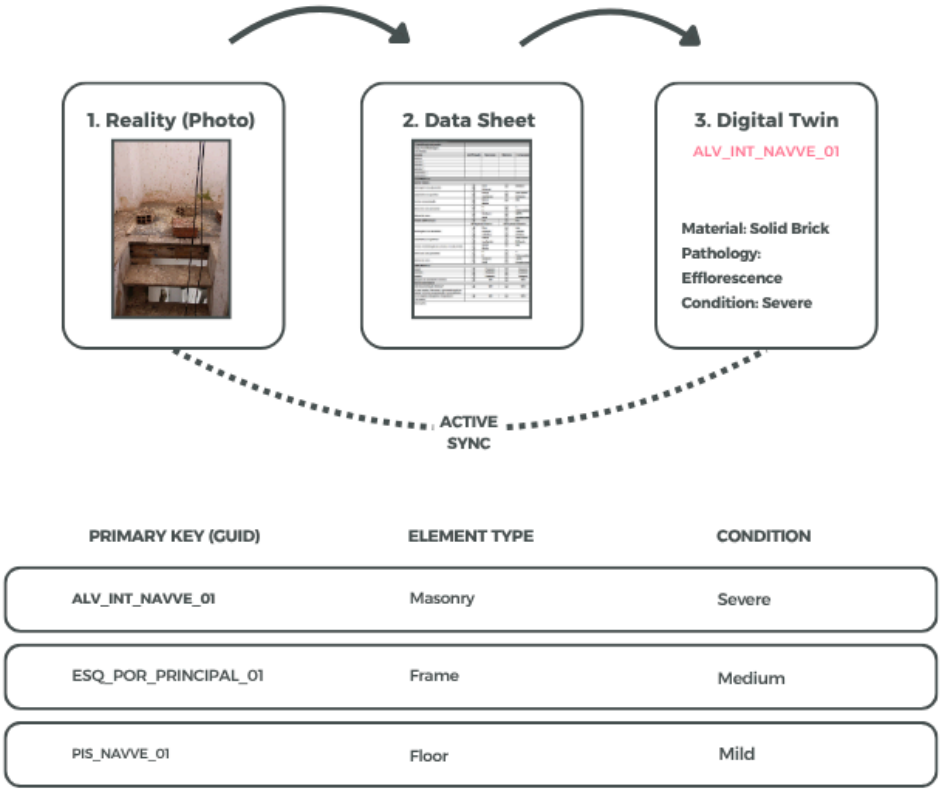

Figure 6– Information transition flowchart: from empirical inspection to the consolidation of the parameterized relational database (GUID) for future application in HBIM.

In this way, the structured semantic database for the Church of Almofala paves the way for the consolidation of an authentic digital twin (*digital twin*By organizing pathological and constructive information in advance under a logical and object-oriented architecture, restoration engineers and architects are provided with the centralized database necessary for the future modeling stage to reach its analytical fullness, enabling the planning of preventive interventions based on quantifiable and historically grounded data.

5. Conclusions

This study demonstrated that the transition from traditional documentation methods to the HBIM (Heritage Building Information Modelling) environment represents a paradigm shift in diagnostic engineering and the conservation of historical heritage. The application of the methodological protocol developed within the scope of the Documenta-CE project, validated at the Church of Our Lady of the Conception of Almofala, proved the technical feasibility of integrating highly accurate reality capture with rigorous semantic cataloging.

For professionals and researchers seeking to replicate this approach in other heritage sites, the study demonstrates that the hybrid digitization strategy does not depend exclusively on a rigid equipment setup, but on a principle of technical complementarity. The integration of laser scanning (either TLS or SLAM) with photogrammetry via UAV constitutes a workflow adaptable to the reality and resources of different teams. This arrangement proved to be the definitive method for suppressing spatial gaps (data voids) and recording the totality of geometric complexity in buildings with accessibility restrictions.

However, the main contribution to methodological replicability lies in the systematization of on-site data collection through Attribute Characterization Sheets (HBIMPath). Replicators can adopt this instrument as

a universal vector for translation between empirical inspection and digital parameterization, regardless of the target BIM modeling platform. By decomposing pre-existing conditions stratigraphically and linking each pathology and material to a Final Modeling Code (GUID), the protocol definitively solves the critical problem of the "semantic void" inherent in traditional point clouds.

From the perspective of structural pathology, the semantic enrichment guided by this method transforms the graphical representation into an active management tool. The documented vulnerabilities—such as the severe degradation due to saline efflorescence in Almofala—feed a relational database that acts as a genuine digital twin. For future architecture and engineering teams, this centralized infrastructure enables the automated extraction of quantities of degraded areas and the precise dimensioning of physically and chemically compatible preventive interventions.

Finally, the results attest to the structuring impact of the support provided by the Chief Scientist of Culture program of the Government of the State of Ceará and the Federal University of Ceará. The workflow validated here transcends the local case study, delivering to the technical-scientific community and public managers a modular, auditable, and high-Level of Information (LOI) methodological protocol. Its systematic adoption by other institutions is the fundamental step for the transition from a merely reactive conservation model to the predictive and continuous safeguarding of Brazilian heritage.

Acknowledgments

The authors express their gratitude to the Government of the State of Ceará and the Ceará Foundation for Support of Scientific and Technological Development (FUNCAP) for the essential support for research through the Chief Scientist of Culture Program. Special thanks are extended to the entire technical and scientific team of the Documenta-CE project, with particular emphasis on the researchers responsible for the preparation of the...*Technical Notebook No. 01 - Reality Capture*(Eugênio Moreira, Renan Nogueira Paulo, Lucas Mendes, Guilherme Lopes de Oliveira, Mylene Melo and Esequiel Mesquita). The methodological rigor established by this team during the digitization campaigns.*in loco*It was the fundamental basis for structuring the semantic database presented in this study.

Diagnóstico de manifestações patológicas em uma edificação comercial de múltiplos pavimentos: estudo de caso no centro histórico de Porto Alegre

Maria Eduarda da Silva DEMBOGURSKI[1]*, Daniel Thomaz FARINA[1]; José Maria de MOURA JUNIOR[1], Angela Borges MASUERO[1] e Denise DAL MOLIN[1]

[1] Laboratório de materiais e ambiente construído, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brasil, mariae.dembogurski@gmail.com

Abstract: O presente trabalho tem como objetivo identificar e analisar as manifestações patológicas presentes em uma edificação de múltiplos pavimentos localizada no município de Porto Alegre. A inspeção teve por finalidade avaliar as condições técnicas, de uso e de manutenção da edificação, de modo a subsidiar a elaboração de um plano de manutenção e a definição de ações corretivas e preventivas, priorizadas de acordo com o grau de risco associado às anomalias identificadas. A metodologia adotada fundamentou-se na norma básica para perícia de engenharia do IBAPE/SP, abrangendo a definição do nível e do tipo de inspeção, a análise da documentação disponível, a coleta de informações junto ao síndico, o estabelecimento de orientações técnicas, a hierarquização das intervenções e o registro fotográfico das ocorrências. Foram realizadas inspeções visuais em todas as áreas de uso comum da edificação, desde a cobertura das caixas d'água até os subsolos, com a devida caracterização das anomalias e a indicação das recomendações técnicas pertinentes. A priorização das intervenções foi efetuada por meio da adaptação da matriz G.U.T (Gravidade, Urgência e Tendência). Os resultados evidenciam a predominância de fissuras e trincas em paredes e lajes, degradação dos revestimentos de fachadas, bem como a presença recorrente de umidade e bolor, condições estas agravadas pela idade da edificação, pela porosidade dos materiais e pela ausência de manutenção sistemática. Conclui-se que as manifestações patológicas identificadas comprometem o desempenho e a vida útil dos sistemas construtivos, além de afetarem as condições de saúde, segurança e habitabilidade, tornando indispensável a implementação de medidas corretivas conforme as recomendações técnicas apresentadas.

Keywords: inspeção predial, manifestações patológicas, patologia, matriz GUT.

1. Introdução

As manifestações patológicas na construção civil correspondem a um conjunto de anomalias que provocam danos às estruturas, aos elementos não estruturais e de vedação, podendo se manifestar de forma superficial ou profunda (Silva *et al.,* 2023). A degradação das edificações ao longo de sua vida útil está associada a diversos fatores, entre eles: à ação de agentes ambientais, deficiências de projeto, falhas executivas, má qualidade dos materiais ou o emprego inadequado dos mesmos, mudança de finalidade construtiva e à ausência ou inadequação de manutenção (Ferreira; Lobão, 2018; Silva *et al*., 2022). Tais fatores contribuem para o surgimento de manifestações patológicas, as quais comprometem o desempenho, a durabilidade e a segurança das construções. Essas manifestações podem se originar devido as ações externas, como variações térmicas, precipitação e radiação solar, mas também devido a condições internas, relacionadas à umidade, ventilação e processos de condensação (Oliveira, 2021; Silva *et al.,* 2023).

A identificação e análise dessas anomalias constituem etapa fundamental para a determinação de suas causas e mecanismos de degradação. A correta caracterização das manifestações patológicas permite a definição de estratégias de intervenção mais assertivas, contribuindo para a recuperação do desempenho e

para a mitigação dos problemas (Bertolini, 2010). Segundo Ferreira e Oliveira (2021), muitas dessas manifestações patológicas poderiam ser evitadas mediante maior rigor nas etapas de concepção, especificação de materiais, execução e planejamento de manutenção. A discrepância entre as condições de projeto e a execução se destaca como fator crítico na redução da vida útil das edificações (Bezerra, 2018).
Diante desse contexto, observa-se a necessidade de estudos aplicados que permitam a caracterização e o diagnóstico de manifestações patológicas em edificações existentes, especialmente em áreas urbanas consolidadas e de relevância histórica. Assim, o presente trabalho tem como objetivo realizar o diagnóstico de manifestações patológicas em uma edificação comercial de múltiplos pavimentos, localizada no centro histórico de Porto Alegre, visando à identificação de suas causas e à geração de subsídios técnicos para intervenções que promovam a recuperação do desempenho e a ampliação da vida útil da edificação.

2. Delimitação do entorno

A edificação em estudo configura o objeto central desta análise, demandando a compreensão do contexto em que se insere no meio urbano. O imóvel, de uso comercial, está localizado no bairro Centro Histórico, na cidade de Porto Alegre, Rio Grande do Sul. Trata-se de uma obra de múltiplos pavimentos com aproximadamente 70 anos de idade, constituída por um pavimento térreo e sete pavimentos tipo, englobando uma área construída superior a 5.500 m².

Sob a ótica construtiva, a edificação foi executada segundo os padrões convencionais de sua época, sendo sustentada por uma estrutura principal em concreto armado com fechamentos externos e internos em alvenaria convencional. O sistema de cobertura apresenta configuração mista, empregando telhas de fibrocimento e lajes com impermeabilização na região dos reservatórios. A consolidação destas características físicas e estruturais evidencia a longevidade da obra, estabelecendo o cenário fundamental para a avaliação do esgotamento natural da vida útil de seus componentes originais.

A dinâmica ambiental e climática do entorno exerce influência contínua e decisiva sobre a preservação e a durabilidade do envoltório da edificação. O ambiente em que o prédio está situado enquadra-se na classe de agressividade 2 (moderada), conforme os parâmetros da NBR 6118:2026 para zonas urbanas. Somado a isso, a cidade de Porto Alegre caracteriza-se por um clima subtropical úmido, com variações extremas de temperatura ao longo do ano e uma umidade relativa do ar que se mantém elevada. A exposição ininterrupta a essas intempéries ao longo de sete décadas atua como o principal agente acelerador do desgaste dos materiais de fachada e dos sistemas de impermeabilização das lajes de cobertura, criando as condições ambientais ideais para a deflagração e o agravamento das manifestações patológicas mapeadas.
A Figura 1, apresenta a fachada da edificação em estudo e a sua localização.

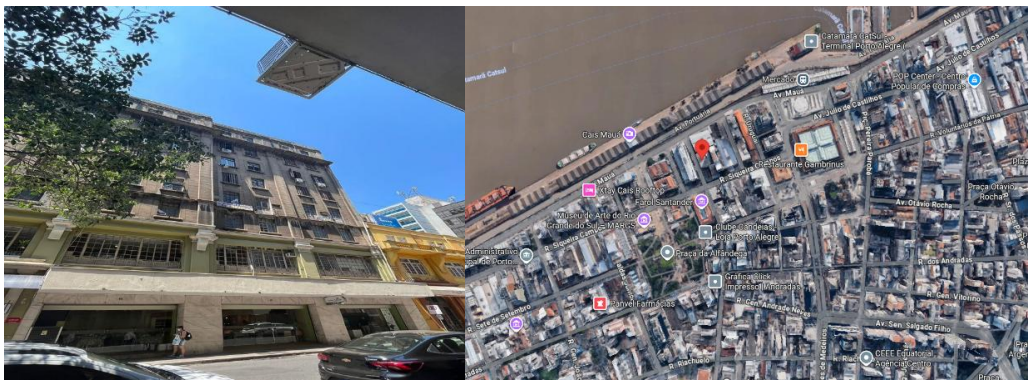

Figura 1 – Fachada da edificação em estudo e sua localização.

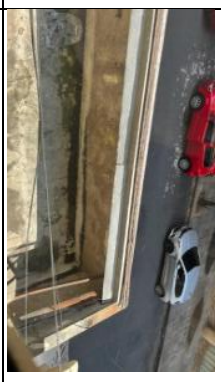
3. Metodologia

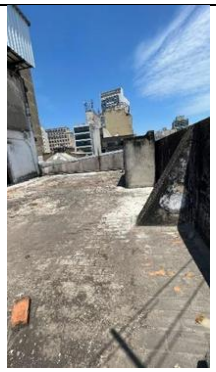
A condução deste estudo fundamentou-se numa abordagem qualitativa, estruturada a partir de uma inspeção predial embasada nas diretrizes do Instituto Brasileiro de Avaliações e Perícias de Engenharia (IBAPE) e nos procedimentos estabelecidos pela ABNT NBR 16747:2020. A classificação da inspeção como Nível 2 fundamentou-se nos critérios propostos pelo IBAPE/SP, sendo esta caracterizada pela realização de vistoria técnica detalhada em edificações de média complexidade, associada à análise documental, levantamento fotográfico e coleta de informações junto à gestão predial. A adoção deste escopo normativo assegura a padronização na recolha de dados, permitindo a identificação de anomalias construtivas e falhas de manutenção que afetam o desempenho do edifício.

O levantamento patológico concentrou-se no mapeamento das manifestações que comprometem diretamente a estanqueidade, a estabilidade e a durabilidade da envoltória. Durante a etapa de campo, os sistemas construtivos (principalmente o revestimento das fachadas, caixilharias, lajes impermeabilizadas e estruturas em balanço) foram inspecionados para correlacionar as manifestações patológicas visíveis (como fissuras, eflorescências e corrosão) com os seus respetivos mecanismos de degradação e causas primárias. Essa investigação transforma o registo visual num diagnóstico técnico do estado de conservação atual, isolando as variáveis necessárias para a posterior quantificação do risco.

Para o tratamento e hierarquização dos dados recolhidos, aplicou-se o método de análise de criticidade adaptado da Matriz GUT (Gravidade, Urgência e Tendência). Cada manifestação patológica mapeada foi avaliada num sistema de pesos (variando de 1 a 10) que quantifica o impacto na saúde e segurança (Gravidade), o tempo disponível para evitar o colapso da função (Urgência) e o potencial de evolução geométrica do dano (Tendência), resultando numa classificação de risco estratificada em níveis Crítico, Regular e Mínimo. A aplicação desta matriz converte as observações qualitativas num índice de priorização numérico e objetivo, estruturando a base para a apresentação e discussão na secção de resultados. A metodologia utilizada para classificação da ordem de prioridades dos vícios construtivos encontrados foi desenvolvida com as funções de criticidade e pesos seguintes (Quadro 1):



Quadro 1 - Parâmetros de avaliação de criticidade aplicados à matriz GUT



GRAU	GRAVIDADE	TENDÊNCIA	QUADRO EVOLUTIVO	PESO
Total	Perda de vidas humanas, falhas graves de concepção e/ou execução de projeto, danos ao meio ambiente ou defeito grave na própria edificação, além de despesas extras com eletricidade, água ou gás no condomínio	Eventos em ocorrência	Evolução imediata	10
Alta	Possibilidade de ferimento em pessoas, danos ao meio ambiente ou à própria edificação	Evento prestes a ocorrer	Evolução em curto prazo	8
Média	Desconfortos, deterioração do meio ambiente e outras anomalias construtivas existentes na edificação	Evento prognosticado para breve	Evolução em médio prazo	6
Baixa	Pequenos incômodos ou pequenos prejuízos financeiros	Evento prognosticado para adiante	Evolução em longo prazo	3
Nenhuma	-	Evento imprevisto	Não vai evoluir	1

4. Resultados

A partir do levantamento de dados e da inspeção visual detalhada da edificação em estudo, procedeu-se ao mapeamento e diagnóstico das manifestações patológicas, culminando na elaboração da matriz de diagnóstico e definição de conduta. O Quadro 2 sistematiza as evidências empíricas coletadas, focando estritamente nos sistemas de envoltória, estruturas e impermeabilização, que apresentaram os níveis mais agudos de degradação. A matriz correlaciona a manifestação patológica observada ao seu mecanismo de ação e provável causa, fornecendo a base técnica necessária para a proposição das terapêuticas adequadas à recuperação e preservação do imóvel.

Quadro 2 – Matriz de diagnóstico e definição de conduta

Manifestação patológica	Registro visual	Local	Manifestação patológica	Mecanismo	Terapêutica adequada
Degradação de Revestimento Externo		Fachadas externas em geral	Bolor extremo, manchas escuras, umidade generalizada e eflorescências	Exposição ininterrupta às intempéries, alta porosidade do material original (argamassa tipo pó de pedra/Cirex) e total ausência de limpeza preventiva	Hidrojateamento com solução fungicida, remoção de áreas desagregadas, aplicação de selador e repintura com tinta acrílica elastomérica
Sobrecarga e Empoçamento		Marquise da fachada principal	Acúmulo de água, vegetação aparente e peso não previsto de múltiplos equipamentos	Subdimensionamento ou obstrução de ralos, falha de impermeabilização e instalação irregular de dezenas de condensadoras de ar-condicionado	Desobstrução do escoamento, refazimento da impermeabilização e elaboração de laudo estrutural para redistribuição ou remoção das cargas térmicas
Corrosão de Armaduras		Laje da casa de máquinas e pilares do 9º andar	Fissuras orientadas no sentido das barras de aço, desplacamento do betão e manchas de oxidação	Infiltração crônica de umidade que rompeu a passivação do concreto, agravada por reparações paliativas anteriores que apenas mascararam o dano	Escarificação do concreto contaminado, limpeza mecânica das barras, aplicação de inibidor de corrosão e recomposição com argamassa polimérica estrutural

Manifestação patológica	Registro visual	Local	Manifestação patológica	Mecanismo	Terapêutica adequada
Perda de Estanqueidade		Terraços descobertos e lajes de cobertura	Infiltrações severas, manchas e mofo nos tetos e paredes dos andares inferiores (ex: restaurante)	Fim da vida útil do sistema de impermeabilização (manta asfáltica antiga), falhas em ralos e ausência de manutenção periódica	Remoção do sistema antigo, regularização do caimento e execução de nova impermeabilização asfáltica com proteção mecânica e revestimento
Oxidação e Falha de Vedação		Esquadrias de ferro em diversos andares	Ferrugem avançada, dificuldade de fechamento e entrada de águas pluviais	Exaustão da proteção anticorrosiva, falta de manutenção lubrificante e ausência de pingadeiras nas fachadas	Lixamento profundo, aplicação de fundo convertedor de ferrugem, pintura adequada e calafetação com selante PU no perímetro da esquadria
Deterioração Biológica		Esquadrias de madeira	Caixilhos empenados, apodrecimento da madeira e furos na estrutura	Exposição contínua à umidade sem renovação de vernizes protetores e ataque ativo de insetos xilófagos (cupins)	Substituição das peças estruturalmente comprometidas, execução de descupinização, aplicação de verniz protetor e selagem das frestas
Fissuras e Trincas		Paredes de fachada e interfaces estruturais	Aberturas lineares no revestimento argamassado	Variações de temperatura intensas nas fachadas leste/norte, dilatação diferencial entre materiais e desgaste do revestimento rígido	Abertura da trinca em perfil "V", limpeza, aplicação de selante elastomérico, estruturação com tela de poliéster e nivelamento superficial

Proliferação de Flora Parasitária		Peitoris de janelas e frestas na fachada	Vegetação invasiva no revestimento	Acúmulo de sujidade atuando como substrato orgânico, retenção crônica de umidade e ausência de higienização da fachada	Remoção manual cuidadosa da raiz, aplicação de herbicida específico, limpeza profunda da área e vedação da fresta original com selante

Deste modo, as anomalias, desconformidades e falhas constatadas na vistoria realizada no local de estudo, com suas respectivas siglas (Quadro 3), foram as seguintes:

Quadro 3 – siglas utilizadas para categorizar as anomalias encontradas

Sigla	Descrição
(FTR)	Tratamento de trincas, fissuras e restauração dos danos nos revestimentos de argamassa das fachadas, paredes e muros, incluindo repintura.
(IMP)	Impermeabilizações nas áreas descobertas.
(ESQ)	Revisão de esquadrias, pingadeiras e vedações.
(UAC)	Uniformização, restauração e disposição dos aparelhos de ar condicionado em locais corretos.
(MEF)	Manutenção e estanqueidade da fachada.
(PPC)	Regularização de itens referentes ao PPCI.
(RSC)	Reparos no sistema de cobertura.
(EQP)	Substituição de equipamentos que estão em más condições e pontos de corrosão (proteções, escadas e guarda-corpos).
(RIE)	Revisão das instalações Elétricas.
(RIH)	Revisão das Instalações Hidráulicas.
(EST)	Análise, parecer técnico de engenharia, monitoramento e recuperação de estruturas (marquise, laje da casa de máquinas e estruturas com corrosão).

De acordo com a metodologia proposta, a priorização das manifestações patológicas foi realizada por meio da aplicação da matriz GUT (Tabela 1), sendo o índice final obtido pelo produto entre os parâmetros de gravidade, urgência e tendência (G × U × T).

Tabela 1 – matriz Gravidade x Urgência x Tendência

SIGLAS	GRAVIDADE	URGÊNCIA	TENDÊNCIA	NÚMERO DE PONTOS	PRIORIDADE
FTR	6	8	6	288	7º
IMP	10	10	10	1000	2º

ESQ	6	8	8	384	6º
UAC	6	8	3	144	9º
MEF	8	10	10	800	4º
PPC	3	6	1	18	11º
RSC	6	6	3	108	10º
EQP	10	10	8	800	3º
RIE	8	6	8	384	5º
RIH	6	6	6	216	8º
EST	10	10	10	1000	1º

Embora os itens relacionados ao PPCI possuam elevada relevância normativa no contexto atual das exigências de segurança contra incêndio, a baixa priorização atribuída na matriz GUT decorre da ausência de inconformidades críticas iminentes identificadas durante a vistoria. Dessa forma, as pontuações mais elevadas foram direcionadas às manifestações patológicas que apresentavam risco estrutural e funcional imediato, como infiltrações severas, corrosão de armaduras e sobrecargas estruturais.

Assim sendo, a ordem de prioridades dos serviços de reparos das anomalias e falhas, com suas respectivas recomendações técnicas é apresentada no Quadro 4

Quadro 4 – Prioridades segundo pontuação

PRIORIDADE	SIGLA	DESCRIÇÃO	PONTOS
1º	EST	Análise, parecer técnico de engenharia, monitoramento e recuperação de estruturas (marquise, laje da casa de máquinas e estruturas com corrosão).	1000
2º	IMP	Impermeabilizações nas áreas descobertas.	1000
3º	EQP	Substituição de equipamentos que estão em más condições e pontos de corrosão (proteções, escadas e guarda-corpos).	800
4º	MEF	Manutenção e estanqueidade da fachada.	800
5º	RIE	Revisão das instalações elétricas.	384
6º	ESQ	Revisão de esquadrias, pingadeiras e vedações.	384
7º	FTR	Tratamento de trincas, fissuras e restauração dos danos nos revestimentos de argamassa das fachadas, paredes e muros.	288
8º	RIH	Revisão das instalações hidráulicas.	216
9º	UAC	Uniformização, restauração e disposição dos aparelhos de ar condicionado em locais corretos.	144
10º	RSC	Reparos no sistema de cobertura.	108
11º	PPC	Regularização de itens referentes ao PPCI.	18

Embora os itens EST e IMP tenham apresentado pontuações equivalentes na matriz GUT, a prioridade superior atribuída ao item EST fundamentou-se no maior potencial de comprometimento da estabilidade estrutural e da segurança dos usuários, especialmente devido à presença de corrosão de armaduras, degradação de elementos estruturais e sobrecargas identificadas na edificação.

O panorama diagnóstico evidencia que a edificação encontra-se num estado crítico de conservação, causado primariamente pelo esgotamento da vida útil da sua envoltória. O revestimento original das fachadas, executado em argamassa porosa (tipo pó de pedra/Cirex), perdeu a sua capacidade devido, principalmente, à ausência de manutenções e limpezas ao longo de décadas. Essa negligência transformou as paredes externas em uma superfície altamente absorvente, catalisando a proliferação severa de bolor, algas e a formação de fissuras generalizadas. Como consequência, a falência desta barreira primária permitiu o ingresso contínuo de umidade para os ambientes internos, degradando acabamentos, esquadrias e comprometendo a salubridade das salas comerciais.

Cabe salientar que o município de Porto Alegre possui legislação específica voltada à obrigatoriedade de inspeções prediais periódicas, instituída pela Lei Complementar nº 806/2016. Entretanto, mesmo diante da existência deste instrumento normativo, a edificação analisada apresentou elevado grau de deterioração, evidenciando que a obrigatoriedade legal, isoladamente, não garante a adequada conservação das construções. Fatores como a ausência de manutenção preventiva sistemática, a postergação de reparos e o acúmulo de degradações ao longo das décadas contribuíram significativamente para a evolução das manifestações patológicas identificadas.

Paralelamente à degradação da fachada, o colapso dos sistemas de impermeabilização atua como o segundo vetor de maior impacto na edificação. A inspeção constatou que os terraços descobertos e as lajes de cobertura perderam integralmente a sua estanqueidade, resultando em infiltrações descendentes agressivas que danificaram severamente os tetos e lajes dos pavimentos inferiores, como observado no restaurante do andar térreo, situação indicada na Figura 2. A incapacidade das coberturas em gerir o escoamento das águas pluviais gera um ciclo de deterioração constante, exigindo a demolição e o refazimento integral dos sistemas de manta asfáltica para que se estanque a origem do dano antes de qualquer intervenção estética nos ambientes internos.

Figura 2 – Ações resultantes de infiltrações localizadas.

Por fim, a sinergia entre a umidade crônica e a sobrecarga não prevista culminou no surgimento de anomalias estruturais de risco elevado. O estudo identificou indícios claros de corrosão de armaduras na laje da casa de máquinas e em pilares. Este risco é drasticamente agravado na marquise principal, que, além de sofrer com o empoçamento de águas pluviais, foi indevidamente convertida numa área técnica para suportar dezenas de condensadoras de ar-condicionado. A combinação de oxidação das armaduras com a imposição de cargas para as quais a estrutura não foi originalmente dimensionada configura um cenário de risco iminente, exigindo ações corretivas imediatas e análises estruturais aprofundados para garantir a segurança dos usuários.

5. Conclusão

O diagnóstico técnico da edificação comercial demonstra que o imóvel atingiu um estado crítico de degradação, resultante da combinação direta entre o esgotamento natural da vida útil dos seus materiais e a ausência histórica de manutenções preventivas. O mapeamento patológico evidenciou que a porosidade do revestimento de fachada altamente degrado, aliada ao colapso crônico dos sistemas de impermeabilização nas coberturas, afetou a estanqueidade da edificação e isso resultou em anomalias estruturais severas, como a oxidação de armaduras. Deste modo, conclui-se que o cenário não se resume a desgastes estéticos pontuais, mas a uma falência sistêmica que exige intervenções corretivas profundas para restabelecer a capacidade de resposta da obra às ações externas de intemperismo.

As consequências desta deterioração vão além do prejuízo puramente material, impondo riscos físicos diretos e imediatos aos usuários. A inspeção in loco constatou que a marquise da fachada principal atua sob sobrecarga não prevista de equipamentos de climatização e empoçamento de água, enquanto lajes e pilares apresentam expansão por corrosão com iminência de desprendimento de fragmentos de concreto. A manutenção do uso diário comum como edificação comercial, com estas vulnerabilidades apresentadas, configura um risco contínuo à vida, justificando a nota máxima de criticidade atribuída a estes elementos e transmitindo a grande importância de reparos focados na estabilidade global.

A matriz de diagnóstico e definição de conduta ilustra com clareza os impactos severos da gestão reativa sobre o custo global de manutenção em edificações longevas. A literatura técnica e a prática pericial demonstram que a omissão de rotinas preventivas simples, como a lavagem periódica das fachadas e a desobstrução de ralos pluviais, acelera a falência dos sistemas constituintes da obra. No caso analisado, essa negligência forçou a necessidade atual de substituição integral das mantas asfálticas, escarificação profunda do concreto armado e repintura total do edifício. Desta forma, evidencia-se que a economia inicial gerada pela ausência de manutenções preventivas culmina em despesas financeiras acumuladas e altamente onerosos para a administração atual do condomínio.

A reversão definitiva deste cenário de degradação demanda uma transição estruturada para a cultura da engenharia de manutenção preventiva. A garantia da durabilidade pós-reforma exige que a gestão predial implemente um programa de revisões periódicas rigorosamente alinhado às diretrizes da ABNT NBR 5674:2024 (Manutenção de edificações - Requisitos para o sistema de gestão de manutenção), monitorando a integridade da envoltória e controlando a inserção de novas cargas estruturais. Ao programar as recuperações imediatas com mão de obra especializada e adotar um controle contínuo dos sistemas construtivos, a instituição não apenas resolverá os problemas atuais, mas assegurará a resiliência do patrimônio e a preservação de um ambiente seguro e plenamente funcional para as suas atividades comerciais.

Inspeção predial e diagnóstico de manifestações patológicas em uma edificação de múltiplos pavimentos: estudo de caso em Porto Alegre

Maria Eduarda da Silva DEMBOGURSKI[1]*, Daniel Thomaz FARINA[1]; José Maria de MOURA JUNIOR[1], Angela Borges MASUERO[1] e Denise DAL MOLIN[1]

[1] Laboratório de materiais e ambiente construído, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brasil, mariae.dembogurski@gmail.com

Abstract: O presente artigo tem como objetivo identificar e analisar as manifestações patológicas existentes em uma edificação residencial de múltiplos pavimentos, visando à avaliação de suas condições técnicas, de uso e de manutenção. A partir dessa análise, busca-se subsidiar a elaboração de um plano de manutenção e a definição de ações corretivas e preventivas nos sistemas construtivos, priorizadas conforme o grau de risco associado. A metodologia adotada consistiu na realização de inspeção visual para identificação das anomalias, seguida da aplicação da matriz G.U.T. (Gravidade, Urgência e Tendência), com o intuito de estabelecer a hierarquização das intervenções necessárias. Os resultados indicam que as manifestações patológicas observadas estão predominantemente relacionadas a falhas ou inexistência de manutenção adequada ao longo da vida útil da edificação. As anomalias identificadas comprometem o desempenho e a durabilidade dos componentes dos sistemas construtivos, além de impactarem negativamente as condições de saúde, segurança e habitabilidade dos usuários. Conclui-se que a adoção de um plano de manutenção estruturado e baseado em critérios técnicos é fundamental para a mitigação dos danos identificados e para a preservação da vida útil da edificação.

Keywords: manifestações patológicas, patologia, matriz GUT.

1. Introdução

As edificações, ao longo de sua vida útil, estão sujeitas a processos de degradação que comprometem seu desempenho, segurança e durabilidade. Nesse contexto, as manifestações patológicas na construção civil constituem um campo de estudo essencial, sendo compreendidas como anomalias ou falhas que afetam os sistemas construtivos, podendo ter origem em erros de projeto, execução, materiais inadequados ou ações externas ao longo do tempo (Cavalcanti, 2022; Caporrino, 2015).

A durabilidade das estruturas está diretamente associada à sua capacidade de resistir às ações ambientais e às condições de uso previstas em projeto (Santos *et al.*, 2023). No entanto, a ausência de manutenção adequada favorece o surgimento e a evolução de manifestações patológicas, comprometendo o desempenho estrutural e funcional das edificações (Dutra, 2023). Dessa forma, práticas de manutenção preventiva tornam-se fundamentais para assegurar a vida útil e a segurança das construções (Santos et al., 2018).

Para mitigar os riscos técnicos e econômicos associados à perda de desempenho, a NBR 16747 (2020) estabelece a inspeção predial periódica como ferramenta fundamental. A inspeção leva em conta as características construtivas do edifício, a idade de seus sistemas e componentes, sua vida útil projetada, a exposição ambiental, a presença de agentes e processos de degradação e uma avaliação geral de seu desempenho durante o uso (Reginato *et al.*, 2025). Embora pareça simples, constitui o ponto de partida crítico para qualquer investigação, permitindo identificar causas de danos e facilitar a tomada de decisão

sobre intervenções e programas de manutenção. A inspeção visual, em particular, é amplamente reconhecida como o ponto de partida para investigações de danos, permitindo a identificação preliminar de sintomas, suas possíveis causas e a definição de estratégias de intervenção (Azevedo *et al.; 2023;* Vargas e Torres, 2025). A correta interpretação das manifestações patológicas é, portanto, indispensável para compreender os mecanismos de degradação, identificar suas causas e propor soluções adequadas, assegurando não apenas a recuperação dos danos existentes, mas também a prevenção de ocorrências futuras.

Diante desse contexto, o presente trabalho tem como objetivo realizar o diagnóstico de manifestações patológicas em uma edificação residencial de múltiplos pavimentos, localizada no centro histórico de Porto Alegre, contribuindo para a compreensão dos processos de degradação em edificações inseridas em ambientes urbanos consolidados e fornecendo subsídios técnicos para intervenções adequadas.

2. Delimitação do entorno

O objeto de estudo desta pesquisa consiste em uma edificação de uso residencial localizada no bairro Azenha, na cidade de Porto Alegre, Rio Grande do Sul. Trata-se de uma obra de múltiplos pavimentos com aproximadamente 45 anos de idade, estruturada por um pavimento térreo, cinco pavimentos tipo que abrigam 30 unidades habitacionais, além de um reservatório superior e casa de máquinas. Sob a ótica construtiva, o edifício foi erguido segundo os padrões convencionais de sua época, sustentado por uma estrutura principal em concreto armado, com vedações externas e internas em alvenaria e sistema de cobertura composto por telhas de fibrocimento. A consolidação destas características físicas e estruturais estabelece o cenário técnico para a avaliação do estado de conservação do imóvel, evidenciando o grau de solicitação imposto aos materiais ao longo de mais de quatro décadas de uso contínuo. A Figura 1, a seguir, apresenta a fachada principal da edificação em estudo.

Figura 1 – Fachada principal da edificação em estudo e localização da edificação.

A preservação e a durabilidade desta edificação são diretamente influenciadas pela dinâmica climática e ambiental do seu entorno. O ambiente urbano no qual o prédio está inserido enquadra-se na classe de agressividade 2 (moderada), conforme os parâmetros da NBR 6118:2026. Somado a isso, a cidade de Porto Alegre caracteriza-se por um clima subtropical úmido, marcado por variações térmicas rigorosas ao longo do ano e uma umidade relativa do ar consistentemente elevada. A exposição ininterrupta a essas

intempéries atua como o principal agente acelerador do desgaste mecânico e higrotérmico dos materiais de fachada e dos sistemas de cobertura, criando o ambiente propício para a deflagração das manifestações patológicas que comprometem a estanqueidade da obra.

3. Metodologia

A condução desta pesquisa pautou-se em uma abordagem principalmente quantitativa, estruturada a partir de uma inspeção predial rigorosa fundamentada nas diretrizes do Instituto Brasileiro de Avaliações e Perícias de Engenharia (IBAPE). O levantamento técnico enquadrou-se no Nível 2 de complexidade, caracterizado pela vistoria tátil-visual minuciosa das áreas comuns, aliada ao registro fotográfico e à anamnese com a gestão predial, dispensando a execução de ensaios destrutivos. A adoção dessa metodologia normativa garante a padronização na coleta dos dados, viabilizando a identificação das anomalias construtivas e falhas de manutenção que comprometem o desempenho geral do edifício.

O mapeamento das manifestações patológicas foi direcionado especificamente para os sistemas que afetam a estanqueidade, a estabilidade estrutural e a integridade da envoltória da edificação. Durante as investigações de campo, os componentes construtivos, com destaque para os revestimentos argamassados de fachada, esquadrias, lajes de cobertura e elementos de concreto armado nas áreas de garagem, foram avaliados para correlacionar os sintomas visíveis (como trincas, eflorescências, umidade e bolor) aos seus respectivos mecanismos de degradação. Essa investigação converte a mera observação visual em um diagnóstico técnico, isolando as variáveis necessárias para a etapa subsequente de quantificação e priorização de riscos.

Para o tratamento e a hierarquização das necessidades de intervenção, empregou-se o método de criticidade adaptado da Matriz GUT (Gravidade, Urgência e Tendência). Cada manifestação patológica catalogada recebeu uma pontuação em uma escala de pesos (variando de 1 a 10) que mensura o risco à saúde e segurança dos usuários (Gravidade), o prazo limite para evitar a falência funcional do elemento (Urgência) e o potencial de progressão física do dano (Tendência), categorizando os resultados finais em graus de risco Crítico, Regular e Mínimo. A aplicação desta ferramenta consolida as constatações qualitativas em índices numéricos objetivos, estabelecendo a base estrutural indispensável para a apresentação da matriz de diagnóstico e discussão das condutas terapêuticas na seção de resultados. A metodologia utilizada para classificação da ordem de prioridades dos vícios construtivos encontrados foi desenvolvida com as funções de criticidade e pesos seguintes, segundo Quadro 1.

Quadro 1 – Parâmetros de avaliação de criticidade (Gravidade, Urgência e Tendência) aplicados à matriz GUT

GRAU	GRAVIDADE	PESO
Total	Perda de vidas humanas, falhas graves de concepção e/ou execução de projeto, danos ao meio ambiente ou defeito grave na própria edificação, além de despesas extras com eletricidade, água ou gás no condomínio	10
Alta	Possibilidade de ferimento em pessoas, danos ao meio ambiente ou à própria edificação	8
Média	Desconfortos, deterioração do meio ambiente e outras anomalias construtivas existentes na edificação	6
Baixa	Pequenos incômodos ou pequenos prejuízos financeiros	3
Nenhuma	-	1
GRAU	**URGÊNCIA**	**PESO**
Total	Eventos em ocorrência	10
Alta	Evento prestes a ocorrer	8

Média	Evento prognosticado para breve	6
Baixa	Evento prognosticado para adiante	3
Nenhuma	Evento imprevisto	1
GRAU	**TENDÊNCIA**	**PESO**
Total	Evolução imediata	10
Alta	Evolução em curto prazo	8
Média	Evolução em médio prazo	6
Baixa	Evolução em longo prazo	3
Nenhuma	Não vai evoluir	1

4. Resultados

A consolidação dos dados recolhidos durante a inspeção predial permitiu o mapeamento e o diagnóstico preciso das manifestações patológicas que acometem a edificação. O Quadro 1 sintetiza as principais anomalias construtivas identificadas, focando estritamente nos sistemas de envoltória (fachadas e esquadrias), cobertura e estruturas de concreto armado, que concentram os danos de maior severidade. A estruturação desta matriz correlaciona diretamente o sintoma visual ao seu mecanismo de degradação, estabelecendo a base necessária para a definição das condutas corretivas.

Quadro 1 – Matriz de diagnóstico e definição de conduta

Manifestação patológica	Registro visual	Sintoma	Mecanismo	Causas prováveis	Terapêutica Adequada
Corrosão de Armaduras e Fissuras Estruturais		Fissuras longitudinais no concreto, destacamento do cobrimento e armaduras expostas com oxidação avançada.	Expansão volumétrica eletroquímica do aço (corrosão) por perda de passivação.	Infiltração crônica de umidade no concreto armado e falhas históricas de manutenção corretiva.	Escarificação do concreto contaminado, limpeza mecânica das barras, aplicação de inibidor de corrosão e recomposição com argamassa polimérica.
Degradação do Revestimento de Fachada		Descascamento da pintura, fissuras generalizadas, manchas escuras e proliferação de microorganismos.	Absorção capilar de água e biodeterioração.	Exposição contínua às intempéries climáticas associada à total ausência de lavagem e manutenção periódica.	Lavagem técnica (hidrojateamento), tratamento perimetral de trincas com selante PU, aplicação de fundo preparador e repintura com tinta acrílica Premium (com biocidas).

Perda de Estanqueidade da Cobertura		Infiltrações severas no forro e paredes dos apartamentos do último pavimento (6º andar).	Infiltração descendente de águas pluviais por gravidade.	Deficiências no capeamento e na vedação das telhas de fibrocimento, além de obstrução por falta de limpeza nas calhas.	Revisão integral das vedações, substituição de telhas danificadas, desobstrução e limpeza do sistema de calhas pluviais.
Recalque de Piso de Garagem (Placas Bailarinas)		Fissuras ramificadas, desagregação do concreto e afundamento irregular das placas do piso sob tráfego.	Perda de suporte de fundação combinada com fadiga mecânica por compressão.	Fuga de material do subsolo (provavelmente lavagem do solo por vazamento em tubulações enterradas) e carga de veículos.	Investigação do subsolo para correção de possíveis vazamentos tubulares, recompactação do subleito e concretagem de nova placa estrutural.
Umidade e Bolor em Áreas Internas		Estufamento do forro de gesso, bolhas na pintura e colônias de fungos (mofo) nas paredes.	Saturação higroscópica e deficiência de trocas de ar.	Falha na estanqueidade da fachada externa, infiltrações oriundas de pavimentos superiores e ventilação mecânica/natural insuficiente.	Correção da infiltração na origem (fachada/tubulação), remoção do material contaminado, instalação de exaustores mecânicos e pintura antimofo.
Oxidação e Falha de Esquadrias		Ferrugem aguda nos perfis metálicos, perda de funcionalidade (fechamento) e ingresso de água da chuva.	Corrosão metálica e desgaste de elementos de vedação.	Esgotamento da película anticorrosiva original, exposição à umidade e ausência de pingadeiras nos peitoris.	Lixamento agressivo do metal, aplicação de fundo convertedor de ferrugem, repintura, calafetação do perímetro com selante e instalação de pingadeiras.

A análise qualitativa da matriz evidencia que a perda de estanqueidade da envoltória atua como o principal vetor de degradação do edifício, desencadeando um efeito dominó sobre os demais sistemas. A falência da

pintura e do revestimento das fachadas, impulsionada por décadas sem manutenção preventiva, permitiu que a umidade constante penetrasse na alvenaria, gerando os quadros severos de insalubridade (mofo e bolor) no interior dos apartamentos e acelerando a oxidação das esquadrias metálicas. Conclui-se que o tratamento isolado das anomalias internas será ineficaz se a barreira primária de proteção do edifício (fachada e telhado) não for integralmente restaurada, comprovando a interdependência sistêmica das falhas construtivas mapeadas.

Para transpor esta avaliação qualitativa para um modelo objetivo de tomada de decisão, as manifestações patológicas foram submetidas à análise de criticidade por meio da Matriz GUT (Gravidade, Urgência e Tendência). O Quadro 2 apresenta o índice de priorização extraído da inspeção técnica, filtrado para os sistemas estruturais e de envoltória que compõem o escopo desta pesquisa. A quantificação dessas variáveis permite hierarquizar os reparos não apenas pelo incômodo estético, mas pelo risco real de colapso ou dano à vida humana, orientando o plano de manutenção do condomínio de forma técnica.

Quadro 2 – Avaliação de prioridades pelo método GUT

Sistema / Manifestação	Gravidade (G)	Urgência (U)	Tendência (T)	Pontuação (G x U x T)	Risco Global
Tratamento de trincas e corrosão estrutural	10	10	10	1000	Crítico (1º)
Manutenção e estanqueidade da fachada	6	10	8	480	Regular (5º)
Reparos no sistema de cobertura (telhado)	6	10	8	480	Regular (6º)
Umidade e bolor interno	6	10	8	480	Regular (7º)
Manutenção do piso de concreto (garagem)	10	8	8	480	Crítico (4º)
Revisão de esquadrias e vedações	6	10	6	360	Mínimo (10º)

A interpretação da Matriz GUT comprova que os danos com potencial de ruína mecânica exigem intervenção em caráter emergencial. O tratamento de trincas e da corrosão estrutural atingiu a pontuação máxima possível (1000 pontos), refletindo o perigo iminente de desprendimento de blocos de concreto armado e o risco de perda de estabilidade, caracterizando um cenário de urgência e tendência de evolução gravíssimas. Por outro lado, a recuperação da fachada, cobertura e contenção de umidade apesar de apresentarem menor risco imediato de colapso (Gravidade 6), receberam nota máxima em Urgência (10), pois a sua negligência contínua atua como o combustível para a degradação dos elementos estruturais. Fica evidente que a priorização deve focar primariamente na integridade física do suporte de concreto para, no mesmo plano de ação, restaurar o envoltório que impede a entrada de novos agentes agressivos.

5. Conclusão

A avaliação pericial do imóvel evidencia um nível avançado de deterioração, provocado pela combinação entre o fim da vida útil dos componentes e a ausência contínua de conservação preventiva. As inspeções identificaram falhas graves, como a alta permeabilidade do revestimento externo, a inoperância da impermeabilização da cobertura e o recalque do piso da garagem, anomalias que comprometeram diretamente a proteção contra umidade e a solidez da edificação. Portanto, a situação atual ultrapassa o mero envelhecimento visual e caracteriza um colapso sistêmico, o que demanda obras de recuperação urgentes para devolver a segurança e a habitabilidade à estrutura diante das condições climáticas.

As consequências dessa deterioração impõem riscos físicos e sanitários diretos aos moradores da edificação. A inspeção constatou a oxidação avançada de armaduras em elementos portantes e o recalque de placas de concreto na garagem, anomalias classificadas com o grau máximo de criticidade devido ao perigo de colapso mecânico, além de quadros de insalubridade gerados pela proliferação de fungos no interior das unidades. A permanência dessas vulnerabilidades compromete a segurança global do condomínio, necessitando uma priorização absoluta das recuperações estruturais e da restauração da envoltória.

O Quadro 1 observado no artigo ilustra o impacto negativo da gestão estritamente reativa sobre o custo global de edificações longevas. A omissão de rotinas preventivas básicas, como a lavagem da fachada, a desobstrução de calhas e a investigação precoce de vazamentos no subsolo, atuou como acelerador para a ruína dos sistemas; na prática, essa negligência forçou a necessidade atual de escarificação do concreto armado, reconstrução da laje de piso da garagem e repintura integral do prédio. Evidencia-se, portanto, que a aparente economia gerada pela falta de manutenção preventiva resultou na transferência de passivos financeiros onerosos para a administração atual.

A reversão definitiva deste cenário de degradação exige a transição para uma cultura da engenharia de manutenção contínua. A garantia da durabilidade pós-reforma demanda que a gestão condominial adote um programa de revisões periódicas rigorosamente alinhado às diretrizes da ABNT NBR 5674, monitorando a integridade da envoltória e a estabilidade das estruturas de concreto. Ao executar os reparos críticos priorizados pela matriz de risco utilizando mão de obra especializada e ao instituir o controle preventivo dos sistemas, o condomínio não apenas sanará as falhas existentes, mas assegurará a durabilidade do patrimônio e a preservação de um ambiente habitacional seguro e salubre.

Abstract: This study is part of a body of research on the historic built heritage of the city of Viseu, Portugal, and presents a detailed characterisation of a building located in its historic centre. The aim is to advance technical and scientific knowledge of timber structures in Portuguese-built heritage, with particular emphasis on tabique walls and timber floors. The methodology included an architectural and structural survey of the building, complemented by in situ inspections and non-destructive testing, including measurements using the Resistograph® and the determination of natural vibration frequencies in the timber floors through environmental vibration analysis using a seismograph. These procedures made it possible to assess the state of conservation of the timber elements, identify potential pathologies and obtain relevant parameters for structural analysis. The environmental vibration tests made it possible to identify the frequencies of the first vertical vibration modes of the floors, which ranged from 16.97 to 23.32 Hz. These results allowed for an indirect estimation of the floors' stiffness and revealed that whether or not the floorboards are included is relevant to the analytical calculation of the floor frequencies. It was also observed that the average Resistograph® values are consistent with the vibration frequencies of the floors, that is, the floor with the lowest frequency also has the lowest Resistograph® value. The study thus contributes to more informed and sustainable rehabilitation interventions.

Keywords: Tabique walls, Inspection, Timber floors, Stiffness of the floors, Resistograph®

1. Introdução

A reabilitação do património exige compreensão aprofundada do comportamento estrutural dos sistemas tradicionais. No contexto português, as paredes de tabique e os pavimentos de madeira maciça constituem soluções amplamente difundidas até o início do século XX. Apesar da sua relevância histórica e estrutural, estes elementos são frequentemente substituídos por desconhecimento do seu desempenho mecânico. A ausência de diagnóstico baseado em dados experimentais conduz a intervenções excessivamente intrusivas.

Esta investigação tem por objetivo complementar um conjunto de estudos conduzidos no Departamento de Engenharia Civil da ESTGV/IPV sobre o edificado histórico do centro urbano de Viseu (Fernandes, 2015; Padrão et al., 2021a; Padrão et al., 2021b). Esses estudos evidenciam que a substituição indiscriminada de paredes de tabique e pavimentos de madeira decorre, sobretudo, da ausência de caracterização experimental sistemática do seu desempenho estrutural, contrariamente à perceção recorrente de que tais elementos desempenham uma função meramente construtiva ou de compartimentação. Padrão et al. (2021a; 2021b) demonstra que as paredes de tabique podem contribuir para a segurança estrutural, quando estão sujeitas a ações gravíticas, bem como para o contraventamento global da estrutura.

Os pavimentos de madeira assumem um papel essencial na distribuição de esforços verticais e na estabilização do conjunto estrutural, como demonstrou Ilharco et al. (2018). Neste tipo de construções,

também é comum a existência de paredes de alvenaria de pedra ao nível do rés-do-chão. Estes elementos de elevada rigidez são capazes de dissipar as cargas gravíticas existentes na zona central do edifício e provenientes dos pisos superiores, conduzidas pelas paredes interiores de tabique que se apoiam diretamente nos elementos horizontais de madeira. Esta interação entre paredes de alvenaria de granito e as estruturas de madeira maciça configuram um sistema híbrido tradicional com comportamento integrado.

O edifício aqui estudado possui um sistema construtivo comum ao património construtivo da zona onde está inserido, isto é, paredes exteriores e em contacto com o solo em alvenaria de granito, paredes interiores (e algumas paredes exteriores situadas em pisos superiores) em tabique e pavimentos e cobertura em estrutura de madeira maciça. Na região de Viseu e em diversas regiões de Portugal, há uma grande presença das paredes de tabique no património edificado.

Com este estudo pretende-se contribuir para um melhor conhecimento dos sistemas construtivos usados neste tipo de edifícios, combinando ensaios semi-destrutivos e não destrutivos, realizados em elementos de madeira, com a análise e discussão dos resultados. A informação obtida poderá vir a ser relevante e contribuir para futuros trabalhos de conservação e/ou reabilitação de edifícios situados em centros históricos, em particular os da cidade de Viseu.

2. Caracterização Construtiva do Edifício

O edifício, objeto de estudo (Nicolau, 2023), localiza-se na Rua do Gonçalinho, n.º 33, na cidade de Viseu. O edifício em estudo é uma habitação multifamiliar do século XIX, com 4 pisos elevados e cobertura (ver Figura 1). Trata-se de uma construção com paredes de alvenaria de granito (situadas nas fachadas e no arranque de paredes interiores em contacto com o solo), com paredes interiores em tabique (encontrando-se, também, em algumas paredes exteriores elevadas, fruto de ampliações posteriores) e pavimentos e cobertura em madeira maciça. Foi observada a presença pontual de alvenaria de tijolo maciço em paredes exteriores situadas em pisos superiores (sobretudo na fachada principal). Foram identificadas variações geométricas entre pisos, associadas a diferentes fases construtivas. A cobertura era revestida em telha cerâmica tradicional. Observou-se que existiam paredes de tabique simples, paredes de tabique com tábuas diagonais incorporadas, todas com fasquio de secção retangular. Foi verificada grande variabilidade dimensional, característica desta técnica artesanal tradicional, tábuas verticais com secção retangular ou costaneira, espaçamento irregular entre elementos e espessuras variáveis de argamassa (Figura 2a).

a) Alçado principal do edifício b) Materiais existentes na fachada

Figura 1 – Edifício objeto de estudo

Os conetores metálicos eram constituídos por pregos forjados de secção variável, característica de edifícios mais antigos. Na ligação entre as paredes de tabique e as paredes de alvenaria resistentes foram encontrados ligadores metálicos em chapa, chumbados na alvenaria de granito e pregados na parede de tabique, também característicos deste sistema construtivo, como ilustrado na Figura 2b. Essas ligações influenciam diretamente a rigidez global, a transferência de esforços horizontais e o comportamento sob ações dinâmicas. A inspeção visual permitiu identificar que se tratava de um edifício com um sistema construtivo idêntico aos descritos e estudados no centro histórico de Viseu (Fernandes, 2025; Padrão et al., 2020).

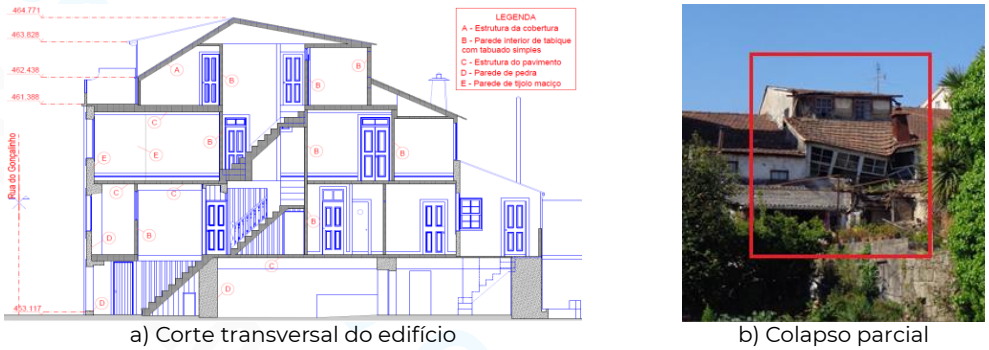
b) Ligação com 1 ligador metálico

Figura 2 – Paredes de tabique com tábuas costaneiras e diagonais, de secção variável, e ligadores metálicos

3. Metodologia Experimental

A metodologia experimental adotada envolveu o levantamento arquitetónico e estrutural do edifício e a sua inspeção e diagnóstico com recurso a ensaios não destrutivos: com um Resistograph®, para aferir o estado de conservação das madeiras e de vibração ambiental em pavimentos de madeira, através de sismógrafo.

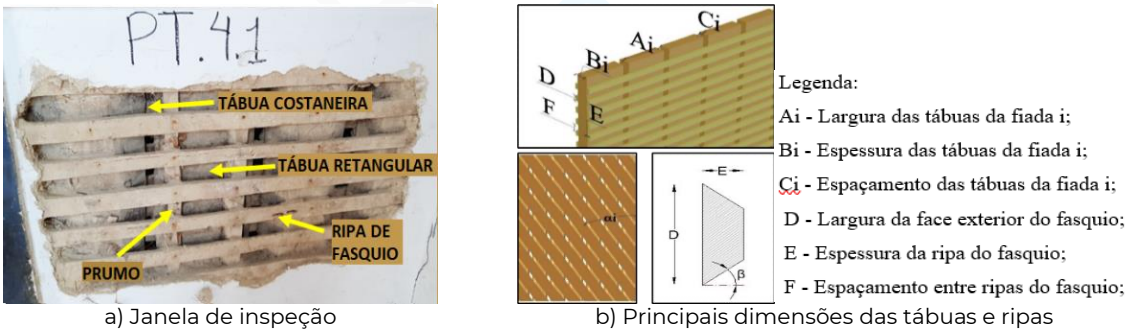
3.1 Levantamento Arquitetónico e Estrutural



O levantamento arquitetónico e estrutural foi desenvolvido através de uma inspeção visual sistematizada, medições diretas, abertura de janelas de inspeção e registo fotográfico detalhado. Inicialmente, procedeu-se ao levantamento métrico completo do edifício, incluindo a determinação das dimensões globais, alturas piso a piso, espessuras de paredes, geometrias de vãos e caracterização volumétrica geral. Estas medições foram auxiliadas pela confrontação com plantas, cortes e alçados de arquitetura recentes, permitindo identificar a organização estrutural e a distribuição dos sistemas construtivos por piso. No corte transversal representado na Figura 3a é possível observar que as paredes exteriores do alçado principal são em alvenaria de pedra (piso 0) e tijolo maciço (pisos superiores, no alçado principal), enquanto as paredes exteriores da envolvente do edifício e as divisórias interiores são em tabique. No momento da primeira inspeção, o edifício encontrava-se desocupado e com elevado grau de deterioração, incluindo o colapso parcial da estrutura posterior (Figura 3b), circunstância que condicionou a seleção das áreas passíveis de inspeção segura.

3.1.1 Levantamento das Paredes de Tabique

Com o objetivo de caracterizar a tipologia das paredes de tabique, foi implementada uma metodologia baseada na abertura controlada de janelas de inspeção, com dimensões aproximadas de 1,00 m x 0,50 m. Cada parede foi identificada segundo nomenclatura específica por piso (ex.: PT.4.13) (ver Figura 4a), permitindo rastreabilidade /e organização dos dados recolhidos.



A abertura das janelas de inspeção possibilitou a identificação da constituição interna das paredes, tábuas verticais (incluindo costaneiras), ripas horizontais (fasquio), eventuais tábuas diagonais associadas a zonas com vãos, contribuindo para maior rigidez local e elementos de ligação e apoios às estruturas adjacentes. Observou-se predominância de paredes simples com tábuas verticais (Padrão et al., 2020). Foram ainda

recolhidos dados dimensionais médios das tábuas verticais e das ripas de fasquio, abrangendo largura, espessura e espaçamento, de acordo com o esquema geral ilustrado na Figura 4b. Os dados obtidos são apresentados na Tabela 1, permitindo posterior comparação com valores da bibliografia (Padrão et al, 2021a; Padrão et al., 2021b). A dimensão dos elementos constituintes, nomeadamente os elementos resistentes em madeira de pinho bravo, revela-se adequada e dentro daquilo que são as características típicas das paredes de tabique inseridas nos edifícios típicos do centro histórico de Viseu (Padrão et al, 2020).

3.1.2 Levantamento dos Pavimentos de Madeira

Os pavimentos eram constituídos por soalho de madeira, com uma espessura média de 2,5 cm, apoiados em vigas secundárias, igualmente de madeira pinheiro-bravo (Pinus pinaster). O pavimento possuía um forro de teto, em tabuado de madeira, com uma espessura média de 2,0 cm, que se desenvolvia perpendicularmente às fachadas principal e posterior, sendo que ao longo do edifício eram apoiadas nas vigas secundárias, paralelas à fachada principal que conjuntamente com os frechais das paredes de tabique

constituíam o pavimento. A inspeção permitiu identificar a orientação dos vigamentos e a disposição das paredes de tabique, paralelas e perpendiculares às vigas principais, influenciando o seu comportamento como elementos de compartimentação, ver as plantas ilustradas nas Figuras 5, 6 e 7.

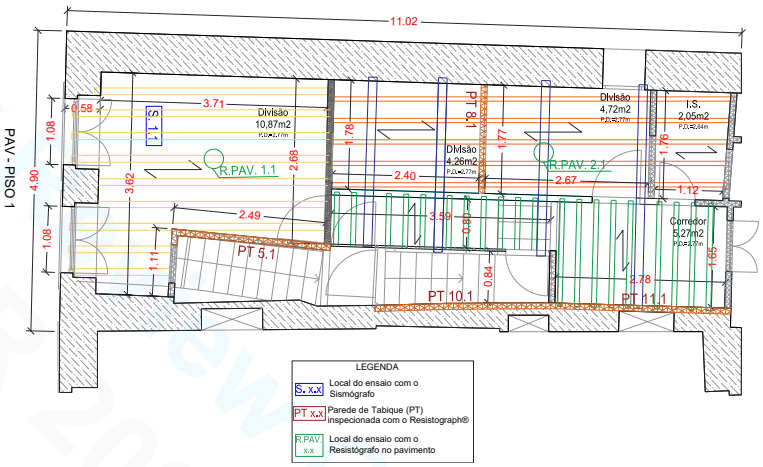

Figura 5 – Planta estrutural do piso 1

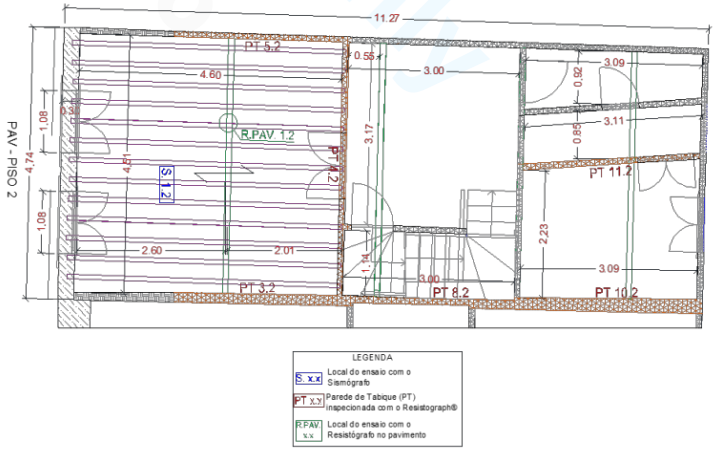

Figura 6 – Planta estrutural do piso 2

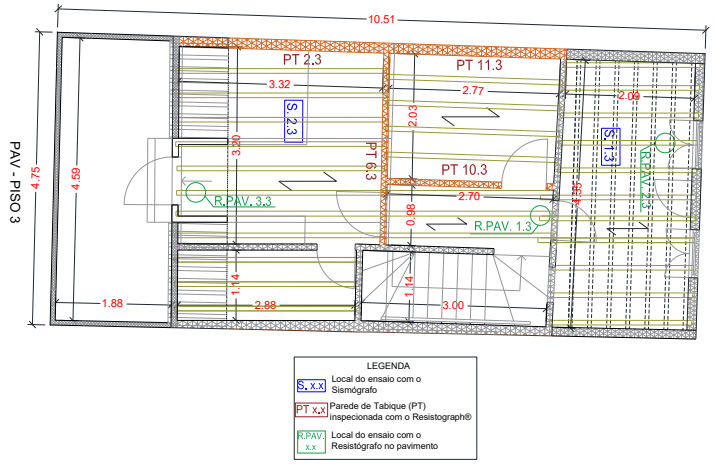

Figura 7 – Planta estrutural do piso 3

Na Figura 8 apresentam-se, em corte, as secções médias dos pavimentos dos pisos 1, 2 e 3. Na Tabela 2 apresentam-se as dimensões médias dos elementos de madeira que compõem essas secções. Identificaram-se diferenças entre pisos, tanto em termos dimensionais como no estado de conservação. Observou-se que algumas vigas apresentavam degradação superficial, devido a ataque de caruncho e de fungos de podridão (ver Tabela 2).

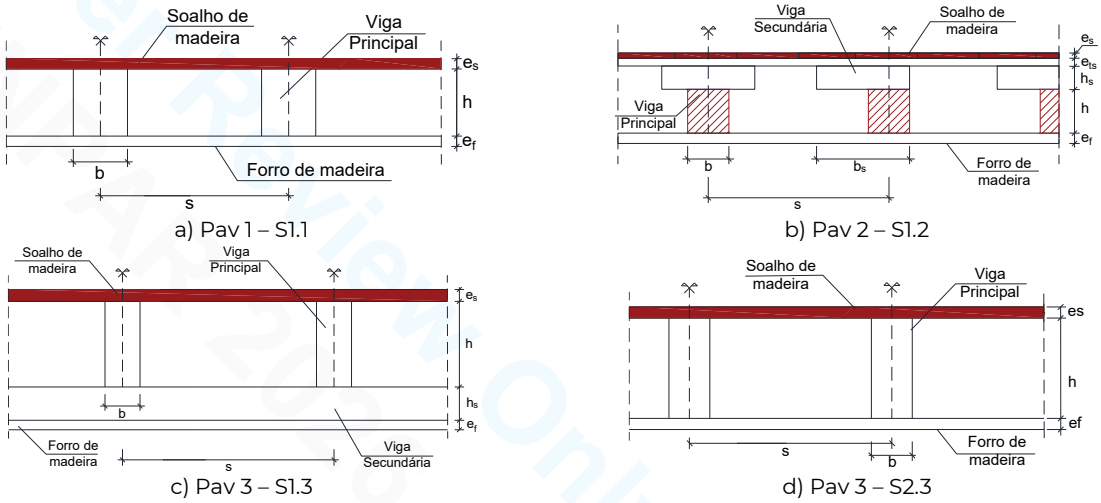

Figura 8 – Secção média dos elementos de madeira que compõem os pavimentos dos pisos 1, 2 e 3

Tabela 2 – Características geométricas médias das secções dos elementos de madeira dos pavimentos

Pavimento	Características geométricas médias (m)										
	Vigas Principais					Soalho	Tabuado Superior	Forro	Vigas Secundárias

Pav. 3 – S2.3	0,075	0,180	0,170	0,390	3,32	0,025	0,000	0,020	0,000	0,000	0,000

Nota: h' representa a altura da viga principal desprezando a área degradada.

3.2 Inspeção e Diagnóstico

Como referido anteriormente, a campanha de ensaios experimentais *in situ* pretendia avaliar o estado de conservação de alguns elementos de madeira, designadamente nos pavimentos e nas paredes de tabique. Para tal, foram realizados dois tipos de ensaios: de vibração ambiental e com o Resistograph®.

3.2.1 Ensaios de Vibração Ambiental

O procedimento utilizado no ensaio de vibração ambiental dos pavimentos, envolveu a utilização de um sismógrafo, para a medição das acelerações verticais dos pavimentos e/ou das vigas dos pavimentos submetidas à vibração ambiente e à aplicação de impulsos verticais espaçados no tempo. Nos ensaios foram utilizados sismógrafos constituídos por acelerómetros triaxiais (GeoSIG GSR-18bit), com uma frequência de aquisição de 250 Hz, tendo os mesmos sido posicionados em pontos de maior deslocamento modal, conforme os modos de vibração com interesse em identificar. Efetuados os registos temporais em aceleração, os resultados são decompostos em frequências através da utilização de algoritmos clássicos de

For Peer Review Only

FFT (Transformada Rápida de Fourier). Neste caso os registos foram analisados através do programa GeoDAS. Posteriormente, estes resultados foram comparados com valores estimados através de um método analítico, considerando diferentes hipóteses para quantificar a rigidez. Neste estudo, o sismógrafo foi posicionado nos pisos 1, 2 e 3 e foram feitos, na totalidade, 4 ensaios em locais diferentes (ver localizações nas Figuras 5, 6 e 7).

3.2.2 Ensaios com Resistograph®

Para avaliar o estado de conservação dos elementos de madeira, foi tida em conta a variação do estado de conservação em profundidade das zonas de madeira da secção de perfuração. O equipamento funciona através da introdução forçada de uma agulha metálica de aproximadamente 1,5 mm no fuste e 3 mm na extremidade de corte, que penetra no elemento de madeira maciça a uma velocidade linear e de rotação constantes. O equipamento apresenta controlo automático da velocidade de avanço e de rotação, sendo a duração típica de uma perfuração da ordem de 1 a 2 minutos para profundidades até cerca de 44 cm (22 a 44 cm/min de velocidade média). O aparelho mede e regista continuamente a resistência à perfuração (energia despendida para avançar através do material), gerando um resistograma (gráfico detalhado).

O estado de conservação das zonas de uma secção de madeira é classificado em função da leitura do Resistograph®, quando comparada com o valor médio:

- **Bom estado de conservação**: quando a leitura é superior a 50% do valor médio, sendo estas zonas assinaladas a verde na barra de abscissas do gráfico (ver Figura 12);
- **Ligeiro estado de degradação**: quando a leitura se encontra entre 25% e 50% do valor médio, sendo estas zonas assinaladas a amarelo na barra de abscissas do gráfico (ver Figura 12);
- **Estado de degradação avançado**: quando a leitura é inferior a 25% do valor médio, sendo estas zonas assinaladas a vermelho na barra de abscissas do gráfico (ver Figura 12).

Refira-se que o valor médio corresponde à média dos valores da ordenada, entre o início e o fim do elemento ensaiado.

A sondagem com o Resistograph® nos pavimentos foi efetuada mediante o possível acesso às vigas dos pavimentos (Figura 9a). Executou-se o ensaio em 6 vigas do pavimento do edifício, 2 vigas do pavimento do piso 1 (ver localização na Figura 5), 1 viga do pavimento do piso 2 (ver localização na Figura 6) e 3 vigas do pavimento do piso 3 (ver localização na Figura 7). A realização do ensaio em paredes de tabique é semelhante (Figura 9b). Executou-se o ensaio em 12 paredes de tabique, 2 paredes do piso 1, 6 paredes do piso 2 e 4 paredes do piso 3. As localizações destes ensaios estão representadas nas Figuras 5, 6 e 7.

a) Vigas b) Paredes de tabique

Figura 9 – Realização do ensaio com Resistograph®

4. Análise e Discussão dos Resultados Obtidos

Inicialmente, são apresentados os resultados dos ensaios realizados nos pavimentos, que são: ensaio de vibração ambiental e o ensaio com a utilização do Resistograph®. Posteriormente, apresentar-se-ão os resultados com o Resistograph® nas paredes de tabique.

4.1 Ensaios nos Pavimentos de Madeira

Os resultados experimentais do ensaio de vibração ambiental dos pavimentos serão comparados com os valores estimados das frequências dos pavimentos. Também se procurou correlacionar os resultados dos ensaios com Resistograph® com os resultados do ensaio de vibração ambiental, de modo a avaliar a influência da degradação dos elementos de madeira na rigidez dos pavimentos.

4.1.1 Ensaio de vibração ambiental

Os ensaios de vibração ambiental permitiram identificar as frequências dos primeiros modos de vibração nas direções longitudinal, transversal e vertical. A Tabela 3 apresenta os resultados referentes ao modo vertical, considerado o mais relevante para este estudo. Estes valores encontram-se na gama de frequência previsível para este tipo de pavimento, de acordo com a bibliografia de referência (Ilharco et al., 2018). Os valores obtidos, afastam-se dos valores da frequência associada às sobrecargas, resultando numa situação de conforto na utilização do pavimento.

Tabela 3 – Registo dos resultados com o Sismógrafo (modo de vibração na direção vertical)

Ensaio	Localização	Vão (m)	Frequência (Hz)
Pav. 1 - S1.1	Teto do piso 0	3,71	16,97
Pav. 2 - S1.2	Teto do piso 1	2,60	22,83
Pav. 3 - S1.3	Teto do piso 2	2,09	20,14
Pav. 3 - S2.3	Teto do piso 2	3,32	23,32

4.1.2 Valores estimados das frequências dos pavimentos

Para se estimar analiticamente os valores das frequências dos pavimentos ensaiados é necessário quantificar as ações permanentes atuantes, estimar a rigidez das secções dos pavimentos e caracterizar as propriedades da madeira. Estimou-se que todos os elementos constituintes dos pavimentos são da madeira de classe de resistência C18 (Espécies coníferas) de acordo com a NP EN 338 (2003). O valor médio do módulo de elasticidade (E_{mean}) admitido foi 9,0 GPa e para a massa volúmica (ρ_{mean}) assumiu-se 380 Kg/m^3.

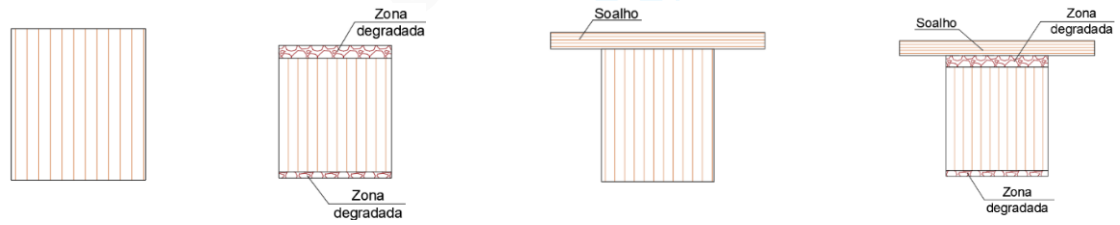
Os cálculos foram efetuados segundo o Eurocódigo 5 (2022), através do procedimento usado em Ilharco et al (2018) na identificação dinâmica dos pavimentos. Para um pavimento simplesmente apoiado em duas faces opostas, a frequência fundamental *f* pode ser calculada usando a Equação 1.

$$f = \left(\frac{\pi}{2 \times L^2}\right) \times \sqrt{\frac{EI_l}{m}} \quad (1)$$

Em que: *L* - vão do pavimento (m); *m* - massa por unidade de área (Kg/m^2); EI_l - rigidez equivalente de flexão (N.m^2/m). A rigidez equivalente de flexão, EI_l, é calculada através da Equação 2, considerando o valor médio do módulo de elasticidade e as características geométricas médias das vigas desses pavimentos.

$$EI_l = \left(E_{mean} \times \frac{I_l}{s}\right) \quad (2)$$

Em que: E_{mean} - valor médio do módulo de elasticidade (GPa); I_l – momento de inércia da secção das vigas (m^4); s – espaçamento entre vigas, medido entre eixos (m).



As secções médias dos pavimentos encontram-se ilustradas na Figura 8 e as características geométricas

estão resumidas na Tabela 2. Na Tabela 4 apresentam-se os valores das ações permanentes adotadas.

Na cálculo das frequências dos pavimentos foram consideradas 4 hipóteses: Hip 1- considerou-se a secção total das vigas principais; Hip 2 - considerou-se a secção das vigas principais, desprezando a área degradada, medida com o Resistograph®; Hip 3 - considerou-se a secção das vigas principais com a contribuição do soalho (secção em T); Hip 4 - considerou-se a secção das vigas principais com a contribuição do soalho (secção em T), desprezando a área degradada das vigas, medida com o Resistograph®. Na Figura 10 representam-se esquematicamente, as 4 hipóteses consideradas, com as devidas adaptações às secções médias dos pavimentos. Na Tabela 5 apresentam-se os valores estimados das frequências dos pavimentos.

Tabela 4 – Valores das ações permanentes utilizados no cálculo das frequências

Ações	Pav. 1 – S1.1	Pav. 2 – S1.2	Pav. 3 – S1.3	Pav. 3 – S2.3
Peso Próprio da Viga Principal (kN/m)	0,054	0,024	0,051	0,051
Peso Próprio do Soalho (kN/m)	0,035	0,020	0,042	0,037

c) Hip 3 – secção da viga principal com a contribuição do soalho

d) Hip 4 - secção da viga principal com a contribuição do soalho, desprezando a área degradada

Figura 10 – Esquema, em corte, das 4 hipóteses consideradas no cálculo das frequências dos 3 pavimentos

Tabela 5 – Valores estimados das frequências dos pavimentos

Pavimento	Vão (m)	Massa (Kg/m²)	Hip 1		Hip 2		Hip 3		Hip 4	
			EI_l (Nm²/m)	*f* (Hz)	EI_l (Nm²/m)	*f* (Hz)	EI_l (Nm²/m)	*f* (Hz)	EI_l (Nm²/m)	*f* (Hz)
Pav. 1 - S1.1	3,71	32,51	489871,62	14,01	136933,28	7,41	1322189,50	23,02	490794,16	14,02
Pav. 2 - S1.2	2,60	37,28	87771,43	11,27	-	-	1256640,69	42,66	1256640,69	-
Pav. 3 - S1.3	2,09	43,98	737191,01	46,56	470714,54	37,20	1950406,06	75,73	1137460,32	57,83
Pav. 3 - S2.3	3,32	30,84	841153,85	23,53	708605,77	21,60	2333235,83	39,20	1183197,25	27,91

Nota: Não existem resultados para o Pav. 2 – S1.2 (Hip 2 e Hip 4) porque a viga principal não apresentava degradação.

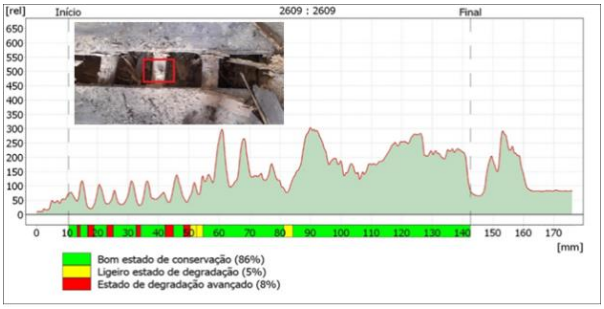
De uma forma geral, os valores obtidos no cálculo das frequências são consistentes com as 4 hipóteses estudadas, isto é, a frequência cresce com o aumento da rigidez da secção. Observa-se que as frequências obtidas *in situ* são normalmente superiores às obtidas pela utilização da Equação 1.

Na Hip 1, o valor obtido para as frequências é mais baixo porque se desprezou a contribuição do soalho, o que mostra que a rigidez real do sistema é superior.

Na análise dos resultados obtidos na Hip 3 (contribuição do soalho) observa-se que eles são consideravelmente superiores, o que leva a concluir que efetivamente a ligação entre o soalho e a viga principal não é tão eficaz como no modelo analítico. A rigidez real encontra-se entre a Hip 1 e a Hip 3. Ao considerar-se a degradação (Hip 2), os resultados analíticos aproximam-se dos experimentais nos Pav. 1 - S1.1 e Pav. 3 - S2.3, evidenciando a relevância para o estado de conservação do material na avaliação estrutural.

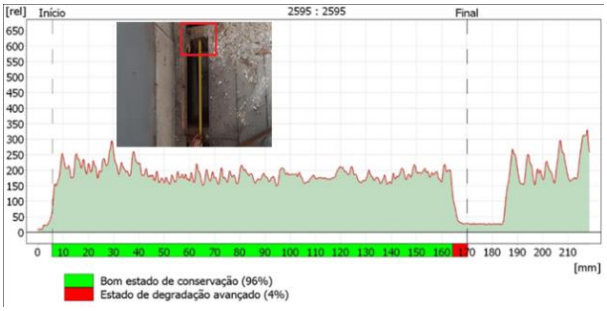
No caso particular do ensaio Pav. 3 - S1.3, os valores teóricos obtidos na Hip 1 são muito superiores (mais do dobro) quando comparados com o valor experimental. Como esta frequência está dentro dos valores obtidos para os outros pavimentos, crê-se que pode existe algum aspeto na parte da inspeção que não tenha sido bem aferido e que condiciona todo o cálculo subsequente.

De referir, ainda, que as incertezas existentes sobre o tipo de apoios (podem não ter a rotação totalmente livre), podem justificar, em parte, as diferenças entre os valores estimados e os experimentais.



De forma global, conclui-se que a rigidez, o estado de conservação e a interação entre elementos são determinantes no comportamento dinâmico, sendo indispensável a validação experimental dos modelos teóricos.

4.1.3 Ensaios com Resistograph®



As sondagens com o Resistograph® nos pavimentos foram efetuadas, quer a partir da face superior do elemento, quer a partir da face inferior, mediante a acessibilidade às vigas. Foram ensaiadas 2 vigas de suporte dos pavimentos (localizações R.PAV.2.1 e R.PAV.1.2) e 4 vigas principais das secções dos pavimentos. Na Tabela 6 resumem-se, apenas, os resultados dos 4 ensaios nas vigas principais dos pavimentos e na Figura 11 ilustram-se dois exemplos dos resistogramas obtidos.

Tabela 6 – Dimensões das vigas e resultados do Resistograph®

Pavimento	Localização	Dimensões – b x h (cm)	Valor médio
Pav. 1	R. PAV.1.1	11,0 x 13,0	149
Pav. 3	R. PAV.1.3	8,0 x 18,0	212
	R. PAV.2.3	7,5 x 18,0	183
	R. PAV.3.3	7,5 x 18,0	229

a) R.PAV.1.1 (b=11cm; h=13cm) - Valor médio = 149

b) R.PAV.2.3 (b=7,5cm; h=18cm) - Valor médio = 183

Figura 11 – Gráficos dos ensaios do Resistograph® realizado em vigas principais dos Pisos 1 e 3

Na Figura 11ª observa-se o gráfico do ensaio efetuado numa viga principal do piso 1 (R.PAV. 1.1), onde se realizou o ensaio de vibração ambiental, assim como, as características do elemento ensaiado (tipo de elemento e respetiva dimensão). Este ensaio foi efetuado a partir da face superior do elemento, atingindo um comprimento de 140 mm, tendo-se verificado que o elemento possui grande heterogeneidade em profundidade, com uma acentuada variação nos primeiros 50 mm do elemento, que indica um estado de degradação avançado, observado visualmente. Na Figura 11b, ilustra-se o gráfico do ensaio efetuado numa

viga principal do piso 3 (R.PAV.2.3), Este ensaio foi efetuado a partir da face superior da viga principal, atingindo um comprimento de 170 mm. O resultado mostra que o elemento é homogéneo em profundidade, com um estado avançado de deterioração na face inferior, que visualmente não se observou. As localizações em planta destes ensaios podem ser visualizadas nas Figuras 5 e 6.

Em quase todos os elementos, constatou-se alguma homogeneidade de valores (estado de conservação). Com efeito, os picos nos gráficos das vigas ensaiadas corresponderam à penetração da agulha nas fibras (situadas na direção perpendicular), nomeadamente nos anéis de Primavera e de Outono. No início e no final da secção, verificaram-se valores de resistência à penetração menores, o que corresponde a alguma degradação superficial. O comprimento de sondagem (perfuração), em quase todos os casos, atingiu a distância face a face do elemento ensaiado (na direção da perfuração).

4.1.4 Efeito aproximado da degradação na madeira na frequência dos pavimentos

Um aspeto que se procurou analisar foi a correlação dos ensaios de vibração ambiental e do Resistograph®. Na Tabela 7 comparam-se os resultados desses dois ensaios. Como o número de ensaios é insuficiente para se estabelecer uma correlação, procurou-se analisar estes resultados na tentativa de se identificar alguma tendência entre eles. Observa-se uma correspondência entre os dois resultados, isto é, o pavimento que tem a menor frequência, também tem o menor "valor de Resistograph®", mostrando, o comportamento esperado, que a perda de resistência de um elemento de madeira provoca uma redução da rigidez do pavimento e, naturalmente, da sua frequência.

Tabela 7 – Registo dos resultados com o Sismógrafo (modo de vibração na direção vertical)

Pavimento	Resistograph® (valor médio)	Frequência Experimental (Hz)
Pav. 1 - S1.1	149	16,97
Pav. 3 - S1.3	183	20,14
Pav. 3 - S2.3	229	23,32

4.2 Ensaios nas Paredes de Tabique

Como referido na secção 3.2.1, executou-se o ensaio com Resistograph® em 12 paredes de tabique do edifício. No Tabela 8 apresentam-se os resultados obtidos, assim como a identificação de todas as paredes de tabique ensaiadas e as espessuras das respetivas tábuas.

Da análise dos resultados, concluiu-se que as tábuas das paredes de tabique ensaiadas (exteriores e interiores, em cada piso) apresentaram um bom estado de conservação, com degradação superficial num número reduzido de elementos.

5. Considerações Finais

A fase de inspeção e diagnóstico demonstrou ser fundamental para a compreensão e preparação, bem como para a escolha dos locais e dos ensaios experimentais a realizar. Neste tipo de edifícios, em que os sistemas construtivos são muitas vezes adaptados a situações específicas que não podem ser previstas é necessário realizar uma inspeção o mais detalhada possível para mitigar as dúvidas que possam existir sobre os materiais utilizados e o sistema construtivo existente.

Através do ensaio de vibração ambiental, constatou-se que as frequências para o primeiro modo de vibração na direção vertical, encontram-se dentro da gama de frequências previsível para este tipo de pavimentos. Este ensaio foi útil para aferir indiretamente a rigidez dos pavimentos de madeira.

Os resultados obtidos com o Resistograph® mostraram que as vigas de madeira dos pavimentos apresentaram um bom estado de conservação, ainda que algumas apresentem degradação superficial

ligeira. As tábuas das paredes de tabique ensaiadas (exteriores e interiores, em cada piso) também apresentaram um bom estado de conservação, com degradação superficial num número reduzido de elementos.

O estudo demonstrou que as soluções construtivas seguem um padrão regional coerente e que a madeira mantém uma capacidade resistente adequada.

Tabela 8 – Resultados com o Resistograph® nas Paredes de Tabique

Localização	Identificação	Espessura das tábuas (cm)	Valor médio
Piso 1	PT 5.1	4,54	157
	PT 8.1	4,10	224
Piso 2	PT 3.2	3,36	82
	PT 4.2	3,99	200
	PT 5.2	4,33	151
	PT 8.2	4,73	182
	PT 10.2	4,25	170
	PT 11.2	4,20	172
Piso 3	PT 2.3	4,34	180
	PT 6.3	3,45	219
	PT 10.3	3,00	237
	PT 11.3	4,20	171

Impacts of Deficient Maintenance on the Integrity and Durability of Reinforced Concrete Reservoirs

Amanda Ávila de **SOUZA**, Marília Carla Araújo Mendonça de ALENCAR

[1] Instituto Nova Engenharia, São Paulo, Brasil, amanda@construpat.com.br
[2] Instituto Nova Engenharia, Fortaleza, Brasil, marilia@construpat.com.br

Abstract: Reinforced concrete reservoirs are widely used in condominiums, industrial facilities, commercial buildings, logistics warehouses, and residential buildings, being intended for the storage of potable water for human consumption and non-potable water for technical uses, such as fire prevention and firefighting systems. These structures play a fundamental role in building water supply systems; however, the absence or insufficiency of systematic technical inspection and maintenance programs is recurrently observed, a condition that favors the progression of deterioration mechanisms throughout their service life.

Cracking constitutes an inherent manifestation in reinforced concrete structures and may be associated with factors such as shrinkage, thermal variations, structural actions, design conditions, and execution-related aspects. In the absence of adequate corrective measures and waterproofing systems with compatible performance, these cracks begin to act as preferential pathways for the ingress of water and aggressive agents into the concrete, favoring the occurrence of persistent infiltration, the advancement of carbonation processes, and, consequently, the depassivation of the reinforcement.

The depassivation of steel triggers corrosive processes characterized by the volumetric expansion of the steel itself, which induces internal stresses in the concrete, promoting cover spalling and the progressive reduction of the effective steel cross-sectional area. These phenomena result in a gradual loss of load-bearing capacity, compromising the structural integrity, durability, and functional performance of the reservoirs. In more severe situations, the evolution of these processes may culminate in localized or generalized structural collapse, in addition to risks associated with contamination of the stored water.

In this context, this article presents and discusses the main pathological manifestations associated with deficient maintenance in reinforced concrete reservoirs, such as efflorescence and failures in waterproofing systems, as well as the risks resulting from this scenario, reinforcing the importance of preventive maintenance as a fundamental strategy for preserving the structural integrity and durability of these structures.

Keywords: Water reservoir; Building maintenance; Concrete degradation; Corrosion; Waterproofing.

1. Introduction

Reinforced concrete reservoirs constitute fundamental elements for the functional performance of buildings, as they ensure water storage and supply regulation, while also meeting, in many cases, demands related to human consumption, technical reserves, and fire prevention and firefighting systems. Due to their function, such structures remain continuously subjected to the action of water, to stresses resulting from hydrostatic pressure, and to exposure conditions that require adequate performance in terms of watertightness, safety, and durability throughout their service life.

Although reinforced concrete is widely recognized for its versatility and robustness, its performance should not be interpreted as inherent or permanent, but rather as the result of the interaction among design, execution, conditions of use, and, above all, maintenance. In this regard, Helene (1992) emphasizes that the durability of concrete structures depends directly on the control of deterioration mechanisms and on the adoption of preventive measures compatible with the exposure conditions, while Souza and Ripper (1998) observe that pathological manifestations should be understood as symptoms of ongoing degradation processes, whose origin is often associated with failures accumulated throughout the structure's service life.

In the case of reservoirs, maintenance assumes an even more critical role, since the constant presence of water and the requirement for watertightness make these structures particularly sensitive to the evolution of construction anomalies, the wear of protective coatings, the deterioration of joints, the onset of cracks, and the progressive loss of performance of surface protection systems. When there is no periodic inspection, monitoring of service conditions, and preventive or corrective interventions in a timely manner, minor nonconformities tend to evolve into more complex pathological conditions, compromising not only the functionality of the reservoir, but also its integrity and durability.

From this perspective, deficient maintenance should not be understood merely as the absence of visible repairs, but rather as the insufficiency of systematic actions of control, conservation, and technical monitoring. This condition favors the onset and intensification of recurrent pathological manifestations in reinforced concrete reservoirs, such as infiltration, persistent moisture, efflorescence, leaching, cracking, carbonation, reinforcement corrosion, concrete cover spalling in relation to the reinforcement, degradation of coatings, and deterioration of waterproofing systems. In structures intended for water storage, such manifestations rarely occur in isolation, and it is more appropriate to interpret them as part of a progressive deterioration process, in which maintenance failures contribute to the acceleration of degradation mechanisms.

This understanding is reinforced by studies applied to reinforced concrete reservoirs. Torres et al. (2016), when analyzing elevated reservoirs constructed in reinforced concrete in the urban area of the city of Pelotas, RS, identified the recurrent occurrence of manifestations such as cracks, dirt accumulation, spalling, reinforcement corrosion, and efflorescence, associating these findings, to a large extent, with execution failures, inadequacies in relation to the design, and the absence of periodic maintenance. The results show that the impairment of the performance of these structures does not arise exclusively from a single pathological mechanism, but from the interaction among construction-related factors, due to design and execution failures, continuous exposure to moisture, and neglect of preventive conservation practices.

Additionally, the degradation of protection and waterproofing systems in reservoirs, when not identified and addressed early, favors the loss of watertightness and intensifies the action of moisture on structural elements, contributing to the onset and progression of pathological manifestations such as efflorescence, moisture stains, reinforcement corrosion, cover spalling, and structural degradation, thereby compromising the performance, watertightness, and durability of the structure (Santos, Silva, and Florian 2022).

Thus, analyzing the impacts of deficient maintenance on reinforced concrete reservoirs implies understanding that the loss of performance of these structures results from a chain of factors, in which the absence of inspection, the postponement of interventions, neglect regarding watertightness, and the progressive degradation of construction systems favor the onset and aggravation of pathological manifestations. More than identifying isolated symptoms, it becomes necessary to recognize maintenance

as a determining variable for the preservation of the structural integrity, functionality, and service life of these structures.

In this context, the present article analyzes the impacts of deficient maintenance on the integrity, durability, and performance of elevated reinforced concrete reservoirs, addressing the main pathological manifestations associated with this scenario and the risks resulting from their progression. It seeks to demonstrate that preventive maintenance, associated with proper technical diagnosis and the adoption of corrective measures in a timely manner, constitutes an essential strategy to contain the evolution of damage, mitigate risks, and preserve the functionality, safety, and service life of these structures.

2. Theoretical Framework

Understanding the impacts of deficient maintenance on reinforced concrete reservoirs requires an integrated analysis of the factors that influence their durability, performance, and behavior when exposed to degradation agents throughout their service life. As pointed out by Torres et al. (2016), the pathological manifestations observed in this type of structure may result from multiple factors, whether isolated or combined, including execution failures, construction deficiencies, exposure conditions, and the absence of adequate maintenance. In this context, the following theoretical framework brings together the main concepts necessary to demonstrate how the insufficiency of preventive actions, periodic inspections, and corrective interventions favors the onset and aggravation of damage in reinforced concrete reservoirs, as well as the technical and functional risks associated with the progression of these manifestations. In order to understand this relationship in a sequential manner, the discussion begins with maintenance and conservation, followed by watertightness, degradation mechanisms, pathological manifestations, and, finally, the risks resulting from performance loss.

2.1 Maintenance and Conservation of Reinforced Concrete Reservoir

The maintenance of reinforced concrete reservoirs comprises the set of technical actions intended to preserve watertightness, durability, functional performance, and structural integrity throughout their service life. Due to continuous exposure to moisture, contact with stored water, and service conditions, these structures require periodic inspections and preventive interventions capable of identifying failures at an early stage and containing the progression of degradation processes.

The absence of periodic maintenance is directly related to the progressive worsening of pathological manifestations, since failures that are initially superficial or localized tend to evolve when not identified and corrected in a timely manner. In this regard, Torres et al. (2016) highlight a high incidence of cracks, reinforcement corrosion, concrete spalling, leaks, efflorescence, and leaching in elevated reinforced concrete reservoirs, associating such occurrences primarily with the absence of periodic maintenance.

Thus, the proper conservation of these structures is not limited to the correction of already established damage, but involves the continuous observation of cracks, signs of infiltration, loss of waterproofing performance, surface manifestations, and other indications of deterioration, in order to prevent initially localized anomalies from evolving into more complex and costly rehabilitation conditions (Torres et al. 2016). Among the most relevant aspects of this conservation process, the preservation of watertightness and the performance of waterproofing systems stands out, since the loss of these conditions favors water ingress and the intensification of deterioration processes.

2.1.1 Watertightness, Waterproofing, and Functional Performance

Watertightness constitutes an essential requirement for the functional performance of reservoirs, since the structure must ensure water storage without losses, infiltration, or undesirable exchange with the external environment. In this context, waterproofing acts as a complementary protection system, contributing to the

reduction of permeability, the preservation of surfaces, and the maintenance of service conditions over time (Sampaio, Silva, and Florian 2021).

When execution failures, construction discontinuities, material aging, or degradation of protective coatings occur, watertightness is lost, favoring the infiltration and percolation of water through structural elements. This process simultaneously compromises the durability of the concrete, the protection of the reinforcement, and the operational efficiency of the system, and may result in leaks, increased internal moisture, and the progressive evolution of damage associated with the continuous presence of water in the structure (Sampaio, Silva, and Florian 2021).

Capraro et al. (2019) emphasize that the recurrent presence of moisture and the loss of protective barriers favor the action of degradation mechanisms that reduce the service life of the structure, especially when associated with insufficient concrete cover, carbonation, and reinforcement depassivation. Thus, watertightness should not be understood merely as a requirement for hydraulic operation, but as a condition directly linked to the durability, conservation, and safety of the reservoir. Once this condition is compromised, a favorable scenario is created for the development of degradation mechanisms that begin to act progressively on both the concrete and the reinforcement.

2.1.1.1 Degradation Mechanisms in Reinforced Concrete Reservoirs

With the loss of watertightness and the intensification of water ingress into structural elements, degradation mechanisms begin to develop progressively. These processes are directly related to the reduction of the natural protection provided by the concrete cover and by the high alkalinity of the solution present in the pores of the concrete. As highlighted by Helene (1992), the concrete cover acts simultaneously as a physical barrier against the ingress of external agents and as a means of chemical protection for the reinforcement.

When this protection is compromised by cracking, failures in watertightness, wetting and drying cycles, aging of protection systems, or other construction discontinuities, favorable conditions are established for the ingress of water and aggressive agents into the structural element. In this context, cracking assumes a relevant role not only as an initial manifestation, but also as a preferential pathway for the penetration of moisture and deleterious substances.

The continuity of this process favors the advancement of carbonation in the concrete cover, with the progressive reduction of the alkalinity of the medium and the consequent loss of the passive condition of the steel. When the carbonation front reaches the depth of the reinforcement, depassivation occurs, creating a favorable environment for the onset of the corrosion process, especially in structures subjected to the recurrent presence of water (Helene 1992).

Once initiated, reinforcement corrosion tends to progress continuously, producing expansive compounds that generate internal stresses in the adjacent concrete. This volumetric increase induces additional cracking, loss of bond between steel and concrete, and subsequently, spalling or detachment of the concrete cover, with exposure of the reinforcement and worsening of the deterioration process. It is, therefore, a self-accelerating mechanism, in which corrosion reduces the effective steel cross-sectional area and simultaneously compromises the durability, integrity, and functional performance of the structure (Helene 1993).

At the same time, the continuous percolation of water through the concrete may promote leaching processes, characterized by the dissolution and transport of soluble compounds from the cementitious matrix. This phenomenon contributes to increased permeability, material weakening, and the transport of salts to the surface, where visible crystalline deposits may occur, often associated with efflorescence. Thus, degradation mechanisms do not act in isolation, but rather in an interdependent manner, composing a progressive deterioration scenario that becomes perceptible through visible manifestations in the structure (Helene 1992).

2.1.1.2 Main Pathological Manifestations in Reinforced Concrete Reservoirs

As a result of the continuous action of these degradation mechanisms, visible pathological manifestations begin to appear, reflecting on the surface the progression of internal damage already established within the structure. Among the most recurrent occurrences in reinforced concrete reservoirs subjected to deficient maintenance are cracking and fissures, infiltration and leaks, concrete spalling and detachment, reinforcement corrosion, efflorescence, moisture stains, waterproofing failures, and biological contamination, among others.

In structures with more advanced deterioration, loss of concrete cover over the reinforcement, exposed reinforcement, concrete spalling, and, in severe cases, reduction of the steel bar cross-sectional area may also be observed. These manifestations are among the most frequent occurrences in elevated reinforced concrete reservoirs, reflecting the direct impact of the absence of preventive and corrective maintenance on the functional performance, durability, and structural integrity of the system (Torres et al. 2016).

The identification of these manifestations makes it possible to understand not only the conservation condition of the reservoir, but also the potential worsening of the pathological condition when damage remains active. In this way, the progression of these manifestations no longer represents merely a localized loss of performance, but becomes directly related to structural, functional, and sanitary risks associated with the continuity of deterioration.

3. Risks Associated with Deterioration and Performance Loss

When pathological manifestations remain uncorrected and degradation mechanisms continue to act, the effects of deficient maintenance are no longer limited to the appearance or superficial performance of the structure and begin to compromise its overall behavior. The continued ingress of water, associated with the persistence of active cracks and the insufficiency of waterproofing systems, keeps the concrete exposed to percolation and favors the progression of carbonation, creating conditions conducive to reinforcement depassivation and the advancement of the corrosion process (Helene 1992).

As corrosion progresses, the expansive products formed around the reinforcement generate internal stresses that intensify cracking, promote cover spalling, and further increase the exposure of the steel to water and oxygen. As a consequence, there is a progressive reduction in the effective cross-sectional area of the bars, loss of bond between steel and concrete, and a decrease in the load-bearing capacity of structural elements. In more severe situations, when this process develops without adequate corrective interventions, the stability of the structure may be compromised, with the possibility of localized or even generalized collapse (Helene 1993).

In addition to structural risks, deficient maintenance also directly compromises the functional performance of the reservoir. The persistence of watertightness failures, infiltration, and leaks reduces the operational reliability of the storage system, which may result in continuous water waste, reduced supply efficiency, and the need for shutdowns for emergency interventions. In public or collective-use reservoirs, this condition goes beyond the material dimension of pathology and directly interferes with the continuity of the service provided and with the operational safety of the building (Torres et al. 2016).

Added to this are the risks related to the persistence of moisture and the continuity of chemical processes within the structure. Continuous leaching promotes the dissolution and transport of compounds from the cement paste, contributing to increased permeability, loss of surface cohesion, and worsening of concrete degradation. In parallel, the formation of efflorescence indicates the existence of water movement within the material and the presence of soluble salts, showing that conditions favorable to the continuity of deterioration remain active. When this condition persists without correction of the source of water ingress,

the tendency is for the conservation state to progressively worsen and for the extent of damage to increase (Menezes et al. 2006).

Finally, the impacts of performance loss in water reservoirs also extend to the sanitary dimension. The continuous presence of moisture, sealing failures, surface deterioration, biofilms, and biological contamination compromises the proper conservation conditions of the system, which may affect the quality of the stored water and increase users' exposure to inadequate sanitary conditions. Thus, the effects of deficient maintenance are not limited to material degradation, but simultaneously affect durability, structural safety, system functionality, and the sanitary reliability of the structure in service.

4. Methodology

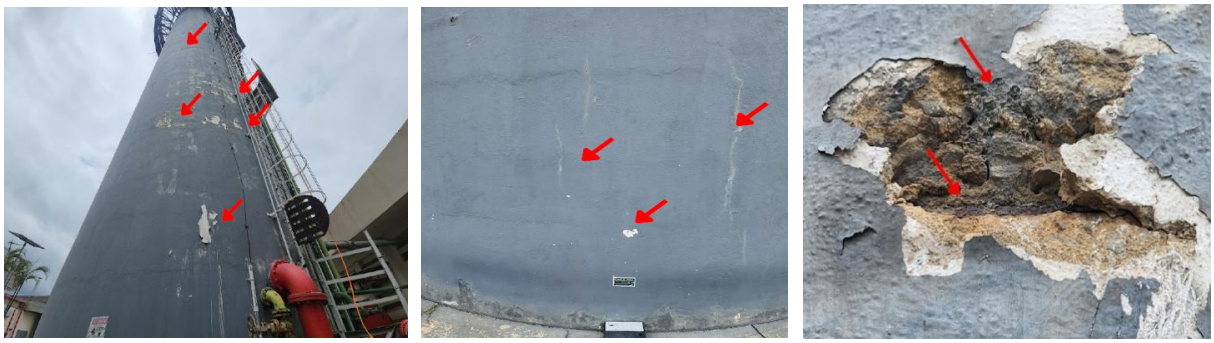
Based on the theoretical framework presented, which demonstrated the relationship between deficient maintenance, degradation mechanisms, and the occurrence of pathological manifestations in reinforced concrete reservoirs, the methodology of this study was defined with the purpose of verifying, in a real-world situation, how such phenomena manifest in the field and how they can be technically analyzed.

For the development of this study, an approach based on bibliographic research and a case study was adopted. The bibliographic research was used to provide the theoretical basis for degradation mechanisms, pathological manifestations, and the impacts of deficient maintenance in reinforced concrete reservoirs, based on previously published technical and scientific references.

Based on this conceptual foundation, the next stage consisted of the practical application of these references through the analysis of a real case, in order to establish a correspondence between the phenomena described in the literature and the conditions effectively observed in the evaluated structure.

Additionally, a case study was carried out with the objective of correlating the concepts addressed in the theoretical framework with the pathological manifestations observed in the field. The analysis was conducted through the damage mapping method, used for the graphical recording and identification of pathological manifestations, associated with the technical anamnesis of the structure.

In this context, the object of study was selected for presenting conditions representative of the degradation scenario discussed in the previous sections, allowing an integrated analysis between theory and practice. The object of study consists of a reinforced concrete reservoir located in an industrial area in the municipality of Sorocaba/SP, whose evaluation was carried out through on-site inspection, photographic records, and mapping of the pathological manifestations observed.



The adoption of these methodological procedures made it possible not only to characterize the identified anomalies, but also to understand their evolution and their possible links with maintenance failures, loss of functional performance, and impairment of watertightness, in line with the approach developed throughout the theoretical framework.

These inspection and anamnesis stages provided sufficient technical support for the diagnosis of the identified pathological manifestations, allowing the analysis of their probable causes and origins, as well as the preparation of the prognosis of the condition and the definition of the applicable therapeutic and repair measures.

Based on these procedures, photographic records and mapping elements were obtained to support the presentation of the anomalies observed in the field, which are presented and discussed in the following section.

5. Results and Discussion

5.1. Characterization of the Observed Pathological Manifestations

Based on the methodological procedures adopted, the main anomalies identified during the inspection of the elevated reinforced concrete reservoir under study are presented below. Initially, the aim is to visually characterize the structure and highlight the general conditions observed in the field, in order to contextualize the pathological manifestations identified and establish the relationship between the records obtained and the degradation scenario discussed in the theoretical framework.

The visual inspection and photographic survey revealed a set of pathological manifestations compatible with a progressive deterioration process associated with deficient maintenance and the loss of performance of surface protection and watertightness systems. figure 1 presents the general view of the inspected structure, allowing the object of study and its overall conservation condition to be contextualized.

On the external surfaces, manifestations such as coating degradation, surface defects, fissures and cracks, as well as localized spalling, were identified, as illustrated in figure 2. These occurrences indicate a reduction in the performance of the surface protection system and favor the exposure of the substrate to environmental actions, in addition to constituting potential pathways for the ingress of moisture and aggressive agents.

In addition to the manifestations observed externally, the internal inspection revealed more critical conditions related to the loss of watertightness and the continuous action of moisture in regions directly exposed to contact with water. Inside the reservoir, evidence of degradation and localized absence of waterproofing, deposits compatible with leaching and efflorescence, the presence of reinforcement corrosion and pipe corrosion, as well as concrete spalling and deterioration in critical regions, especially at interfaces and pipe penetrations, were observed, as shown in figures 3 to 7.

Taken together, the records indicate that the observed manifestations do not occur in isolation, but rather constitute an interdependent pathological condition, in which the absence of preventive and corrective maintenance contributes to the continuity and worsening of damage. This finding leads to the need for a technical interpretation of the identified anomalies, seeking to relate the signs observed in the field to the degradation mechanisms and impacts discussed in the theoretical framework.

5.1.1 Technical Analysis of the Identified Anomalies and Their Relationship with Degradation Mechanisms

The analysis of the photographic survey reveals a pathological condition directly associated with deficient maintenance and the loss of performance of the reservoir's surface protection and watertightness systems. The observed manifestations, such as coating degradation, cracking, efflorescence, failures in the waterproofing system, concrete spalling, and reinforcement corrosion, demonstrate that deterioration occurs in a progressive and interdependent manner.

In general, the presence of cracks and discontinuities favors the ingress of water and aggressive agents into the concrete, intensifying mechanisms such as carbonation, reinforcement depassivation, corrosion, and subsequent cover spalling. At the same time, the continuity of water percolation contributes to leaching processes and the formation of efflorescence, indicating loss of watertightness and reduction in the functional performance of the structure.

On the external surfaces, paint peeling and the observed spalling areas indicate impairment of surface protection and progressive exposure of the substrate to environmental actions, which accelerates material aging and increases the vulnerability of the concrete to moisture ingress. In more advanced areas, exposed reinforcement and signs of corrosion reveal that the degradation process has already gone beyond the coating layer, reaching structural elements with potential impairment of durability.

Inside the structure, stains, efflorescence, and areas with waterproofing failures reinforce the occurrence of watertightness loss over time. These identified anomalies are technically compatible with continuous percolation processes, dissolution and transport of compounds from the cementitious matrix, characterizing phenomena associated with leaching and efflorescence, while also favoring the worsening of degradation at construction interfaces and pipe penetrations.

It is therefore observed that the pathological manifestations identified in the field corroborate the theoretical framework previously developed, especially regarding the relationship between deficient maintenance, loss of watertightness, progression of degradation mechanisms, and the emergence of interdependent pathological manifestations. In this sense, the records obtained not only confirm the presence of visible damage, but also demonstrate a continuous process of performance loss with structural, functional, and sanitary implications.

5.2.Summary of the Identified Pathological Manifestations

In order to systematize the findings observed in the field and to establish an integrated interpretation between the identified evidence, the associated mechanisms, and their predominant technical impacts, Table 1 was developed, presenting a summary of the main pathological manifestations identified in the studied reservoir.

The organization of these data demonstrates that the observed manifestations are not limited to isolated or punctual occurrences, but rather constitute a pathological condition consistent with the progressive loss of structural performance. The correlation between observed evidence, associated mechanisms, and technical impacts reinforces that the absence of preventive and corrective maintenance has favored not only the onset of damage, but also its evolution and interdependence over time.

Table 1 – Summary of the pathological manifestations identified in the studied reservoir

Pathological manifestation	Evidence observed in the field	Associated mechanism / relation to deficient maintenance	Predominant technical impact
Paint peeling	Loss of adhesion, detachments and surface defects on the shaft	Lack of maintenance and loss of performance of surface protection	Increased exposure of the substrate to weathering and moisture
Cracking and fissures	Visible cracks on external and internal surfaces	Lack of monitoring and treatment, allowing ingress of water and aggressive agents	Loss of watertightness and intensification of deterioration
Infiltration and leakage	Persistent moisture, percolation and water flow marks	Continuity of uncorrected defects and degradation of interfaces	Compromised functional performance, worsening of the pathological condition and potential acceleration of carbonation
Waterproofing system failures	Areas with discontinuities, adhesion failures, degradation and loss of performance	Absence of preventive and corrective maintenance of the watertightness system	Reduced watertightness and increased vulnerability of the concrete
Efflorescence	Whitish deposits, stains and runoff with compound transport	Continuous water percolation and dissolution of compounds from the cementitious matrix	Indication of loss of watertightness and progressive substrate degradation
Reinforcement corrosion	Exposed reinforcement, oxidation signs and deterioration of structural elements	Continuous ingress of moisture and aggressive agents, without repair of affected areas	Reduction of steel cross-section and compromise of structural durability
Concrete cover spalling	Localized material loss, detachment and exposure of reinforcement	Expansion of corrosion products and progression of damage without intervention	Direct exposure of reinforcement and aggravation of structural deterioration
Corrosion in metallic components	Oxidation signs in pipes and internal metallic elements	Humid environment and lack of component maintenance	Loss of performance of elements and indication of environmental aggressiveness

5.3. Impacts of Deficient Maintenance on the Structure, Service Life, and Associated Risks

The analysis of the real case demonstrates that the absence or insufficiency of maintenance in elevated reinforced concrete reservoirs contributes decisively to the progressive loss of structural performance, promoting the worsening of the observed pathological manifestations and increasing the risks associated with their continued operation. In the studied reservoir, it was verified that the identified degradation does not result from an isolated event, but rather from a continuous process of exposure to moisture, associated with the loss of watertightness, deterioration of surface protection and waterproofing systems, and discontinuity of conservation actions over time.

In this context, manifestations such as paint peeling, fissures and cracks, infiltration, failures in the waterproofing system, spalling, and signs of moisture should not be understood merely as localized anomalies, but as indicators of performance loss and progressive worsening of the pathological condition. The persistence of these occurrences without systematic technical monitoring and without the adoption of appropriate corrective measures favors the evolution of damage, increases the extent of affected areas, and enhances the occurrence of more severe degradation mechanisms, gradually compromising the integrity of structural elements and reducing the service life of the structure.

From a risk perspective, deficient maintenance simultaneously compromises the functionality, durability, and structural safety of the reservoir. At an initial level, the damage affects watertightness and the operational performance of the structure, potentially leading to water loss through leakage, reduced reliability of the storage system, the need for emergency interventions, and increased rehabilitation costs. At more advanced stages, the progression of pathological manifestations may compromise the conservation condition of structural elements, accelerate the overall deterioration of the structure, and increase the risk of performance loss in service and localized instability (Torres, Silva, and Paliga 2016).

In addition to structural and functional effects, deficient maintenance in water reservoirs may also lead to significant sanitary implications. The continuous presence of moisture, sealing failures, surface degradation, and possible biological contamination processes compromise the adequate conservation conditions of the system, potentially affecting the quality of the stored water and increasing users' exposure to inadequate sanitary conditions. Thus, the impacts of deficient maintenance in reinforced concrete reservoirs are not limited to material degradation, but simultaneously affect structural durability, structural safety, system functionality, operational reliability, and sanitary conditions in service (Torres, Silva, and Paliga 2016).

From a maintenance management perspective, the results obtained reinforce that periodic and technically guided inspection constitutes an essential tool for the early identification of anomalies and for the adoption of appropriate interventions before damage evolves into more severe stages with higher recovery costs. Therefore, maintenance should be understood not only as a corrective practice, but as an indispensable strategy for preserving the service life, safety, performance, and reliability of elevated reinforced concrete reservoirs throughout their operation.

6. Conclusions

The present study demonstrated that deficient maintenance in elevated reinforced concrete reservoirs has a direct influence on the evolution of deterioration mechanisms and the progressive loss of structural performance. The pathological manifestations identified, such as cracks, infiltration, waterproofing system failures, efflorescence, reinforcement corrosion, concrete cover spalling, and coating degradation, should not be interpreted merely as isolated occurrences, but rather as part of a continuous and interdependent deterioration process favored by the absence of periodic inspections and adequate preventive maintenance actions.

In the analyzed case study, evidence of loss of watertightness was observed, including degradation and localized absence of waterproofing, signs of leaching, efflorescence, reinforcement corrosion, corrosion of

metallic components, and concrete spalling. These manifestations indicate the simultaneous action of mechanisms associated with continuous water percolation, transport of compounds from the cementitious matrix, reduction of the protection provided by the concrete cover, and the progression of corrosion processes, demonstrating that the observed deterioration already affects elements directly related to durability and structural performance.

The results obtained reinforce that the loss of performance of waterproofing systems is one of the main triggering factors of pathological processes in reinforced concrete reservoirs. The continuous ingress of water through cracks, construction interfaces, and sealing failures promotes carbonation, reinforcement depassivation, corrosion, leaching, and efflorescence formation, establishing a progressive deterioration cycle capable of significantly accelerating the reduction of the structure's service life.

The application of technical inspection combined with damage mapping proved effective for the characterization of the identified pathological manifestations and for correlating the symptoms observed in the field with the deterioration mechanisms described in the literature, contributing to the diagnosis of the structure's conservation condition and to the definition of appropriate corrective interventions.

Therefore, it is concluded that the adoption of systematic inspection, monitoring, and preventive maintenance programs is essential to preserve the structural integrity, extend the service life of elevated reinforced concrete reservoirs, and minimize operational and structural risks. The findings of this study practically demonstrate the impacts of deficient maintenance on the integrity and durability of these structures, showing that the absence of technical monitoring favors the progression of damage, increases rehabilitation costs, and raises risks related to structural safety, operational functionality, and the sanitary conditions of water storage systems. In this context, maintenance should be regarded not as a cost, but as an essential investment for preserving built assets, mitigating risks, and ensuring the safety, reliability, and durability of reinforced concrete reservoirs throughout their service life.

Advanced Resilience Techniques for Historical and Understudied Sacral Architecture – The ARTHUR Project

Mislav STEPINAC[1]

[1] Faculty of Civil Engineering, University of Zagreb, Croatia, mislav.stepinac@grad.unizg.hr

Abstract: This paper presents an ongoing research framework aimed at improving the seismic resilience of historical and understudied sacral architecture through an explicitly multidisciplinary approach. The study focuses on unreinforced masonry churches, which represent a significant portion of the European cultural heritage yet remain insufficiently characterized in terms of structural behaviour, material properties, and vulnerability under seismic loading. The research integrates structural engineering, material characterization, social science perspectives, and digital technologies into a unified methodological framework. Building upon these findings, an expeditious seismic vulnerability assessment method is being developed to enable rapid yet sufficiently reliable evaluation at regional scale. At the current stage, the results are preliminary, as data collection and analysis are ongoing. The expected outcomes include improved assessment methodologies, enhanced understanding of URM behaviour, and transferable strategies for the preservation and strengthening of sacral architecture in seismic regions.

Keywords: church, sacral architecture, URM, earthquake, masonry

1. Introduction

Stone and masonry have been predominant construction materials in Mediterranean regions for centuries, shaping the architectural identity of the area. For monumental structures such as urban churches and cathedrals, stone was carefully cut and laid in courses to ensure stability and durability. In contrast, more modest buildings, including small regional churches, were often constructed using rubble and irregular stones. Over time, these structures incorporated brick masonry as well, creating a distinctive hybrid construction method that blended traditional and evolving techniques. This is particularly evident in sacral traditional (and vernacular) buildings in Croatia, especially in continental regions. While cathedrals and central religious institutions were constructed following the best practices of their time, smaller to medium sacral buildings often adhered to local traditions, using available materials and the limited knowledge of local craftsmen. These types of structures represent a significant portion of sacral buildings worldwide and are important from engineering, architectural, and conservation perspectives. They also hold considerable social and ethnographic significance.

The ARTHUR project, funded by Croatian Science Foundation (HRZZ) will focus on these smaller, understudied but very important sacral buildings. The proposed research aims to address existing gaps by integrating structural, social, and technological approaches into a unified framework for resilience assessment. As these buildings have a profound influence on their communities but are particularly vulnerable to earthquakes, the project will address several critical aspects often overlooked in societal development.

2. State-of-the-art

Historic masonry is a generic term and does not result from industrial or controlled processes; rather, it is an artisan product, influenced by factors such as the availability of materials, the period of construction, the

building's importance, and the skills of the masons (Borri *et al.*, 2018). The seismic vulnerability of historical stone masonry and unreinforced (URM) buildings has been extensively demonstrated by recent earthquakes worldwide (Turkey (Günaydin *et al.*, 2021), Italy (Penna *et al.*, 2019), Greece (Vlachakis, Vlachaki and Lourenço, 2020) and Croatia (Stepinac *et al.*, 2021)). Focusing just on 2nd earthquake in Croatia, more than 57,000 buildings were damaged. Many historical and cultural buildings partially collapsed and/or were severely damaged. The region which suffered the most is characterized by small historical settlements with important parish churches, chapels and isolated noble residences with palaces (Salaman *et al.*, 2022). In the affected region, 308 immovable cultural assets with 4,416 heritage buildings were damaged. According to the World Bank report (*World Bank Report: Croatia Earthquake – Rapid Damage And Needs Assessment, 2020, June 2020, Government of Croatia*) and HCPI (*The Database of Usability Classification, Croatian Centre of Earthquake Engineering (HCPI—Hrvatski Centar za Potresno Inženjerstvo); Faculty of Civil Engineering, University of Zagreb: Zagreb, Croatia, 2020.*), 206 religious heritage buildings were damaged, 52 were severely damaged or demolished. In addition, 50 more churches were damaged but are not under heritage protection. In total, damage to churches is estimated to be 406,7 million euros. When accounting for the Zagreb earthquake, which affected an additional 100 religious buildings with an estimated damage of €778 million, the financial significance of investigating this topic becomes even more evident. Two common types of damage to such churches are shown in Figure 1.

Figure 1 – Damages to traditional churches after Petrinja earthquake in 2020

A comprehensive literature review reveals that sacral architecture is particularly vulnerable to earthquake damage due to its distinctive geometry, construction materials, building techniques, etc. This issue is evident worldwide, with numerous case studies from Italy providing clear evidence of the widespread impact of seismic activity on these structures. Analysis of damage patterns was done by numerous research groups (Casolo *et al.*, 2000; Lagomarsino and Podestà, 2004a, 2004b; Olivito *et al.*, 2019; Uva *et al.*, 2019; Fuentes *et al.*, 2021; Formisano *et al.*, 2022; Imperatore, Lignola and Ferracuti, 2023). The preliminary assessment and damage classification of Croatian sacral architecture was already done by the author and supported with the private company (Studio Arhing) (Anđić, Stepinac and Pojatina, 2024) and will be done extensively by established research group of ARTHUR project. Structural damage is only one of many critical factors; understanding the composition and quality of construction materials is equally essential. If the masonry material is particularly poor, the primary failure mechanism may not be a large-scale structural collapse, but rather the progressive disintegration or crumbling of the masonry itself. Furthermore, the building's overall seismic response depends on the stiffness and interaction of all structural components, including horizontal elements such as floors, vaults, and roof systems. Churches, for instance, often lack

intermediate floors, which distinguishes them from ordinary buildings and renders them more vulnerable to seismic forces. In many cases, churches do not exhibit a unified global behaviour under seismic actions but instead respond as assemblages of macro-elements with autonomous responses. Beyond these considerations, numerous other factors, such as construction techniques, material degradation, and previous modifications must be carefully evaluated. Consequently, earthquakes pose significant risks not only to human life and property but also to heritage. This project will focus on heritage-protected buildings, with a particular emphasis on the understudied sacral architecture of continental Croatia. However, the developed methodology, with appropriate adaptations, has the potential for broader application across the entire Mediterranean region. In addition to engineering perspectives, interdisciplinary studies emphasize the integration of social factors in resilience strategies. The studies on post-disaster social vulnerability assessments (Lo Monaco *et al.*, 2023; Onescu *et al.*, 2024) illustrate how community engagement and ethnographic data enhance understanding of cultural risks. This approach will be mirrored in the Croatian context, ensuring that the proposed methodologies are culturally sensitive and community-focused. Preserving the existing building stock addresses also social challenges, environmental protection, and resource efficiency, and represents a complex engineering process. Sustainable development, a long-term goal of global policy, aims to extend the lifespan of existing buildings. The general concept of building renovation processes emphasizes the principle of "build back better" to retrofit and strengthen damaged buildings, aiming to reduce earthquake risks and improve quality of life.

3. Research group and methodology

The ARTHUR project will diverge by focusing on classifying stone and mixed stone-brick masonry structures and developing a database of their mechanical properties. The proposed research will systematically collect and categorize material properties from approximately 50 churches, incorporating data from existing renovation projects and new on-site investigations. ISCARSAH guidelines will be applied to ensure consistency. The locations of the churches are shown in Figure 2.

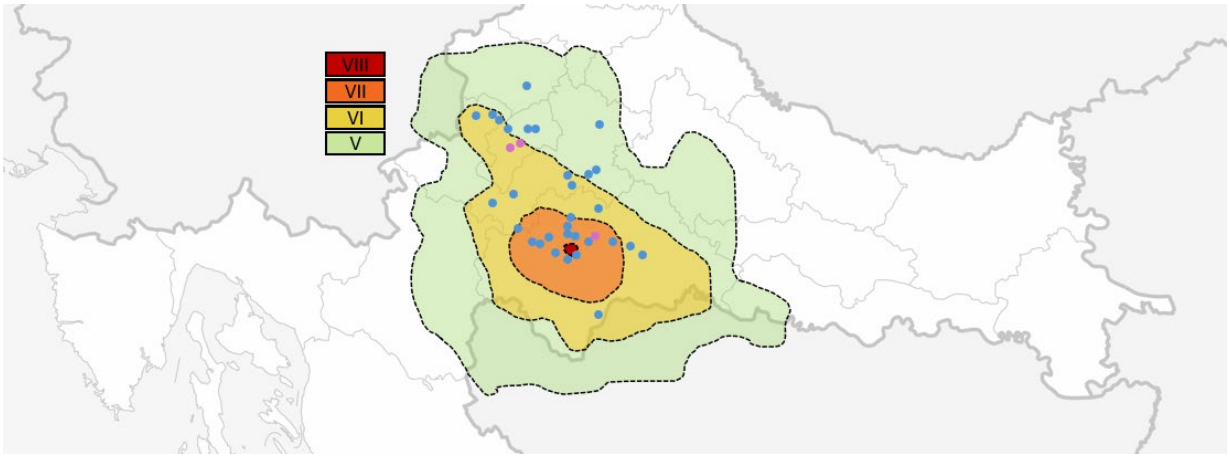

Figure 2 – The distribution of churches to be investigated within the project. Rural churches are marked in blue, while urban city churches are marked in purple, overlaid on the EMS-98 [38] intensity map of Petrinja earthquake

The final step of the project will involve digitalization, representation, and dissemination. Churches will be scanned by laser scanner and/or LiDAR, modelled in 3D and produced as scaled physical models through 3D printing. The project objectives align with several guidelines and global initiatives:

- Venice Charter (1964) and all other International Charters for the Conservation and Restoration of Monuments and Sites.

- Sendai Framework for Disaster Risk Reduction 2015–2030 and United Nations Office for Disaster Risk Reduction to prevent new disaster risks, reduce existing ones, and strengthen resilience through multi-hazard disaster risk management.
- The UN Sustainable Development Goals, particularly Goals 9, 11, and 12, which focus on building resilient infrastructure, making cities inclusive and sustainable, and ensuring responsible consumption and construction patterns.
- UNESCO's Recommendation such as the Recommendation concerning the Preservation of, and Access to, Documentary Heritage Including in Digital Form (2015) and the Recommendation on Science and Scientific Researchers (2017) which underscore the significance of preserving cultural heritage and supporting scientific research in this domain.
- The Kyoto Protocol (1997), Paris Agreement (2015) and all World Climate Summits related to existing buildings and engineering works.
- The European Education Agenda guidelines for actively contributing to improving skills in the construction sector and promoting innovation and sustainability.
- The European Commission's Investment Plan acknowledges that the renovation and maintenance of buildings are fundamental to achieving numerous political objectives, including economic growth, social inclusion, and cultural preservation.
- The New European Bauhaus aims at three fundamental values: sustainability, aesthetics, and inclusion, with a focus on maintaining existing buildings.
- ICOMOS-IFLA Principles (2017): These principles address the preservation of rural landscapes, recognizing their cultural, natural, and historical significance.
- The Smart Specialization Strategy of the Republic of Croatia until 2029 and EU Digital Decade Policy Programme by 2030, setting specific targets in areas like digital skills, infrastructure, and public engagement.

The proposed research is highly interdisciplinary as it involves many fields of technical sciences (civil engineering, fundamental technical sciences, architecture and urban planning, environmental engineering, material science, geodesy, etc.). The multidisciplinary approach is evident in the use and implementation of data from natural sciences (seismology, applied mathematics, and mathematical modelling) and their impact on social (economics, law) and humanities (heritage protection, sociology, ethnology) sciences.

The ARTHUR project's research methodology is designed to provide a comprehensive understanding of the resilience of sacral architecture by integrating structural, social, and technological analyses. The project will be divided into four working groups shown in Figure 3. The project is led by University of Zagreb and supported with numerous scientists from European universities and professionals from Croatian design and architectural offices highly involved in the post-earthquake(s) renovations (also shown in Figure 3).

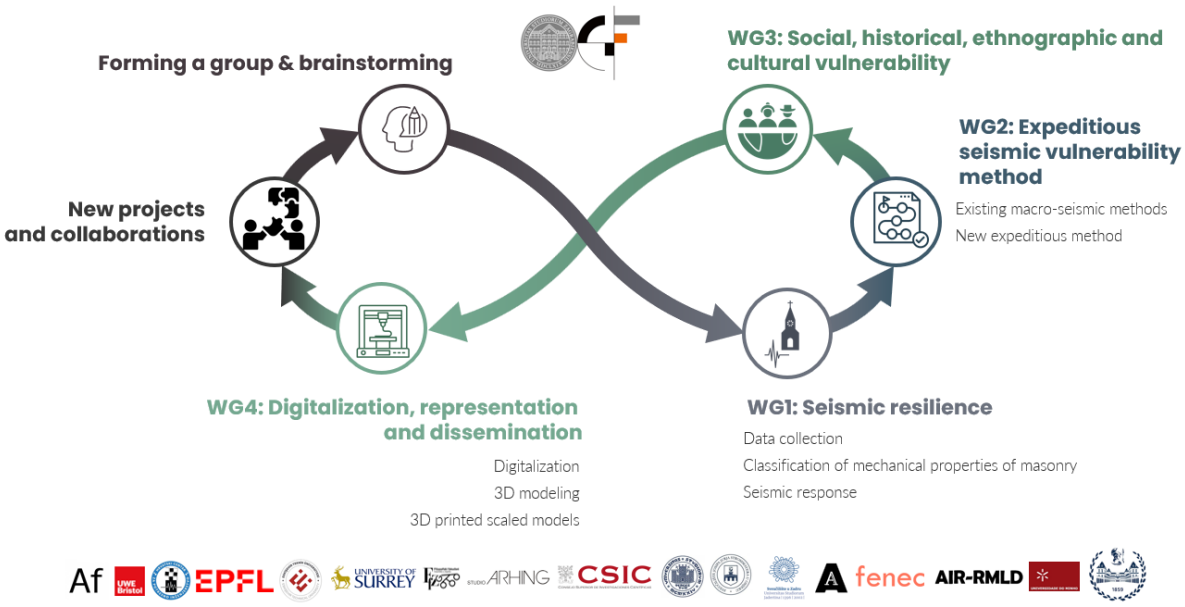

Figure 3 – Working groups of ARTHUR project

4. Conclusion

The presented research establishes a structured and explicitly multidisciplinary framework for addressing the seismic resilience of historical and insufficiently investigated sacral architecture. The approach deliberately moves beyond purely structural considerations by integrating engineering analysis with social-science perspectives and advanced digital technologies, thereby aligning technical performance with cultural significance and community relevance. The ARTHUR project consolidates these dimensions into a coherent methodology that combines seismic vulnerability assessment, detailed structural evaluation, historical and ethnographic interpretation, and digital representation.

At the current stage, the results remain preliminary and should be interpreted as part of an ongoing and progressively expanding research process. A substantial body of documentation is being systematically collected, including data from approximately seventy professional projects, field surveys, and in-situ investigations. This dataset will be further analysed to establish statistically and mechanically consistent classifications of material properties and structural typologies. Particular attention is directed toward the characterization of masonry behaviour through a combination of semi-destructive testing, laboratory analysis, and numerical modelling.

The research is structured through a sequence of interrelated objectives. The initial phase is dedicated to a comprehensive state-of-the-art review and preliminary investigations (O1), ensuring a critical positioning within existing scientific and professional knowledge. This is followed by systematic on-site testing and material classification (O2), which directly inform the development and calibration of numerical models used to simulate seismic response (O3). Building upon these validated models, an expeditious vulnerability assessment method (O4) is being developed to enable rapid yet sufficiently accurate evaluations applicable at regional scale. The final objective (O5) focuses on digitalization, dissemination, and representation, where 3D modelling and additive manufacturing are employed to translate analytical findings into accessible visual and physical formats, supporting both expert interpretation and broader communication.

The integration of digital tools is not treated as a representational afterthought but as an analytical and communicative extension of the research itself. Three-dimensional models, parametric representations, and

scaled printed elements facilitate the exploration of intervention strategies, enabling iterative testing of strengthening approaches while preserving architectural authenticity. In parallel, the inclusion of ethnographic inquiry and stakeholder engagement introduces a dimension that is frequently absent in engineering-driven studies. By systematically incorporating local knowledge, perceptions of risk, and cultural narratives, the project expands the definition of resilience beyond structural capacity toward a more comprehensive socio-cultural construct.

Although definitive conclusions cannot yet be drawn, the anticipated contribution of this research lies in the development of a validated, scalable, and interdisciplinary framework for the assessment and enhancement of sacral architecture. The ongoing expansion and analysis of the dataset are expected to significantly improve the reliability of vulnerability assessments and to bridge the persistent gap between advanced analytical methods and their practical application in heritage contexts.

Abstract: Soiling is one of the most prevalent pathologies affecting building façades. While often dismissed as an aesthetic issue, soiling patterns serve as critical indicators of how surfaces interact with moisture, rainfall and environmental degradation agents. Typifying these patterns is essential for understanding the relationship between constructive details, material properties and environmental orientation. However, manual classification is subjective and time-consuming. This paper presents an automated approach to translate digital images of rendered façades in Lisbon, Portugal, into quantified soiling maps using a custom Python-based tool. The framework assigns a Soiling Index to each façade pixel and derives zone-based dirty fractions following the literature. It extracts CIELAB colour metrics and anisotropy indicators. Two case studies with contrasting soiling mechanisms were analysed: Case Study 1 exhibits simultaneous dirt washing and white washing driven by floor-level cornices, with an anisotropy of 3.63 confirming horizontal band dominance, dirt washing producing a strongly achromatic darkening ($\Delta L^* = -14.2$; $\Delta E = 14.3$) and white washing a chromatic yellowing shift ($\Delta b^* = +4.7$; $\Delta E = 4.9$) reflecting the re-emergence of the warm-yellow substrate. Case Study 2 exhibits detail-drip dominated dirt washing with the highest colourimetric contrast in the dataset ($\Delta L^* = -39.8$; $\Delta E = 42.0$) concentrated beneath protruding balconies while the broad panel areas remain clean. The results demonstrate that the proposed image-based method can objectively distinguish and co-locate multiple soiling mechanisms and generate physically interpretable indicators for comparative assessment of façade pathology and for future runoff modelling and predictive maintenance strategies.

Keywords: Façade Pathology, Soiling Patterns, Runoff, Image Processing

1. Introduction

The maintenance and monitoring of building façades represent a persistent challenge in construction management as surfaces age and accumulate soiling driven by runoff, atmospheric deposition and biological colonisation. Façade soiling is more than an aesthetic concern: the spatial distribution of dirt records how surfaces interact with moisture and environmental agents over time (Blocken et al. 2013; Dorsey et al. 1996).

Traditional assessment methods rely on manual visual inspection and established pathology atlases and classification schemes, such as the one proposed by Pereira et al. (2021) in the CIB W86 Report regarding New Trends on Building Pathology. Although widely used in practice, manual surveys are inherently

subjective, labour-intensive and difficult to reproduce across observers or building typologies. Developing systematic, repeatable image-based procedures for classifying and quantifying soiling patterns would substantially accelerate and standardise the assessment of façade soiling. In this context, image processing offers a compelling pathway, as digital façade photographs encode both spatial and chromatic information that can be exploited to distinguish between soiled and unsoiled surface areas and to characterise the nature, extent and distribution of soiling typologies.

This paper presents a custom Python-based image analysis framework for observing and interpreting soiling patterns on rendered building façades. The tool assigns a Soiling Index (SI) to each façade pixel based on its Euclidean distance to empirically defined clean and dirty colour prototypes and derives spatial indicators such as zone-level dirty coverage based on Gaspar and de Brito (2005), which are then interpreted considering existing façade pathology classifications. Two case studies in Lisbon, Portugal, are examined to illustrate how the framework helps distinguish between white washing and dirt washing and to derive physically meaningful quantitative descriptors that form a basis for further analysis.

2. Literature review

2.1 Runoff mechanics

Façade soiling can be interpreted as the visible outcome of rainwater runoff interacting with deposited pollutants, material properties and architectural detailing. On vertical envelopes, wind-driven rain (WDR) is the dominant moisture source because, in still air, façades receive virtually no rainwater apart from local splashback near ground level or at projecting elements (Snape and Atkinson 1999). After impact, each raindrop's mass is partitioned between splashing, bouncing, adhesion, evaporation, absorption and runoff, so only a fraction of the impinging water contributes to surface flow (Abuku et al. 2009; Blocken et al. 2013). Runoff develops once the WDR intensity exceeds the material's instantaneous absorption rate or when the outer zone approaches capillary saturation, marking a transition from inward moisture transport to continuous surface films capable of mobilising and redistributing contaminants (Dorsey et al. 1996; Hens 2010).

Both WDR and the resulting runoff are highly non-uniform in space. Their distribution is governed by building geometry, façade orientation, surrounding topography, wind speed and direction, rainfall intensity and raindrop-size distribution, which together generate strong wetting gradients over façades (Blocken and Carmeliet 2006; Chen et al. 2022; Kubilay et al. 2013). At the material and detail scale, parameters such as surface roughness, contact angle and capillary absorptivity, as well as elements like drips, ledges, joints and projections, further control how water films form, break up and re-attach (Dorsey et al. 1996; Robinson and Baker 1975; Park et al. 2018). Smooth or lightly textured surfaces promote concentrated streams and sharp streaks, while rougher textures induce "broken flow" and more diffuse wetting (Dorsey et al. 1996). Hydrophilic surfaces slow films through strong adhesion, whereas hydrophobic ones favour fast, narrow streams (Park et al. 2018).

2.2 Soiling Typologies

Blocken et al. (2013) distinguish three principal outcomes of repeated runoff over contaminated surfaces: white washing (WW), dirt washing (DW) and dirt accumulation (DA). In white washing, frequent or rapid runoff on exposed surfaces removes deposited particles, leaving zones that appear comparatively clean or lighter than their surroundings. In dirt washing, the same water film concentrates and deposits particles at specific locations, particularly at the runoff termination line where the water film loses momentum or evaporates (Dorsey et al. 1996). Dirt accumulation occurs in sheltered zones where particles settle in the absence of significant surface flow (Blocken et al. 2013).

Architectural details strongly amplify these effects. Horizontal ledges, recessed returns, window perimeters, misaligned joints and protruding fixtures create locally concentrated flow paths and recurring stain

signatures (Chew and Tan 2003; Robinson and Baker 1975). Where vertical flow encounters panel breaks or horizontal joints, part of the water is diverted laterally, producing characteristic vertical streaks below the discontinuity (Chew and Tan 2003). The absence of adequate drip details increases the risk that surface tension causes water to wrap around edges and continue along adjacent surfaces, increasing both wetting duration and staining extent (Robinson and Baker 1975). In rendered façades, prolonged and uneven wetting can also produce ghost-like stains in which non-uniform dust deposition makes the underlying structural grid visible at the surface (Flores-Colen et al. 2008).

2.3 Image Processing

Because soiling mechanisms are visually expressed, image processing provides a logical tool for façade assessment. Manual mapping of stains remains labour-intensive and subjective, whereas image-based analysis can detect localised discoloration in a more systematic and repeatable manner (Torres-Gonzáles et al. 2023). Analysis benefits from segmenting the façade into physically meaningful zones associated with specific runoff and deposition mechanisms (Gaspar and de Brito 2005). This allows image processing results to be interpreted in relation to geometry and moisture exposure rather than as isolated colour variation.

Colour-space selection is therefore critical. In principle, CIELAB is better aligned with human perception, because it separates lightness from chromatic variation and supports ΔE-based thresholds such as the just noticeable difference at $\Delta E \approx 2.3$ (Torres-Gonzáles et al. 2023; Muratbekova et al. 2025). However, exploratory tests in this research showed substantial overlap between clean and soiled areas in the a* and b* channels, so that meaningful separation could only be achieved through the L* component, which is highly sensitive to shadowing and illumination changes. By contrast, all three RGB channels exhibited relatively low overlap between classes, and the discriminative signal was distributed in a similar way across R, G and B, allowing the classifier to exploit both chromatic differences and overall brightness variations without relying exclusively on a lightness-like dimension. For this reason, despite its known perceptual limitations, the RGB colour space was ultimately adopted as the primary working space for the façade image analysis in this study.

3. Methodology

3.1 Case Study Selection and Location

Two buildings with rendered façades in Lisbon, Portugal, were selected to evaluate the image processing framework. The selected buildings exhibit contrasting soiling typologies under comparable urban conditions. Both buildings are situated in areas characterised by high population density, which is associated with elevated atmospheric particulate concentrations and restricted airflow, conditions known to intensify façade soiling (D'Orazio et al. 2023).

Case Study 1, located at R. Dona Filipa de Vilhena 7 (Figure 1), presents an east-oriented coating mortar façade showing evidence of white washing across exposed surface zones. Case Study 2, situated at Av. de António José de Almeida 46 (Figure 1), presents a south-oriented façade with pronounced dirt washing concentrated below architectural details. The contrasting soiling mechanisms of the two buildings (Figure 2) provide a suitable basis for evaluating the discriminative capacity of the image processing tool across different physical conditions.

Figure 1 - Geographic context and location of the selected case study buildings in Lisbon, Portugal. Case Study 1 is indicated in blue (R. Dona Filipa de Vilhena 7) and Case Study 2 in green (Av. de António José de Almeida 46).

Figure 2 - Ground-level views of the façades of Case Study 1 (left) and Case Study 2 (right).

3.2 Image acquisition and Preprocessing

Façade images were captured at ground level using a smartphone camera. To enhance chromatic consistency across the image dataset, a colour calibration procedure was applied using a ColorChecker reference chart. The ColorChecker comprises colour patches with known spectral properties. When present in an image, recorded colours can be compared with their reference values to generate a correction profile that addresses white balance, exposure, and sensor response deviations.

Prior to analysis, each image was manually masked in Photoshop to exclude non-façade elements such as windows, balconies, pipes and sky. All excluded regions were replaced with uniform white pixels (RGB values ≥ 245 across all three channels). This masking step ensures that the classifier operates exclusively on exposed façade material and is not influenced by architectural elements or background (Figure 3).

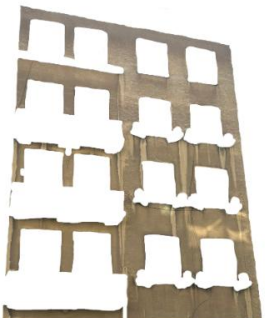

Figure 3 - Overview of the façade of Case Study 1 after manual removal of non-façade elements with Photoshop.

3.3 Image Processing Framework

The analysis tool was implemented in Python and comprises eight processing steps. The framework proceeds from image loading through prototype selection, classification, spatial analysis and cross-case export. The accompanying Figure 4 provides a flowchart illustrating the overall process.

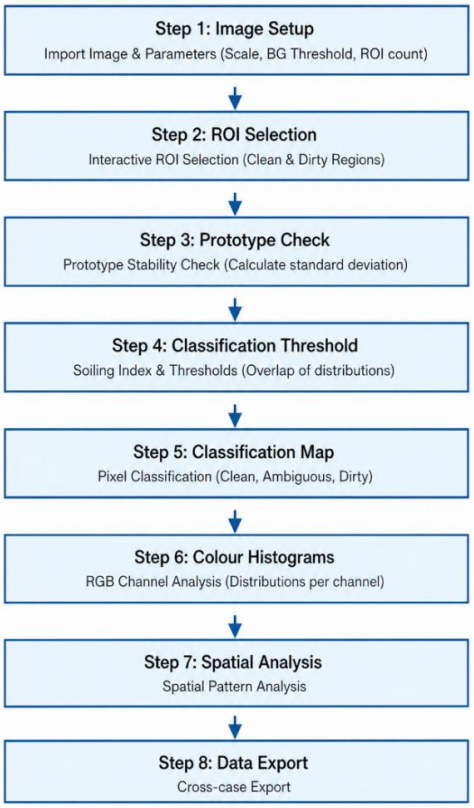

Figure 4 - Overview of the methodological workflow adopted in this study.

Step 1, “Settings and Image Loading”, is where the image is imported, the scale of the picture is chosen, the threshold to delete the background (BG_TRESH) is set and the amount of Region of Interests (ROIs) that the user wants to select for dirty and clean are defined. The background mask removes white sky or border pixels above BG_THRESH = 245, so only real facade pixels are analysed.

Step 2, “Multi ROI-selection”, selects the ROIs of clean and dirty regions on the façade depending on the amount chosen in step 1. The user varies the position of each ROI on the façade so that the prototypes represent the full range of clean and dirty zones, not just one localised spot. Each selected rectangle is cropped from the image and stored as a flat array of RGB pixel values. The coordinates are also saved for later visualisation.

Step 3, “Prototype stability check”, verifies whether the selected ROIs are consistent for R, G and B using the standard deviation (std) across the ROI means:

- std < 10: stable;
- std 10–20: moderate;
- std > 20: unstable.

Step 4, “Soiling index and thresholds”, calculates the Soiling Index (SI) for every ROI pixel and determines the classification threshold from the histogram overlap of the two ROI distributions (clean and dirty), with Equation (1).

$$Soiling\ index\ (SI) = \frac{d_{clean}}{d_{clean} + d_{dirty}} \tag{1}$$

Where:

$$d_{clean} = \sqrt{\left(R_{pixel} - R_{mean,\ clean}\right)^2 + \left(G_{pixel} - G_{mean,\ clean}\right)^2 + \left(B_{pixel} - B_{mean,\ clean}\right)^2} \tag{2}$$

$$d_{dirty} = \sqrt{\left(R_{pixel} - R_{mean,\ dirty}\right)^2 + \left(G_{pixel} - G_{mean,\ dirty}\right)^2 + \left(B_{pixel} - B_{mean,\ dirty}\right)^2} \tag{3}$$

A histogram with 50 bins is constructed for the clean and dirty SI distributions. A bin counts as overlap only if both distributions have at least 5% of their own peak density in that bin, preventing tail pixels from inflating the ambiguous zone. The lower and upper bounds of this overlap define the classification thresholds, with THRESH_CLEAN set to the lower bound and THRESH_DIRTY to the upper bound:

- Overlap found: THRESH_CLEAN to THRESH_DIRTY forms the ambiguous zone;
- No overlap: single boundary at SI = 0.5, classification is fully reliable.

Step 5, “Classification and visualization”, classifies every façade pixel using the thresholds from step 4 and produces a 3-panel figure: original image, colour-coded segmentation map and SI heatmap. Each pixel receives one of three labels:

- Clean (green): SI < THRESH_CLEAN;
- Ambiguous (yellow): THRESH_CLEAN ≤ SI ≤ THRESH_DIRTY;
- Dirty (red): SI > THRESH_DIRTY.

If no overlap is found in step 4, THRESH_CLEAN = THRESH_DIRTY = 0.5, and there is no ambiguous zone. Coverage is computed by counting pixels per class and dividing by the total, ensuring the three percentages always sum to exactly 100%.

Step 6, “RGB channel histograms”, show the distribution of raw R, G and B pixel values from the clean and dirty ROIs separately, one panel per channel. For each channel the overlap area between the two distributions is calculated. A lower overlap means that channel alone can better separate the two classes. These plots help to understand which colour channel carries the most discriminative information.

Step 7, “Spatial Pattern Analysis”, assesses the spatial distribution of soiling across the façade to identify where soiling concentrates through zone-based analysis and to detect directional patterns in soiling distribution, known as anisotropy. The façade is divided into four analytical zones adapted from the framework proposed by Gaspar and de Brito (2005), who originally developed six zones for comprehensive assessment of façade degradation: (1) at or near floor level, (2) on continuous walls, (3) around openings, (4) at parapets, below copings and eaves, (5) below balconies or soffits and (6) in the corners and edges. The adapted zones for this research are summarized in Table 1.

Table 1 - Façade zones used in the spatial analysis.

Zone	Position	Physical significance
Z1	v < 0.15 (roof edge / parapet)	Highest wind-driven rain catch ratio
Z2	0.15 ≤ v < 0.70 (central façade plane)	Main exposed surface, presence of architectural elements
Z3	0.70 ≤ v < 1.00 (lower façade plane)	Main exposed surface, presence of architectural elements
Z4	u < 0.05 or u > 0.95 (vertical edges and corners)	Streamline compression and runoff concentration

For each of the four zones (Z1–Z4), the percentage of dirty pixels is extracted from the classification map generated in the previous step. The zone with the highest percentage is identified as the most affected zone, indicating where soiling is most concentrated on that façade.

Step 8, "Cross-case export", exports all key results to a cross-case CSV file, allowing multiple façades and case studies to be compared in a single table. For each façade, the following metrics are saved:

- Coverage: % clean, % ambiguous, % dirty;
- SI statistics: mean, std;
- Thresholds: THRESH_CLEAN, THRESH_DIRTY, separability gap;
- Colour prototypes: mean R, G, B for clean and dirty;
- Pattern metrics: anisotropy;
- Zone analysis.

A new script (detail_analysis) performs a zoom-level analysis of façade images to inspect local soiling patterns in more detail. It computes ΔE and ΔL*, Δa*, Δb*, as well as RGB values for clean and dirty reference regions and for each identified soiling type and appends these results to the same cross-case CSV file generated in step 8.

3.4 Spatial and Colour metrics

3.4.1 ΔE and ΔL*, Δa*, Δb*

Colour characterisation at the soiling-type level is performed on detailed photographs analysed separately from the full-façade classification. For each soiling zone, mean CIELAB values are extracted for both the soiled area and an adjacent unsoiled reference area on the same façade. The total perceptual colour difference ΔE (CIE76) is computed as the Euclidean distance between the two mean Lab vectors, in Equation (4):

$$E = \sqrt{\Delta L^2 + \Delta a^2 + \Delta b^2} \tag{4}$$

Perception thresholds follow those of Torres-Gonzáles et al. (2023):

- ΔE ≤ 1.0 is imperceptible;
- 1.0 < ΔE < 2.3 is perceptible only upon close inspection;
- ΔE = 2.3 defines the just noticeable difference (JND);
- ΔE > 5.0 is clearly visible to an average observer.

The lightness component ΔL* indicates whether the soiled zone is darker (ΔL* < 0) or lighter (ΔL* > 0) than the unsoiled reference. The chromatic components Δa* and Δb* describe shifts along the red–green and

yellow–blue axes, respectively. A negative Δa* indicates a shift toward green, which can be associated with biological colonisation such as algae or moss growth.

3.4.2 Anisotropy

The anisotropy ratio is defined as the variance of the vertical dirt profile divided by the variance of the horizontal dirt profile. Values exceeding 2.0 indicate that dirtiness varies predominantly with height, consistent with horizontal banding. Values below 0.5 indicate that dirtiness varies predominantly with horizontal position, consistent with vertical streaks. Values close to 1 indicate a diffuse spatial pattern.

4. Results

4.1 Case Study 1

Case Study 1 presents an east-oriented façade exhibiting the highest mean soiling index in the dataset (SI = 0.615) and a clear progressive increase in runoff concentration from top to bottom. The soiling index heatmap (Figure 5) reveals strongly banded soiling organised in persistent horizontal bands at each floor level, driven by the protruding cornices that act as runoff concentrators. The anisotropy value of 3.63 confirms that soiling is directionally organised horizontally, consistent with runoff-dominated deposition rather than a diffuse or vertically streaked pattern.

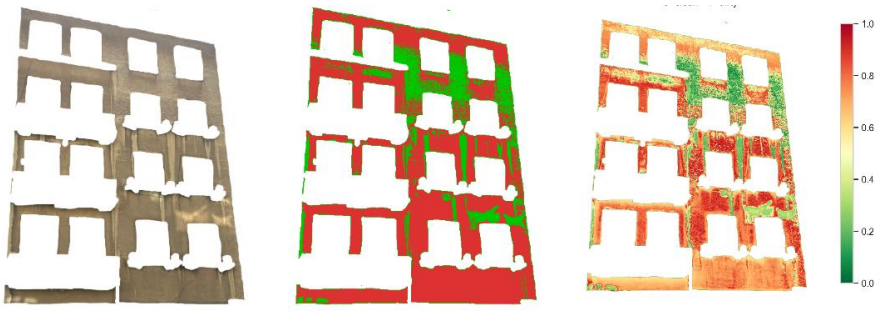

Figure 5 - Classification output for Case Study 1. Left: original image, centre: segmentation map (green = clean, red = dirty), right: Soiling Index heatmap (0 = clean, 1 = dirty).

Table 2 - Summary of zone-level soiling metrics for Case Study 1.

Case study	% dirty per zone			Anisotropy
	Z1	Z2	Z3	
1	62.24	57.19	86.28	3.63

The zone-level results (Table 2) confirm a progressive floor-by-floor soiling gradient: the lower zone Z3 registers 86.28% dirty surface, substantially higher than the upper zone Z1 at 62.24%. This vertical gradient results from the cumulative superimposition of runoff streams from successive upper floors. At each cornice, particle-laden water intercepted from the panel above is channelled along the underside until it detaches at the drip edge and impacts the panel below, depositing a concentrated runoff termination line. Because each lower floor receives contributions from all floors above, the particle load increases progressively toward the façade base (Chew and Tan 2003; Blocken et al. 2013).

The detailed colourimetric analysis (Table 3) reveals that two mechanisms operate simultaneously on the same runoff bands in zone Z2 and are colourimetrically distinguishable. Dirt washing produces a strongly achromatic darkening: ΔE = 14.3 is almost entirely carried by ΔL* = −14.2, with negligible chromatic shifts (Δa*

= 0.0; Δb* = −1.1), consistent with the deposition of spectrally neutral urban particulates. White washing, understood as light streaks and bands produced where frequent or rapid runoff on exposed surfaces removes previously deposited particles, results in a smaller but clearly perceptible colour difference (ΔE = 4.9), dominated by a shift towards yellow (Δb* = +4.7) with modest lightening (ΔL* = +1.2). This behaviour is consistent with flow-based weathering models in which runoff selectively washes out fine particulate deposits along preferential flow paths, leaving locally cleaner, lighter zones adjacent to darker, particle-laden runoff bands (Dorsey et al. 1996; Blocken et al. 2013). In the present case, the observed yellow shift most likely reflects the re-emergence of the façade's inherent warm-yellow substrate colour in these lighter bands, which appears muted in the adjacent dirt-washed zones. The easterly orientation of the façade promotes frequent wetting–drying cycles after rain events, which is known to intensify moisture-related degradation and soiling by increasing the number of cycles over which particles and dissolved material can be redistributed and fixed along runoff paths (Robinson and Baker 1975; Blocken et al. 2013).

Table 3 - CIELAB colorimetric shifts for dirt washing and white washing in zone Z2 of Case Study 1.

Soiling type	ΔE	ΔL*	Δa*	Δb*
Dirt washing	14.3	−14.2	0.0	−1.1
White washing	4.9	+1.2	0.5	+4.7

4.2 Case Study 2

Case Study 2 presents a rendered south-facing façade that illustrates the detail-drip mechanism with exceptional clarity. Despite an overall Moderate soiling level of 16.65%, the soiling index heatmap (Figure 6) concentrates soiling almost exclusively beneath protruding architectural details, balconies and window sills, leaving the broad panel areas between them comparatively clean. This binary contrast is consistent with the runoff termination mechanism described by Dorsey et al. (1996).

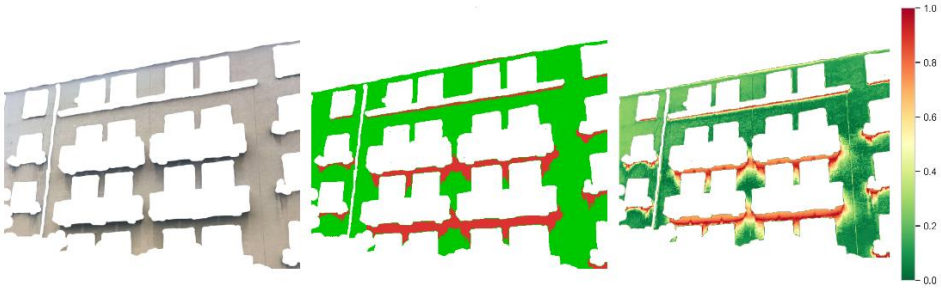

Figure 6 - Classification output for Case Study 2. Left: original image, centre: segmentation map (green = clean, red = dirty), right: Soiling Index heatmap (0 = clean, 1 = dirty).

Table 4 - Summary of zone-level soiling metrics for Case Study 2. % dirty per zone, anisotropy and CIELAB colour metrics for the dominant dirt washing mechanism (detail-drip).

Case study	% dirty per zone			Anisotropy	ΔE	ΔL*
	Z1	Z2	Z3			
2	0.69	11.40	29.52	1.03	42.0	-39.8

The zone-level results (Table 4) confirm the spatial localisation of soiling. The lower façade zone (Z3) carries the highest dirty fraction (29.52%), whereas the roof edge (Z1) remains largely unaffected. The central zone

(Z2) and lower façade zone (Z3) reflect partial staining from detail elements in the mid-height range. This pattern is mechanistically explained by a three-phase runoff sequence operating at each protruding balcony. First, the balcony intercepts the downward-moving water film and concentrates it along its upper surface. Second, once the flow intensity exceeds the surface tension, the water detaches at the outer edge and falls as a narrow-concentrated jet. Third, this jet impacts the wall directly below, depositing a dense particle band — the runoff termination line, that dries out and progressively fades with distance from the balcony edge (Robinson and Baker 1975; Blocken et al. 2013). This repetitive motif reappears identically at each architectural element, confirming that the detailed geometry is the primary organiser of soiling on this façade.

The colourimetric analysis confirms the extreme contrast between the clean panels and the soiled drip zones. The lightness shift $\Delta L^* = -39.8$ and the total colour distance $\Delta E = 42.0$ are the highest values in the dataset, substantially exceeding the clearly visible threshold ($\Delta E > 5.0$). The strongly negative ΔL^* confirms that soiling manifests as an intense, purely achromatic darkening consistent with concentrated atmospheric particulate deposition. The anisotropy of 1.03 indicates a diffuse spatial pattern at the whole-façade scale, reflecting that the individual dark bands beneath details occupy only a small fraction of the total surface and do not dominate the directional statistics. Because the south-facing orientation receives significant wind-driven rain loading only during limited intense rainfall episodes, the large panel areas remain dry between events, while the zones beneath the details are recharged and re-stained at each event (Blocken et al. 2013).

5. Conclusion

This study demonstrates that image processing can classify and quantify façade soiling patterns in a systematic and physically interpretable manner. The nearest-prototype Soiling Index classifier, operating in RGB colour space with reference prototypes derived from user-selected regions of interest and thresholds determined by histogram overlap of ROI distributions, successfully differentiates between soiled and unsoiled surface areas across two case studies exhibiting contrasting soiling mechanisms.

Case Study 1 showed a progressive, floor-by-floor runoff-concentration along the cornices, with two antagonistic processes acting on the same cornice-driven bands. Dirt washing is dominant, producing a strong achromatic darkening ($\Delta L^* = -14.2$; $\Delta E = 14.3$) with an almost neutral chromatic shift ($\Delta b^* = -1.1$). White washing, understood as light streaks and bands produced where frequent or rapid runoff on exposed surfaces removes previously deposited particles, results in a smaller but clearly perceptible colour difference ($\Delta E = 4.9$), dominated by a shift towards yellow ($\Delta b^* = +4.7$), indicating renewed visibility of the façade's warm-yellow substrate in these lighter bands (Dorsey et al. 1996). An anisotropy of 3.63 confirms the dominance of horizontally aligned bands.

Case Study 2 confirmed a detail-drip soiling regime in which protruding balconies and sills function as runoff concentrators, producing the highest colourimetric contrast in the dataset ($\Delta E = 42.0$; $\Delta L^* = -39.8$) while leaving the broad panel areas clean. The method successfully resolved the co-occurrence of two colourimetrically distinct mechanisms in Case Study 1 and identified the governing architectural detail in Case Study 2, demonstrating its capacity to generate physically interpretable indicators beyond simple classification. The quantitative outputs of the framework, SI coverage by class, zone-level dirty fractions, anisotropy and CIELAB colour metrics are mutually consistent and align with the physical mechanisms documented in the literature.

The key innovation of the approach lies in bridging visual observation and quantitative assessment: the soiling index heatmap functions as a structured visual support that guides and validates the observer's interpretation, while the extracted metrics provide an objective, reproducible basis for drawing conclusions that would otherwise depend on subjective judgment. This combination allows soiling typologies, their spatial organisation and their colourimetric signatures to be characterised from standard digital

photographs without specialised equipment, making the method accessible for practical inspection workflows. The framework, therefore, provides a reproducible basis for comparative façade degradation assessment that is not dependent on the subjectivity of manual visual inspection.

Key limitations include sensitivity to ROI selection, variable image quality under field conditions, and the inability to correct for spatially structured illumination differences such as shadows or surface reflections, which can introduce systematic bias into the soiling index.

Several directions for future research emerge from these findings. Extending the method to a larger and more diverse building stock would allow the relationship between architectural typology, material properties, orientation and soiling severity to be systematically characterised across different urban contexts. At the methodological level, automating ROI selection through supervised or self-supervised learning would reduce observer dependency and improve reproducibility across operators. Finally, coupling the image-based soiling index with runoff modelling frameworks would enable the observed spatial patterns to serve as validation data for physically based simulations, closing the loop between field observations and predictive modelling of façade weathering.

Abstract: The building envelope significantly influences the durability, safety, and functional performance of buildings throughout their service life. However, maintenance is frequently managed reactively, limiting its potential to mitigate degradation and optimize life-cycle costs. While predictive models have been developed and applied in different fields of maintenance in engineering, their alignment with observed in-situ performance remains insufficiently explored.

This study discusses how maintenance affects the durability, costs, and safety of building-envelope elements by integrating empirical inspection data with a stochastic condition-based maintenance model. The analysis is based on nineteen case studies located in Portugal, comprising different building typologies and envelope systems.

Fieldwork inspections were conducted before and after maintenance interventions. Degradation was documented through visual assessment and software-assisted quantification. A stochastic condition-based maintenance framework was applied to simulate degradation progression and intervention strategies. Corrective maintenance was incorporated when elements reached unacceptable degradation levels. This approach made it possible to evaluate how well the model reflected real in-situ performance and to assess how different maintenance strategies affect the claddings' service life and related maintenance costs.

The results reveal that maintenance actions have a measurable impact on service life. The stochastic model was slightly conservative compared with *in situ* observations, but it adequately reproduced overall degradation patterns. The findings demonstrate that maintenance, when strategically planned and condition-based, can be quantified in terms of durability gains and cost implications, supporting its integration as a structured decision-making component in building life-cycle management.

Keywords: Manutenção baseada na condição, envolvente dos edifícios, durabilidade, modelação de degradação.

1. Introdução

A envolvente de um edifício pode ser entendida como a sua "pele", uma vez que estabelece a interface entre os espaços interiores e os agentes externos de degradação (Derakhshi 2020). Através desta função, garantindo níveis contribui para garantir condições adequadas de conforto interior, segurança, e capacidade de adaptação a novas exigências ao longo da vida útil do edifício. Assim, o seu desempenho

assume um papel decisivo na durabilidade e na qualidade global do edifício (Brito et al. 2020; Silva, De Brito, and Gaspar 2016; Watt 2007).

Apesar da sua relevância, a envolvente está particularmente exposta a processos de envelhecimento e deterioração, frequentemente agravados pela ausência de manutenção adequada(Brito et al. 2020; Silva, De Brito, and Gaspar 2016; Watt 2007). Na Europa, e em particular em Portugal, as estratégias de manutenção são maioritariamente corretivas, onde as reparações são realizadas após a ocorrência da "falha", ou no caso dos revestimentos, após presença de anomalias que comprometem o desempenho do revestimento (Jernberg et al. 2004; Long, Henderson, and Montgomery 2001). Esta prática contribui para uma deterioração mais rápida, custos de ciclo de vida mais elevados, redução da vida útil e comprometem o desempenho a longo prazo dos edifícios (Brito et al. 2020; Lopes 2011; Mouratidis 2021; Sandak 2019; Sarja 2002).

Em contrapartida, a manutenção baseada na condição concilia a monitorização ou inspeção do elemento com a análise do seu estado e a subsequente execução de intervenções (CEN 2021). Esta metodologia permite correlacionar o desempenho dos elementos construtivos com a sua probabilidade de falha, promovendo uma recolha sistemática de informação (Cláudia Ferreira et al. 2023). Adicionalmente, esta abordagem prolonga o patamar mínimo de desempenho do edifício e otimiza os custos face à manutenção preventiva predeterminada, enquanto prioriza a redução do risco de falha em comparação com a estratégia corretiva (Lind and Muyingo 2012).

Este estudo combina inspeções in situ com um modelo estocástico de manutenção baseada na condição para examinar a sua influência no desempenho da envolvente do edifício. Embora investigações anteriores neste domínio tenham recorrido a redes de Petri, as suas aplicações assumem pressupostos teóricos com base em dados empíricos, ou seja, com base em vários dados de inspeções a edifícios in situ, anos após a sua aplicação (Dias 2025). O contributo deste trabalho consiste na validação empírica de modelos através da comparação entre as condições reais observadas imediatamente antes e após intervenções. A partir da avaliação de dezanove casos de estudo antes e depois das intervenções de manutenção, esta investigação propõe uma abordagem baseada em evidência empírica que vai além da aplicação isolada de modelos preditivos ou de estratégias corretivas. A recolha de dados in situ permite quantificar a melhoria no estado de conservação dos revestimentos associada às intervenções, avaliar a adequação das transições estocásticas previstas pelos modelos e analisar os seus impactes nos custos e na segurança. Desenvolvida no âmbito do projeto BestMaintenance-LowerRisks (Cláudia Ferreira et al. 2023), esta abordagem integrada contribui para uma calibração mais fiável dos efeitos da manutenção e para uma representação mais rigorosa do desempenho observado em condições reais de serviço.

2. Metodologia

Para avaliar a influência da manutenção na durabilidade, nos custos e na segurança, implementou-se uma metodologia baseada em inspeções nos dezanove casos de estudo selecionados. As inspeções foram realizadas antes e após as intervenções de manutenção, permitindo a comparação direta dos estados de degradação e da evolução do desempenho. Posteriormente, analisaram-se os custos, o estado de degradação e a segurança através de uma matriz de risco de queda de revestimentos em pedra natural aplicados em fachadas.

O estado de degradação dos elementos foi determinado com base no índice de severidade da degradação (S_w). Este índice quantifica o estado global de degradação de um elemento através da razão entre a área degradada, ponderada em função do nível de degradação e da gravidade das anomalias identificadas, e uma área de referência, que corresponde à superfície total do elemento no estado de degradação mais grave possível (Equação 1).

$$S_w = \frac{\Sigma\left(A_n \times k_n \times k_{a,n}\right)}{A \times \Sigma k_{max}} \quad (1)$$

A severidade de degradação S_w correspondente a ação do elemento considera A_n como a área afetada pela anomalia n (m^2), k_n como o fator multiplicador associado à anomalia *n*, de acordo com o seu nível de degradação (variando entre 0 e 4), $k_{a,n}$ como o coeficiente de ponderação que expressa a importância relativa da anomalia *n* (igual a 1 quando não é definida uma ponderação específica), *A* como a área total do elemento m^2 e Σk_{max} representa a soma dos fatores de ponderação correspondente ao nível de degradação mais elevado para um elemento de área *A* (Silva, De Brito, and Gaspar 2016; Cláudia Ferreira et al. 2023; Pedro L. Gaspar and De Brito 2008; Pedro Lima Gaspar 2009).

As estratégias de manutenção foram definidas através de um modelo estocástico de manutenção baseada na condição, no qual uma determinada ação é executada quando o elemento atinge um estado de degradação específico. Neste âmbito, as redes de Petri são utilizadas para representar a dinâmica de degradação e a lógica de intervenção, servindo de apoio ao planeamento da manutenção e à tomada de decisão. Em contraste com os modelos convencionais baseados na avaliação por peritos, esta abordagem é calibrada com dados empíricos de inspeção, o que garante um maior alinhamento entre as trajetórias de degradação simuladas e as condições reais observadas *in situ*, aumentando a robustez e a transferibilidade dos resultados. A aplicação prática deste modelo fundamentou-se na análise comparativa de indicadores de desempenho antes e após as ações de manutenção. Os dados recolhidos permitiram quantificar o impacto imediato de cada intervenção através da redução direta do índice S_w. Adicionalmente, a modelação por redes de Petri possibilitou a simulação de diferentes cenários de manutenção a longo prazo, avaliando o impacto das intervenções tanto na extensão do ciclo de vida dos elementos quanto na mitigação dos custos acumulados. Este processo de calibração contínua reduz a incerteza intrínseca aos modelos de previsão de vida útil, fornecendo uma base matemática sólida para a transição de políticas de manutenção puramente reativas para estratégias proativas e otimizadas (Cláudia Ferreira et al. 2023).

2.1 Casos de Estudo e Modelação Avançada

Foram analisados dezanove casos de estudo em oito edifícios localizados em Portugal. O trabalho *in situ* decorreu entre julho de 2020 e janeiro de 2023, tendo a sua duração alargada, resultado das restrições associadas à pandemia de COVID-19. Durante este período, foram contactadas 42 entidades, das quais 12 aceitaram colaborar. Os edifícios analisados compreenderam imóveis de uso misto (com pisos superiores residenciais e pisos térreos comerciais ou de serviços), edifícios exclusivamente de serviços, edifícios residenciais e instalações industriais. Os elementos da envolvente avaliados incluíram rebocos correntes (63%), caixilharias em alumínio (16%), revestimentos cerâmicos aderentes (11%), revestimentos em pedra natural (5%), e revestimentos cerâmicos em coberturas inclinadas (5%). Para apresentar uma visão global e detalhada dos casos analisados, a Tabela 1 sistematiza o resumo dos casos de estudo em análise, categorizados por edifício (B) e elemento (E), bem como a sua utilização específica e o tipo de elemento da envolvente.

As inspeções foram realizadas em dois momentos distintos: primeiro, para avaliar o estado de conservação atual dos edifícios e, segundo, após as intervenções. O procedimento de levantamento incluiu a utilização de câmara fotográfica, fita métrica, fissurómetro, fichas de inspeção normalizadas, um sistema de classificação do estado de degradação e peças desenhadas dos elementos inspecionados para o mapeamento esquemático de anomalias (Dias 2025).

Para efeitos de modelação, foi necessária a obtenção dos desenhos digitais de cada elemento, preferencialmente em formato CAD, o que em alguns casos exigiu um levantamento dimensional (Dias, Flores-Colen, and Silva 2021).

2.2 Manutenção baseada na condição

A manutenção baseada na condição foi adotada neste estudo para evitar calendários de manutenção excessivamente conservadores, comummente associados a estratégias preventivas predeterminadas que priorizam a redução do risco de falha em detrimento da otimização de custos (Lind and Muyingo 2012). O modelo proposto assume, portanto, a manutenção baseada na condição, onde uma ação é desencadeada sempre que um elemento atinge um nível de degradação específico (C. Ferreira et al. 2021) (por exemplo, ações de limpeza para estados de degradação ligeira ou a substituição total no fim da vida útil).

As redes de Petri foram utilizadas como abordagem de modelação para representar o fluxo de informação e de controlo em sistemas dinâmicos, através de um formalismo matemático com componente gráfica. Este método adequa-se a sistemas nos quais as interações entre componentes são concorrentes, assíncronas, distribuídas, paralelas e estocásticas (Dias 2025; Cláudia Ferreira et al. 2023; Petri 1962; Murata 1989; Ajmone Marsan 1995; C. Ferreira et al. 2018). Uma rede de Petri é definida como um grafo orientado bipartido ponderado com um estado inicial, designado por marcação inicial, composto por lugares e transições interligados por arcos orientados (Peterson 1977; Schneeweiss 2006). Os lugares, as ações e os recursos encontram-se representados na lógica de interação entre a degradação e a manutenção, implementada no modelo estocástico de redes de Petri.

2.3 Custos e segurança pós-intervenção

Uma vez definidos o estado de degradação de cada caso de estudo e a modelação estocástica da manutenção baseada na condição, foram escolhidas as estratégias de intervenção a aplicar nos edifícios, dando continuidade à quantificação dos custos despendidos. Além disso, apresenta-se a matriz que estabelece o risco de queda de revestimentos em pedra natural nas fachadas dos edifícios, como auxílio para identificar as ações necessárias para garantir a segurança dos utilizadores e transeuntes da região onde estão localizados.

2.3.1 Custos

A estrutura económica da metodologia proposta considera os encargos financeiros associados aos custos de manutenção decorrentes da execução das intervenções. A estimativa dos encargos com materiais, mão de obra e equipamentos para cada intervenção baseou-se na plataforma digital *Gerador de Preços* (CYPE 2019). Os custos de intervenção foram expressos por unidade de área (€/m²) para permitir a comparação entre os diferentes casos de estudo.

No presente estudo, as operações de limpeza focam-se na mitigação de anomalias visuais e de superfície na envolvente. O orçamento desta ação contempla a montagem de andaimes ou de sistemas de ancoragem; no caso específico de coberturas, a lavagem com jato de água sob pressão; e a aplicação de biocidas para a erradicação de colonizações biológicas. As intervenções ligeiras caracterizam-se por reparações localizadas, combinando trabalhos de limpeza, correções pontuais e a substituição parcial de componentes danificados, cujas especificidades dependem do elemento construtivo em questão. À semelhança da operação anterior, este custo engloba as estruturas de acesso e de proteção necessárias (andaimes ou linhas de vida em coberturas).

Por fim, o custo de substituição total reflete a renovação integral do elemento, cenário que ocorre tipicamente quando este atinge o fim da sua vida útil. Este encargo inclui o aluguer de meios de acesso, o desmonte e a demolição da solução degradada, o transporte, a gestão e o depósito de resíduos de construção e demolição (RCD), bem como a instalação do novo elemento da envolvente. Excluem-se desta regra as caixilharias em alumínio, cujo custo associado aos meios de acesso não foi contabilizado de forma sistemática em todas as ações.

2.3.2 Segurança

Para avaliar a segurança dos edifícios, foi aplicada uma matriz de risco para fachadas com Revestimento em Pedra Natural (RPN) desenvolvida por Dias (2025). Os parâmetros de cálculo baseiam-se no histórico de anomalias do RPN, no impacto da sua queda e no fluxo de peões na envolvente do edifício. A matriz cruza a probabilidade de queda (*PQ*) com a consequência da queda (*IQ*), definindo o Risco de Queda (*RQ*) através da Equação (2):

$$RQ_{percentual} = PQ \times IQ \times {}^{1}/_{25} \times 100 \quad (2)$$

O valor obtido determina a prioridade da intervenção de manutenção. A probabilidade de queda (*PQ*) é definida em cinco níveis ordenados em função do tempo de serviço do revestimento: o nível 1 corresponde a uma probabilidade de 0% a 10%; o nível 2 abrange o intervalo de 10% a 30%; o nível 3 situa-se entre 30% e 50%; o nível 4 compreende o intervalo de 50% a 70%; e o nível 5 representa uma probabilidade de 70% a 100%.

Por sua vez, o nível de impacto da queda (*IQ*) é calculado através do fluxo diário de transeuntes na envolvente da fachada, sendo categorizado em cinco intervalos de circulação: nível 1 (muito baixa, com menos de 20 pessoas por dia); nível 2 (baixa, de 20 a 100 pessoas por dia); nível 3 (moderada, de 100 a 400 pessoas por dia); nível 4 (alta, de 400 a 1000 pessoas por dia); e nível 5 (muito alta, com mais de 1000 pessoas por dia).

A Matriz de Risco de Queda (Tabela 2) correlaciona a probabilidade de queda (*PQ*) com o nível de impacto (*IQ*). Através desta associação, quanto maior for o valor obtido, mais elevado é o risco e, por conseguinte, maior é a prioridade de intervenção. A matriz categoriza o risco em três níveis de severidade operacional através de um código de cores: baixo (0% a 20%, sinalizado a verde), médio (20% a 50%, sinalizado a amarelo) e alto (50% a 100%, sinalizado a vermelho).

A integração das variáveis anteriormente descritas permitiu o desenvolvimento do Indicador de Risco de Queda (*IRQ*) para o RPN, calculado através da multiplicação do Risco de Queda (*RQ*), obtido na Equação (2),

pelos fatores de majoração: Exposição do Elemento (*E*), Altura do Revestimento (*H*), Área da Placa (*AP*) e Espessura da Placa (*EP*), conforme estabelecido na Equação (3):

$$IRQ = RQ \times E \times H \times AP \times EP \quad (3)$$

Tabela 2. Matriz de Risco de Queda. Fonte: Dias (2025).

		Impacto da Queda *(IQ)*				
		Nível 1	**Nível 2**	**Nível 3**	**Nível 4**	**Nível 5**
Probabilidade da Queda *(PQ)*	**Nível 1**	4%	8%	12%	16%	20%
	Nível 2	8%	16%	24%	32%	40%
	Nível 3	12%	24%	36%	48%	60%
	Nível 4	16%	32%	48%	64%	80%
	Nível 5	20%	40%	60%	80%	100%

Os parâmetros de ponderação para cada uma das variáveis são definidos analiticamente em função das características físicas e funcionais da fachada. A Exposição do Elemento (*E*) é classificada como baixa (1) se existir proteção contra queda em toda a extensão da fachada, média (2) se a proteção for parcial, e alta (3) na ausência de qualquer dispositivo de proteção. A Altura do Revestimento (*H*) é categorizada como baixa (1) até 2 pisos de altura, corrente (2) até 4 pisos, e alta (3) para fachadas com mais de 4 pisos. A Área da Placa (*AP*) assume o valor 1 para pequenas dimensões (áreas inferiores a 0,1 m^2), 2 para médias dimensões (entre 0,1 m^2 e 0,4 m^2) e 3 para grandes dimensões (placas com área superior a 0,4 m^2). Por fim, a Espessura da Placa (EP) é definida como corrente (1) para espessuras até 2,5 cm e alta (2) para valores superiores.

O valor final do IRQ determina o nível de urgência e os prazos limite para as ações de manutenção. Para valores de IRQ entre 0 e 25, a intervenção é considerada não urgente, recomendando-se apenas a monitorização anual do elemento. No intervalo de 26 a 50, torna-se necessária uma intervenção num prazo máximo de 2 anos, reduzindo-se este limite para 1 ano caso o indicador se situe entre 51 e 100. Valores de IRQ entre 101 e 150 exigem uma intervenção imediata num prazo máximo de 6 meses. Por último, um resultado entre 151 e 1350 sinaliza um perigo iminente, exigindo a aplicação imediata de medidas de contingência e a execução da intervenção num prazo limite de 1 mês.

3. Resultados e Discussão

Com base na totalidade dos dados recolhidos, determinou-se a estratégia de intervenção através da modelação estocástica por redes Petri. Nos casos de estudo analisados, as soluções adotadas compreenderam intervenções ligeiras (IL) ou a substituição total (ST) dos elementos, de acordo com o sistematizado na **Tabela *3***.

As estratégias de intervenção foram definidas pelos proprietários e visaram a reabilitação geral ou pontual do edifício, alteração funcional (mudança de uso), modernização, renovação motivada por um estado elevado de degradação ou cumprimento de critérios estéticos. Após a aplicação das respetivas estratégias de intervenção, realizou-se uma nova inspeção com o objetivo de verificar a eventual persistência de anomalias nos elementos da envolvente.

Baseando-se nestas inspeções, o impacto quantitativo da manutenção traduziu-se numa redução do índice de severidade da degradação (ΔS_w) de 26,10% nas caixilharias de alumínio, 9,80% nos rebocos correntes e 2,03% nos revestimentos em pedra natural. Este valor empírico apresenta um elevado alinhamento com a previsão do modelo estocástico do reboco corrente, que estimou uma redução de 8,94% para o nível de intervenção correspondente. Nas caixilharias, o decréscimo médio de ΔS_w obtido *in situ* foi significativamente superior ao previsto, atingindo 26,10% face aos 2,99% estimados pelo modelo estocástico.

Em sentido inverso, o ΔS_w do RPN registado em campo (2,03%) revelou-se inferior ao valor estimado pelo modelo (7,06%).

Tabela 3. Síntese das intervenções dos casos de estudo recolhidos.

Casos de Estudo	Tipo de intervenção	Elemento da Envolvente
B1-E1	Substituição Total	Reboco corrente
B1-E2	Substituição Total	Reboco corrente
B2-E1	Intervenção Ligeira	Reboco corrente

B8-E1	Intervenção Ligeira	Revestimentos em Pedra Natural

De uma forma geral, a diferença relativa entre os valores observados e previstos evidencia a capacidade do modelo para reproduzir o efeito das intervenções de manutenção, sendo a sua influência maior do que a estimada nos modelos, exceto em RPN. O desvio para um valor inferior ao expectável no RPN pode dever-se ao facto de as intervenções não terem sido integralmente realizadas no estado de condição previsto pelo modelo teórico de manutenção. Os rebocos correntes, que constituíram a amostra maior e estatisticamente mais significativa, serviram de base principal para esta comparação. Embora tenha sido encontrada uma forte correlação entre as observações *in situ* e o modelo teórico, o valor ligeiramente superior registado *in situ* sugere que a parametrização teórica permanece conservadora para os rebocos de fachada. Adicionalmente, as caixilharias em alumínio exibiram uma resposta significativa às intervenções de manutenção, com melhorias de desempenho que frequentemente superaram as previsões teóricas.

Este comportamento conservador pode ser considerado favorável do ponto de vista da gestão da manutenção, uma vez que reduz a possibilidade de sobrestimar o desempenho dos elementos do edifício. A adoção de previsões conservadoras, portanto, pode ser considerada um contributo para minimizar riscos.

Relativamente à eficiência económica, as ações de limpeza resultaram em custos mais baixos, compreendidos entre 14,00 €/m² e 31,37 €/m². As reparações ligeiras apresentaram custos entre 24,14 €/m² e 68,80 €/m², enquanto as substituições totais oscilaram entre 36,68 €/m² e 149,51 €/m². Destaca-se que os limites superiores destes intervalos estiveram consistentemente associados aos revestimentos em pedra natural, refletindo os custos mais elevados de mão de obra especializada e materiais pétreos inerentes a

este elemento e os requisitos adicionais de segurança e acessibilidade normalmente exigidos durante a execução das intervenções.

A monitorização dos revestimentos em pedra natural revelou que a ação de manutenção foi realizada quando o revestimento ainda apresentava um nível de degradação reduzido. Isto ocorreu porque o revestimento exibia defeitos críticos, designadamente o descolamento de elementos pétreos, o que constitui uma anomalia grave e um risco imediato para a segurança e a aptidão ao uso. Perante a presença deste defeito, as decisões de manutenção passam a ser orientadas pelo risco, e não pela progressão da degradação: a prioridade inverte-se da otimização da vida útil para a prevenção do risco de queda de elementos e da perda rápida de funcionalidade. Neste sentido, uma intervenção motivada pelo desprendimento traduz-se tipicamente numa substituição localizada, podendo não resultar numa redução global expressiva da gravidade da degradação quando captada por um índice ponderado pela área, como o S_w. Por outras palavras, a intervenção é motivada por um mecanismo de falha crítico que não é necessariamente proporcional à extensão global da degradação visível.

Sob o ponto de vista da modelação, este cenário evidencia uma condição de fronteira: o modelo estocástico teórico de manutenção foi concebido essencialmente para prever um comportamento de degradação gradual ao longo do tempo, no qual as intervenções são acionadas quando se atinge um limiar de condição predefinido e convencional. O modelo não está estruturado para representar eventos associados a falhas abruptas e críticas à segurança. Os resultados demonstram, portanto, que a avaliação da condição por si só pode não ser suficiente para basear as ações de manutenção em determinados elementos construtivos, como o caso do RPN. Nestes elementos suscetíveis a falhas abruptas, a integração simultânea de indicadores, como o Indicador de Risco de Queda (IRQ), assegura a utilização mais segura da edificação, preservando tanto os utilizadores e transeuntes quanto os ativos construídos.

Em síntese, as evidências *in situ* indicam que a prática real da manutenção integra critérios dinâmicos de gestão do risco que complementam os pressupostos integrados em modelos estocásticos puramente baseados na condição física dos modelos estocásticos. Para o setor industrial e profissional, estas conclusões confirmam a utilidade dos modelos estocásticos como ferramentas de apoio à decisão para o planeamento e orçamentação da manutenção de rotina, mas também sublinham os benefícios de integrar indicadores de riscos para defeitos críticos, refletindo a forma como as intervenções são priorizadas na prática. Esta perspetiva integrada pode auxiliar os *stakeholders* na definição de políticas de manutenção mais realistas, mitigando incertezas e otimizando a fiabilidade do planeamento dos custos do ciclo de vida de sistemas de fachada.

4. Conclusão

Este estudo implementou uma metodologia que combina inspeções *in situ* e modelação estocástica de manutenção baseada na condição, com processos definidos de inspeção pré-intervenção e pós-intervenção, mapeamento esquemático de anomalias, e acompanhamento das estratégias de ações definidas pelos proprietários. Assim, foi possível avaliar o estado de degradação dos elementos da envolvente antes e após as intervenções de manutenção. A viabilidade operacional desta abordagem foi demonstrada através de dezanove casos de estudo, permitindo quantificar os ganhos de desempenho associados a diferentes estratégias de intervenção, avaliar os custos e compreender o papel da manutenção na segurança dos edifícios.

Os resultados indicam que os modelos estocásticos de degradação tendem a ser conservadores na previsão da vida útil. A comparação entre as condições observadas pós-intervenção e as trajetórias de degradação previstas demonstra que os efeitos da manutenção podem ser quantificados e que o seu impacto na durabilidade e no desempenho é frequentemente subestimado.

A integração de dados recolhidos *in situ* na estrutura estocástica de redes de Petri reduziu as discrepâncias entre as curvas teóricas de degradação e o desempenho real observado, aumentando a fiabilidade do

planeamento da manutenção. Demonstrou-se também que os ajustes nas técnicas de intervenção e nas estratégias de acesso *in situ* influenciam a eficiência de custos sem comprometer o desempenho ou a segurança.

O trabalho desenvolvido demonstra a complementaridade entre a modelação estocástica da degradação e a análise de risco proposta. Enquanto os modelos estocásticos fundamentam o planeamento a longo prazo, as ações de manutenção do Revestimento em Pedra Natural (RPN) devem incorporar, em paralelo, os indicadores de risco de queda, mesmo na ausência de degradação superficial avançada. Situações em que anomalias graves afetam o sistema de fixação oculta configuram eventos que, embora discretos, apresentam elevada severidade e urgência. Nestes cenários, torna-se essencial a aplicação conjunta de ferramentas de diagnóstico adequadas, tais como a Matriz de Risco de Queda ou o Indicador de Risco de Queda, salvaguardando a segurança, bem como a validade dos modelos estocásticos.

Em suma, as conclusões validam o posicionamento da manutenção como uma componente estruturada de tomada de decisão ao longo do ciclo de vida do edifício, com implicações mensuráveis na durabilidade, no controlo de custos e na gestão da segurança da envolvente. Os resultados obtidos demonstram que a manutenção baseada na condição é uma metodologia eficaz para apoiar a fase de uso dos edifícios. A integração de dados reais permite visualizar a incerteza associada a esse tipo de manutenção e reforça a sua fiabilidade. Isto contribui para o aumento da durabilidade dos elementos da envolvente e para a utilização mais eficiente de recursos financeiros.

Assim, a manutenção baseada na condição em conjunto com o indicador de risco de queda de RPN se afirmam como ferramentas multifuncionais para a utilização dos edifícios conciliando desempenho, custo e segurança.

Agradecimentos

Avaliação da conservação de edificações públicas com base em ordens de serviço e classificação de criticidade pela matriz GUT

Mariana Silva Pires[1], Jessica Siqueira de Souza[1]

[1] Civil and Environmental Engineering Department, PECC—University of Brasília, Campus Darcy Ribeiro, Asa Norte, Brasília 70910-900, Brazil; mari_pires09@hotmail.com

Resumo: A manutenção predial é essencial para preservar o desempenho, a durabilidade e a vida útil dos sistemas construtivos, especialmente em edificações públicas submetidas ao uso contínuo e a restrições de recursos para intervenção. O monitoramento das falhas em operação permite compreender o comportamento das edificações em uso e subsidiar avaliações mais consistentes de seu estado de conservação. Entretanto, embora as ordens de serviço (OS) constituam uma fonte relevante de informação sobre essas falhas, seus registros são frequentemente utilizados apenas para fins operacionais, sendo pouco explorados em análises técnicas sistematizadas. Este trabalho objetiva analisar as ordens de serviço como instrumento de apoio à avaliação da conservação de edificações públicas, por meio de estudo de caso em blocos residenciais pertencentes a uma instituição pública. A metodologia baseia-se na análise de 308 ordens de serviço, das quais foram extraídas e classificadas ocorrências técnicas segundo bloco, sistema construtivo e nível de prioridade, com avaliação da criticidade pela matriz GUT. Os resultados permitiram identificar padrões recorrentes de solicitação, sistemas mais suscetíveis à degradação e diferentes prioridades de intervenção, com destaque para os sistemas hidrossanitário e de vedação e revestimentos. Verificou-se, ainda, que a edificação mais antiga não apresentou o maior número de registros, indicando que fatores como histórico de manutenção, intensidade de uso, condições de exposição e particularidades construtivas também influenciam o estado de conservação. Conclui-se que a análise sistematizada das OS contribui para transformar registros operacionais em indicadores técnicos, subsidiando o diagnóstico e a priorização das ações de manutenção.

Palavras-chave: manutenção predial; durabilidade; ordens de serviço; matriz GUT; conservação de edificações.

1. Introdução

A manutenção das edificações constitui um requisito essencial para a preservação do desempenho ao longo da vida útil. Em consonância com a ABNT NBR 15575 (2024), sua função está associada à conservação das condições de uso, segurança, habitabilidade e durabilidade dos sistemas construtivos, de modo a assegurar que a edificação mantenha, ao longo do tempo, o desempenho previsto em projeto. Além de sua relevância técnica, a manutenção apresenta impacto econômico expressivo no ciclo de vida das edificações. Em edifícios com vida útil de 50 anos, os custos de operação e manutenção podem representar cerca de 75% a 80% do custo total, evidenciando que o adequado planejamento das intervenções é determinante tanto para a conservação do ativo quanto para a racionalização dos recursos empregados (Mahpour, 2023).

Quanto à forma de intervenção, a manutenção das edificações pode ser classificada em três tipos: preventiva, corretiva e preditiva. A ABNT NBR 5674 (2024) trata a manutenção como um conjunto de ações voltadas a prevenir ou corrigir a perda de desempenho da edificação, o que evidência, no âmbito normativo, a centralidade das abordagens preventiva e corretiva. Flores *et al.* (2022) classificam a manutenção

preventiva como aquela realizada de forma planejada, antes da ocorrência da falha, e a manutenção corretiva como a intervenção executada após a identificação de anomalias ou perda de desempenho. Bouabdallaoui *et al.* (2021), por sua vez, incluem a manutenção preditiva como uma estratégia baseada no monitoramento da condição do sistema, permitindo definir o momento mais adequado para a intervenção. Embora essa modalidade não seja apresentada de forma explícita na ABNT NBR 5674 (2024), sua relevância é amplamente reconhecida na literatura, uma vez que possibilita intervenções fundamentadas no estado real dos elementos, contribuindo para a redução de falhas inesperadas, para o melhor planejamento das ações de manutenção e para o uso mais eficiente dos recursos ao longo da vida útil da edificação.

A elaboração de um plano de manutenção adequado é fundamental para orientar as intervenções ao longo da vida útil da edificação. Nesse contexto, o monitoramento de dados históricos, como os registros de ordens de serviço, representa uma importante fonte de informação para a tomada de decisão, pois permite identificar padrões de ocorrência, recorrências e sistemas mais suscetíveis a falhas (D'Orazio et al., 2022; Chelaru et al., 2024; Salzano et al., 2023).Em contrapartida, a literatura aponta que a avaliação das necessidades de manutenção ainda é frequentemente baseada em inspeções visuais e em julgamentos técnicos, o que pode tornar o processo decisório mais subjetivo (Begić *et al*., 2024). Assim, o uso integrado de dados históricos e critérios técnicos contribui para decisões mais consistentes na priorização das intervenções e na definição de ações compatíveis com as condições reais da edificação (Salzano *et al*., 2023).

A insuficiência ou ausência de manutenção favorece o aparecimento e a progressão de diferentes anomalias construtivas, com destaque para problemas relacionados à umidade e infiltração, fissuração, corrosão de elementos metálicos ou armaduras, destacamento de revestimentos e desplacamento de componentes superficiais. Na análise de defeitos em áreas molhadas, Chew (2005) observou elevada ocorrência de vazamentos, corrosão de tubulações e desplacamento de concreto, associando parte desses problemas a falhas de manutenção. Em revisão recente sobre fontes de informação para defeitos em edificações, Berg Oppedal *et al.* (2024) também destacam como recorrentes manifestações como vazamentos em tubulações, falhas no sistema de abastecimento, fissuras em paredes de concreto e umidade em superfícies internas. De forma convergente, Resende *et al.* (2022), ao avaliarem uma edificação histórica, identificaram umidade, fissuras e regiões com destacamento de argamassa como danos que comprometem a integridade e a vida útil do edifício. Em conjunto, esses estudos indicam que a falta de manutenção não apenas intensifica a frequência dessas anomalias, mas também acelera a perda das condições de conservação e desempenho das edificações.

Dessa forma, a padronização dos registros de ordens de serviço e sua conversão em métricas analíticas emergem como uma estratégia promissora para a análise da conservação das edificações ao longo do tempo. A sistematização dessas informações permite identificar recorrências, reconhecer sistemas com maior incidência de falhas, estabelecer ordens de intervenção e produzir indicativos acerca do nível de conservação dos edifícios, ampliando o uso de registros históricos como base empírica para a avaliação das condições construtivas (Alavi *et al*., 2022; Chelaru *et al.,* 2024). Além disso, ao transformar dados operacionais dispersos em informações comparáveis, essa abordagem contribui para reduzir a dependência exclusiva de inspeções visuais e julgamentos subjetivos, frequentemente apontados na literatura como limitações dos

processos convencionais de avaliação da condição predial (Begić e Krstić, 2024; Tan *et al*. 2024; Valença *et al*. 2024).

Diante desse contexto, o presente estudo tem como objetivo analisar os registros de ordens de serviço como fonte de informação para a avaliação da conservação de edificações públicas, buscando identificar padrões de ocorrência, recorrências de falhas, sistemas construtivos mais críticos e parâmetros que subsidiem a definição de prioridades de intervenção a partir de dados históricos reais.

2. Metodologia

O presente estudo desenvolve um estudo de caso a partir da análise de ordens de serviço (OS) relacionadas à manutenção predial de edificações públicas, visando investigar sua aplicabilidade como base empírica para a análise da conservação dos edifícios. Para isso, busca-se compreender a distribuição das demandas de manutenção em função dos blocos, dos sistemas construtivos e das prioridades de atendimento. A análise foi realizada com base em 308 ordens de serviço referentes a doze edificações públicas situadas em Brasília, Distrito Federal, considerando o recorte temporal do ano de 2024. O procedimento metodológico foi organizado em três etapas principais: estruturação da base de dados, definição das prioridades de execução e avaliação do nível de conservação das edificações analisadas, conforme apresentado na Figura 1.

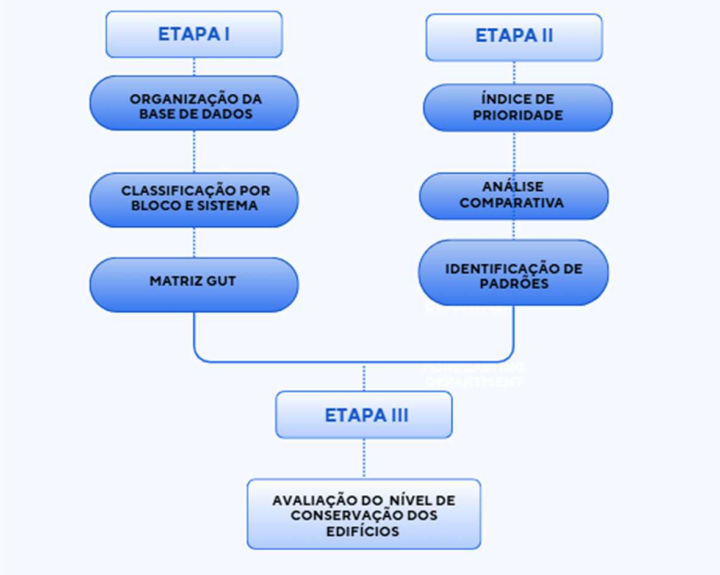

Figura 1 – Fluxograma metodológico

A metodologia foi organizada em três etapas sucessivas.

2.1 Etapa I

Na Etapa I, realizou-se a estruturação da base de dados a partir dos registros de Ordens de Serviço (OS), os quais reúnem informações sobre o bloco, a natureza da ocorrência e o sistema construtivo envolvido. Para viabilizar a análise, as demandas foram padronizadas e agrupadas em oito sistemas construtivos: hidrossanitário, elétrico, estrutural, vedações e revestimentos, áreas sociais, cobertura, comunicação e redes e proteção contra incêndio. Posteriormente, as ocorrências foram avaliadas segundo os critérios de Gravidade, Urgência e Tendência, por meio da matriz GUT. Essa etapa permitiu consolidar e classificar os dados de forma sistemática, possibilitando sua análise segundo os edifícios e os sistemas mais recorrentes. Ressalta-se que as edificações consideradas na amostra foram construídas entre as décadas de 1977 e 2001.

2.2 Etapa II

Na Etapa II, a definição do índice de prioridade das ocorrências foi realizada por meio da matriz GUT, método desenvolvido por Kepner e Tregoe (1981) com o objetivo de apoiar a hierarquização de problemas segundo os critérios de gravidade, urgência e tendência. Em estudos aplicados às edificações, sua utilização tem se mostrado útil na classificação de manifestações patológicas e no direcionamento das ações de manutenção conforme a criticidade observada (Holanda *et al*., 2022 e Braga *et al*., 2019). Para cada ordem de serviço, foram atribuídos valores inteiros de 1 a 5 para cada critério, em que os valores mais elevados correspondem às situações de maior criticidade. A gravidade expressa o impacto da anomalia sobre o desempenho, a segurança e a habitabilidade; a urgência representa a necessidade temporal de intervenção; e a tendência indica a possibilidade de agravamento da ocorrência. Os critérios utilizados para atribuição das pontuações da matriz GUT foram padronizados conforme apresentado na Tabela 1, de modo a reduzir a subjetividade da classificação e permitir maior consistência na avaliação das ordens de serviço.

Tabela 1 – Critérios de pontuação para avaliação da Gravidade, Urgência e Tendência

Pontuação	Gravidade	Urgência	Tendência
1	Impacto insignificante sobre o desempenho ou sobre os usuários.	Não há necessidade imediata de intervenção.	Condição estável, sem expectativa de agravamento.
2	Impacto localizado de baixa intensidade.	A intervenção pode ser postergada sem consequências relevantes.	Espera-se progressão lenta da ocorrência.
3	Impacto funcional moderado ou desconforto aos usuários.	A intervenção deve ser realizada em prazo razoável.	Espera-se agravamento gradual da ocorrência.
4	Impacto significativo sobre o desempenho, o uso ou as condições de segurança.	Requer intervenção em curto prazo.	Há probabilidade de agravamento rápido.
5	Impacto crítico sobre a segurança, a habitabilidade ou a continuidade do serviço.	Requer intervenção imediata.	Há agravamento severo ou acelerado da ocorrência.

Após a atribuição das pontuações de Gravidade, Urgência e Tendência, foi calculado o Índice de Prioridade (IP) de cada ordem de serviço. O IP foi obtido pelo produto entre os três critérios avaliados, conforme apresentado na Equação 1.

$$IP = G \times U \times T \quad (1)$$

em que IP corresponde ao Índice de Prioridade, G à Gravidade, U à Urgência e T à Tendência. Considerando a escala adotada, com pontuações variando de 1 a 5 para cada critério, o valor mínimo possível do índice é 1, correspondente à menor condição de criticidade, e o valor máximo possível é 125, correspondente à condição de maior criticidade.

A utilização do produto entre os critérios permite evidenciar ocorrências em que há simultaneamente maior impacto técnico, maior necessidade temporal de intervenção e maior potencial de agravamento. Dessa forma, o índice não considera apenas a frequência das ordens de serviço, mas também o grau de criticidade associado a cada ocorrência, contribuindo para uma priorização mais consistente das ações de manutenção. A classificação das ocorrências segundo o IP foi organizada em três faixas de prioridade, conforme apresentado na Tabela 2.

Tabela 2 – Classificação das ocorrências segundo as faixas do Índice de Prioridade

Faixa do IP	Nível de prioridade	Interpretação técnica
1 a 41	Médio prazo	Ocorrências de menor criticidade, com impacto limitado e possibilidade de programação da intervenção em horizonte mais amplo.
42 a 83	Curto prazo	Ocorrências de criticidade intermediária, que exigem intervenção programada para evitar agravamento da anomalia ou perda progressiva de desempenho.
84 a 125	Ação imediata	Ocorrências de alta criticidade, associadas a impacto relevante sobre segurança, habitabilidade, funcionalidade ou continuidade do serviço, demandando intervenção prioritária.

Para fins de classificação, os valores obtidos foram agrupados em três níveis de prioridade: médio prazo, curto prazo e ação imediata. A divisão das faixas considerou a amplitude total possível do índice, permitindo organizar as ocorrências em classes progressivas de criticidade. Assim, as demandas enquadradas como ação imediata correspondem às situações de maior relevância técnica, enquanto as classificadas como curto e médio prazo representam ocorrências que podem ser planejadas de acordo com sua evolução, impacto e disponibilidade de recursos.

Diversos autores têm proposto métodos para padronizar dados históricos de manutenção e convertê-los em informações analíticas. Madureira *et al.* (2017) e Flores-Colen, Gomide e Della Flora (2022), utilizaram uma abordagem multicritério para apoiar a priorização de intervenções em fachadas. D'Orazio *et al.*(2022) aplicaram uma abordagem orientada por dados para analisar registros de manutenção e identificar padrões de ocorrência em edifícios. De forma complementar, Chelaru *et al.* (2024) integraram registros históricos, dados de inspeção e informações geométricas em ambiente HBIM para apoiar a avaliação das condições construtivas. Em conjunto, esses estudos demonstram que diferentes métodos podem ser empregados para estruturar dados históricos e ampliar seu uso na análise da conservação das edificações.

2.3 Etapa III

Na Etapa III, procedeu-se à análise integrada dos resultados obtidos a partir da base de ordens de serviço classificada. A avaliação considerou a distribuição das ocorrências por conjunto habitacional, bloco, sistema construtivo e nível de prioridade, permitindo identificar padrões de recorrência, concentração espacial das demandas e sistemas com maior incidência de falhas.

Inicialmente, foram quantificadas as ordens de serviço por sistema construtivo e por bloco, com o objetivo de reconhecer os subsistemas mais suscetíveis à degradação e os setores com maior demanda de manutenção. Em seguida, os resultados do Índice de Prioridade foram agrupados em três classes de intervenção, médio prazo, curto prazo e ação imediata, possibilitando avaliar não apenas a frequência das ocorrências, mas também seu grau de criticidade.

A análise comparativa entre os conjuntos edificados considerou ainda o ano de construção, o número total de ordens de serviço, a distribuição das ocorrências por sistema e a concentração das demandas prioritárias. Essa abordagem permitiu verificar se a idade da edificação apresentava relação direta com o volume e a criticidade das manifestações registradas, bem como identificar possíveis influências de outros fatores, como condições de uso, histórico de manutenção, intervenções anteriores e particularidades construtivas de cada bloco.

Dessa forma, a Etapa III buscou transformar os registros operacionais de manutenção em indicadores técnicos de conservação, subsidiando uma leitura comparativa entre os edifícios avaliados e permitindo a identificação dos sistemas e blocos que demandam maior atenção no planejamento das ações de manutenção.

3. Resultados e Discussões

A análise comparativa das Ordens de Serviço (OS) permitiu avaliar a distribuição das demandas de manutenção entre conjuntos edificados com diferentes períodos de construção. Entre as edificações analisadas, a SQN 206, construída em 1977, corresponde ao conjunto mais antigo, seguida pela SQN 205, de 1981, e pela SQN 109, de 2001, que representa o conjunto mais recente da amostra. De modo geral, os resultados indicam que a idade da edificação constitui um fator relevante para a compreensão das demandas de manutenção, especialmente em sistemas sujeitos ao uso contínuo, à exposição à umidade e ao envelhecimento natural dos componentes, como os sistemas hidrossanitário e de vedação e revestimentos. Entretanto, a distribuição das ocorrências não se mostrou estritamente proporcional ao tempo de construção, indicando que a conservação predial também é influenciada por fatores como histórico de manutenção, intervenções anteriores, intensidade de uso, condições de exposição e particularidades construtivas de cada bloco.

A Tabela 3 apresenta a síntese dos principais indicadores obtidos a partir das ordens de serviço analisadas, considerando o ano de construção, o número total de registros, o bloco com maior concentração de ocorrências, o sistema predominante e a classificação das intervenções segundo o Índice de Prioridade. Essa organização permite uma leitura comparativa inicial dos conjuntos avaliados e contribui para relacionar frequência de ocorrências, criticidade das demandas e estado de conservação das edificações.

Tabela 3 – Síntese dos indicadores obtidos a partir das ordens de serviço analisadas

Conjunto	Ano de construção	Total de OS analisadas	Bloco com maior nº de OS	Sistema predominante	Ocorrências de Ação imediata	Ocorrências de Curto prazo	Ocorrências de Médio prazo
SQN 205	1981	132	Bloco H	Hidrossanitário	24	60	58
SQN 206	1977	102	Bloco K	Hidrossanitário	12	37	54
SQN 109	2001	74	Bloco J	Hidrossanitário	5	25	47

Ressalta-se que o total de ordens de serviço analisadas corresponde ao número de registros administrativos existentes na base de dados. As categorias de prioridade, por sua vez, referem-se às ocorrências técnicas classificadas pelo Índice de Prioridade, uma vez que uma mesma ordem de serviço pode envolver mais de uma manifestação patológica, demanda de manutenção ou sistema construtivo. Assim, a soma das ocorrências classificadas por prioridade pode diferir do número total de ordens de serviço, pois a análise buscou representar tecnicamente as manifestações identificadas em cada registro, e não apenas contabilizar os documentos administrativos de solicitação.

Na SQN 205, construída em 1981, foi observado o maior número total de ordens de serviço entre os conjuntos analisados, com 132 registros. A distribuição interna das ocorrências indicou maior concentração no Bloco H, com 44 OS, correspondente a 33,3% do total, seguido pelo Bloco C, com 34 OS (25,8%), pelo Bloco G, com 29 OS (22,0%), e pelo Bloco L, com 25 OS (18,9%), conforme apresentado na Figura 2. A predominância de registros no sistema hidrossanitário e em vedação e revestimentos indica maior suscetibilidade desses subsistemas a manifestações associadas ao uso contínuo, à umidade, ao envelhecimento dos componentes e à perda progressiva de desempenho.

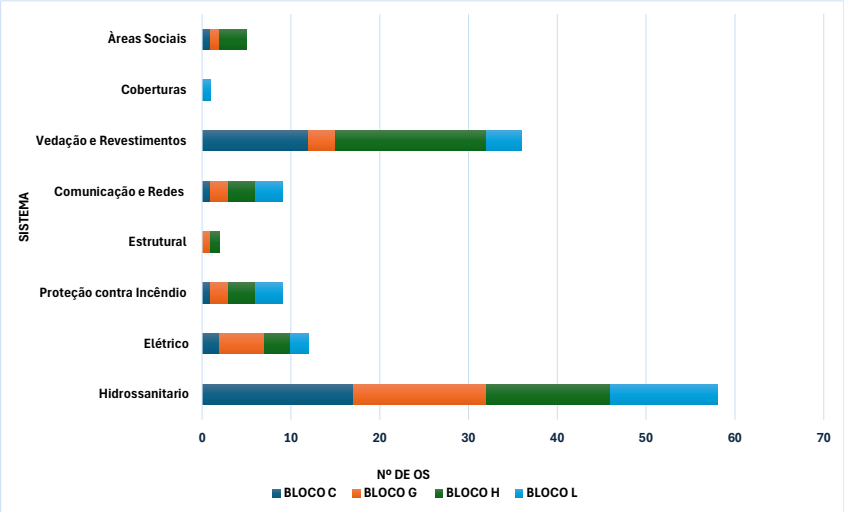

Figura 2 – Distribuição das Ordens de Serviço por sistema e por bloco na SQN 205

Na SQN 206, construída em 1977, foram contabilizadas 102 ordens de serviço. Embora esse conjunto corresponda à edificação mais antiga da amostra, o número total de ocorrências foi inferior ao observado na SQN 205. A maior concentração de registros ocorreu no Bloco K, com 30 OS (29,4%), seguido pelo Bloco B, com 27 OS (26,5%). Os Blocos A e F apresentaram 17 ocorrências cada, equivalentes a 16,7%, enquanto o Bloco J registrou 11 OS, correspondente a 10,8% do total, conforme ilustrado na Figura 3. Esses resultados indicam que a antiguidade da edificação contribui para a intensificação das demandas de manutenção, mas não determina isoladamente sua distribuição nem seu nível de criticidade.

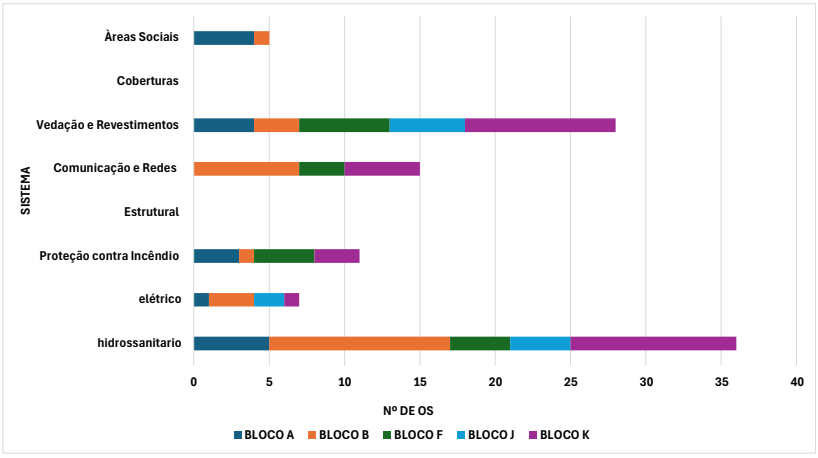

Figura 3 – Distribuição das Ordens de Serviço por sistema e por bloco na SQN 206

Na SQN 109, construída em 2001, foi registrado o menor quantitativo total de ordens de serviço, com 74 registros administrativos. A distribuição interna, entretanto, revelou elevada concentração no Bloco J, responsável por 46 registros, equivalentes a 62,2% do total do conjunto, enquanto o Bloco I concentrou 20 OS (27,0%) e o Bloco H apresentou 8 OS (10,8%), conforme demonstrado na Figura 4. Apesar de se tratar do conjunto mais recente, a concentração das demandas em um único bloco evidencia que a conservação predial deve ser analisada também em escala local, considerando as particularidades de uso, manutenção e desempenho de cada setor da edificação.

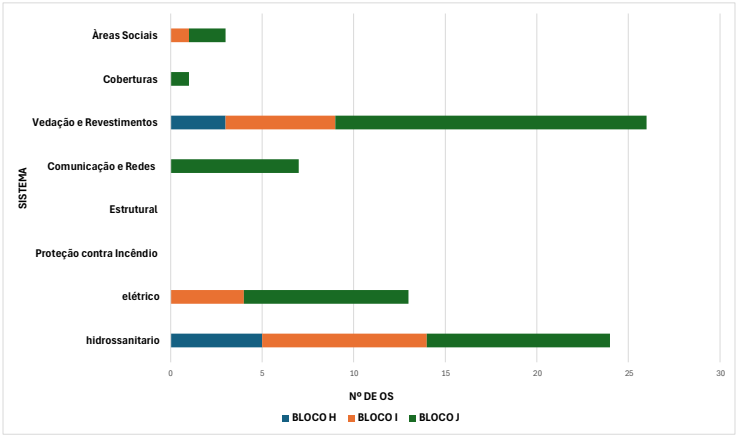

Figura 4 – Distribuição das Ordens de Serviço por sistema e por bloco na SQN 109

A comparação entre os três conjuntos demonstra que as demandas de manutenção não se distribuem de forma homogênea entre as edificações nem entre os blocos pertencentes ao mesmo conjunto. A SQN 205 apresentou o maior número total de ocorrências, embora não seja a edificação mais antiga, enquanto a SQN 109, mesmo sendo a mais recente, apresentou forte concentração de registros em um único bloco. Esses resultados indicam que a idade cronológica é um fator relevante, mas insuficiente para explicar isoladamente o comportamento das manifestações registradas. Assim, a avaliação da conservação deve considerar, de forma integrada, a idade da edificação, o histórico de manutenção, a intensidade de uso, a concentração espacial das ocorrências e os sistemas construtivos mais afetados.

Alguns estudos recentes confirmam que os sistemas hidrossanitários e os sistemas de vedação e revestimentos figuram entre os componentes mais suscetíveis à degradação e, consequentemente, entre os mais recorrentes nas demandas de manutenção predial. Berg Oppedal *et al.* (2024), ao revisarem diferentes fontes de informação sobre defeitos em edifícios, observaram a elevada frequência de ocorrências associadas a erros em tubulações, danos por água, vazamentos internos e fissuração de paredes, evidenciando a relevância das instalações hidrossanitárias e dos elementos de fechamento e acabamento no quadro geral de falhas construtivas. De modo convergente, Gurmu *et al.* (2025), em revisão sistemática sobre defeitos induzidos por ingresso de água, identificaram como componentes mais vulneráveis paredes internas e externas, fachadas, áreas molhadas e sistemas de tubulação, destacando que falhas de impermeabilização, juntas e conexões favorecem manifestações com impactos estruturais, funcionais e estéticos. Essas evidências indicam que os resultados obtidos no presente estudo não representam um comportamento isolado do caso analisado, mas se alinham a tendências observadas em diferentes contextos internacionais, nos quais falhas relacionadas à água, tubulações, vedações e revestimentos figuram entre os principais vetores de degradação e demanda de manutenção em edificações em uso.

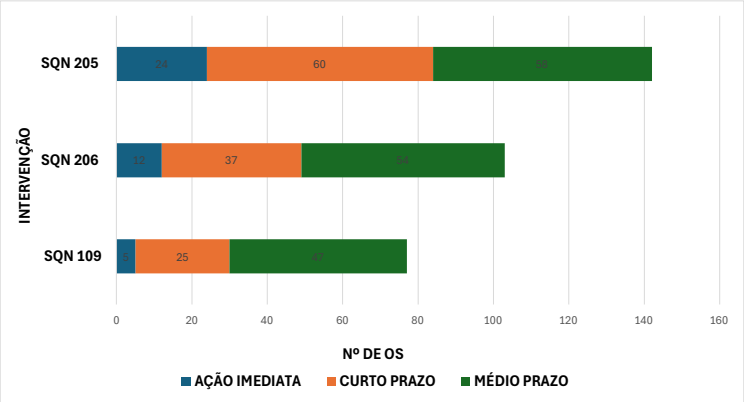

Figura 5 – Classificação das ocorrências segundo o Índice de Prioridade

Conforme apresentado na Figura 5, a classificação das ocorrências pelo Índice de Prioridade permitiu diferenciar as demandas de manutenção segundo seu horizonte de intervenção. Na SQN 205, foram identificadas 24 ocorrências de ação imediata, 60 de curto prazo e 58 de médio prazo. Na SQN 206, registraram-se 12 ocorrências de ação imediata, 37 de curto prazo e 54 de médio prazo. Já na SQN 109, observaram-se 5 ocorrências de ação imediata, 25 de curto prazo e 47 de médio prazo.

Esses resultados indicam que, nos três conjuntos, predominam demandas classificadas como curto e médio prazo, sugerindo que parte significativa das manifestações identificadas ainda pode ser incorporada ao planejamento técnico da manutenção. Entretanto, a presença de ocorrências de ação imediata, especialmente na SQN 205, evidencia a existência de situações com maior impacto potencial sobre o desempenho, a habitabilidade, a segurança ou a continuidade de uso dos sistemas construtivos.

A comparação entre frequência e criticidade demonstra que o volume absoluto de ordens de serviço deve ser interpretado em conjunto com o nível de prioridade das ocorrências. Dessa forma, a classificação pelo IP contribui para uma avaliação mais consistente da conservação predial, evitando que a definição das prioridades de intervenção seja baseada exclusivamente na quantidade de solicitações registradas.

4. Conclusão

Os resultados obtidos demonstram que os registros de ordens de serviço constituem uma fonte empírica relevante para a avaliação da conservação de edificações públicas, pois permitem identificar padrões de recorrência, sistemas construtivos mais suscetíveis à degradação e diferentes níveis de prioridade de intervenção. A análise das ordens de serviço evidenciou maior incidência de ocorrências nos sistemas hidrossanitário e de vedação e revestimentos, confirmando a relevância desses subsistemas nas demandas de manutenção predial e sua maior vulnerabilidade a manifestações como vazamentos, infiltrações, umidade, fissuração, destacamento e perda de desempenho funcional.

A aplicação da matriz GUT mostrou-se adequada para qualificar essa análise, uma vez que possibilitou classificar as ocorrências com base nos critérios de gravidade, urgência e tendência. Ao considerar não apenas a frequência dos registros, mas também o potencial de agravamento e os impactos associados a cada manifestação, o Índice de Prioridade permitiu diferenciar ocorrências que demandam intervenção imediata daquelas que podem ser tratadas no curto ou médio prazo. Dessa forma, a metodologia contribuiu para uma priorização mais racional das ações de manutenção, apoiando a tomada de decisão técnica em contextos de limitação de recursos e necessidade de planejamento das intervenções.

Os resultados também demonstraram que a idade das edificações, embora relevante, não explica isoladamente o comportamento das demandas de manutenção. A edificação mais antiga da amostra não foi aquela que apresentou o maior número de ordens de serviço, indicando que o estado de conservação está relacionado a um conjunto mais amplo de variáveis, como histórico de manutenção, intensidade de uso, qualidade das intervenções anteriores, condições de exposição, desempenho residual dos sistemas e particularidades construtivas de cada bloco. Esse achado reforça a necessidade de avaliar a conservação predial por meio de uma abordagem integrada, que considere simultaneamente a frequência das ocorrências, sua distribuição espacial, os sistemas afetados e o nível de criticidade das manifestações.

Dessa forma, conclui-se que a associação entre dados históricos de manutenção e a matriz GUT representa uma estratégia aplicável para o diagnóstico da conservação predial em edificações públicas. A sistematização das ordens de serviço permite transformar registros administrativos, frequentemente utilizados apenas para fins operacionais, em indicadores técnicos capazes de subsidiar o planejamento da manutenção, a definição de prioridades de intervenção e a identificação de sistemas e setores com maior demanda de atenção.

Como limitação, destaca-se que o estudo foi desenvolvido em um único contexto institucional e geográfico, considerando edificações públicas residenciais vinculadas a uma mesma instituição e registros referentes a um recorte temporal específico. Além disso, embora a matriz GUT tenha permitido estruturar tecnicamente a classificação das ocorrências, a análise estatística das relações entre idade, sistema construtivo, frequência de registros e nível de criticidade ainda pode ser aprofundada. Recomenda-se, portanto, que estudos futuros ampliem a amostra analisada, incorporem séries históricas mais longas e associem os registros de ordens de serviço a inspeções técnicas em campo, de modo a validar os indicadores obtidos a partir dos dados operacionais de manutenção e ampliar sua aplicabilidade em processos de diagnóstico, conservação e planejamento de intervenções em edificações públicas.

Abstract: Reducing clinker content in low-carbon cements and developing alternative binders are essential strategies for mitigating emissions from the cement industry, which accounts for approximately 7% of global anthropogenic CO_2 emissions. Implementing cement decarbonization solutions requires adjustments to the material's physicochemical properties and reactivity. Partial clinker substitution affects cement hydration, C-S-H formation, and portlandite release, thereby highlighting the need for a deeper understanding of the implications of these changes for durability and the life-cycle performance of structures, topics that remain insufficiently addressed in an integrated manner in the literature. From this perspective, this paper presents a systematic review, based on the Methodi Ordinatio approach, of studies published over the last decade in indexed databases, using keyword combinations to critically examine the relationship between low-emission cements, durability, and the service life of structures incorporating them. A total of 48 articles were selected, with the primary focus on quantifying the CO_2 avoidance during cement production, primarily through clinker reduction, without comprehensively addressing the use phase with respect to durability and service life. Durability assessment is typically conducted in a fragmented manner, particularly in studies of novel binders such as LC3 (limestone calcined clay cement) and geopolymers. Compressive and tensile strength tests predominate in evaluating mechanical properties, while resistance to chloride ingress and carbonation are commonly used as indicators of durability. Microstructural and physicochemical analyses are used to evaluate morphology, hydration products, and pore structure. The reviewed studies indicate a tendency for low-emission cements to exhibit higher fineness, in some cases increased C3S and C3A contents, and a lower alkali reserve. Establishing correlations between these parameters and durability, from application through the end of the life cycle, is fundamental to simultaneously ensuring resource-use efficiency, sustainability, and the long-term performance of structures incorporating low-carbon cements.

Keywords: Service life; Clinker; Concrete; Net zero; Decarbonization.

1. Introduction

The civil construction sector is responsible for a significant share of global anthropogenic atmospheric emissions – Portland Cement (PC) production alone accounts for approximately 7% of global carbon emissions. This necessitates technical and scientific strategies on the path toward carbon neutrality, projected for 2050 (Soldado et al. 2021; IEA, WBCSD, and CSI 2018; GCCA 2021). To mitigate environmental impacts, the cement sector has implemented various strategies to reduce CO_2 emissions from its products and processes. Among these, the strategies that contribute most significantly to reaching climate targets at a low cost, in order of implementation, are: reducing the use of clinker in PC manufacturing by substituting it with supplementary materials (SNIC and ABCP 2019; Van Deventer et al. 2015; Griffiths et al. 2023); increasing energy efficiency in the cement production process (Beguedou et al. 2023; Scrivener, John, and Gartner 2018; Chew et al. 2025) and carbon capture, storage and utilization (CCUS) (GCCA 2021; Amran et al. 2022), which possess distinct characteristics and technological maturity levels (Sun et al. 2025).

Cements categorized as "low-emission" generally achieve this status by reducing clinker content, as the clinker production process accounts for 55% to 70% of total process emissions (Y. Wang et al. 2024; Z. Li et al. 2024; Thorne et al. 2024). In this context, the international outlook is for the clinker/cement ratio to reach between 0.52 and 0.57 by 2050 (GCCA 2021; IEA 2023), while in Brazil, this ratio is currently 0.66, with emissions of around 564 kg of CO_2 for every ton of cement produced (SNIC and ABCP 2019), as illustrated in

. On the other hand, despite the efforts, global cement production is still expected to grow slightly over the next decade, with a small decline starting in 2035. In Brazil, consumption is projected to continue growing until 2050 (

).

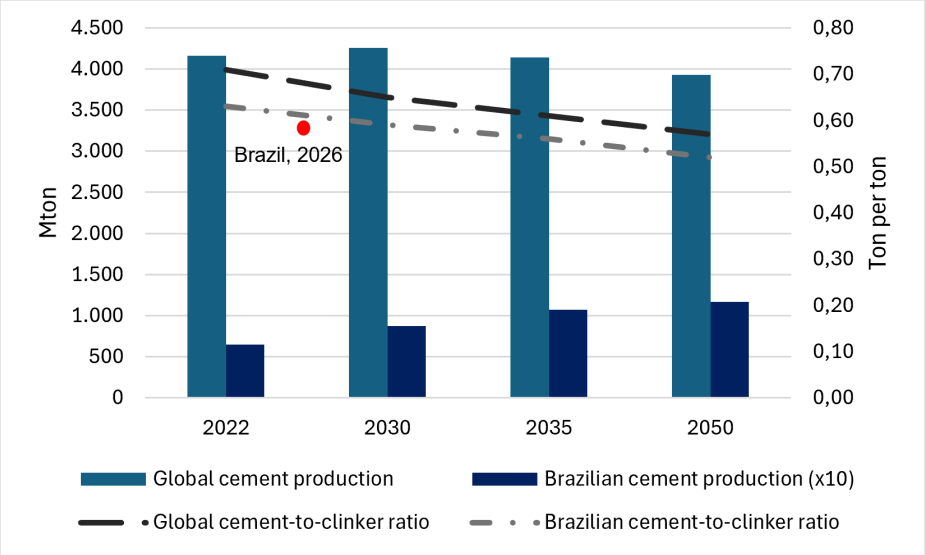

Figure 1 – Correlation between global and Brazilian production outlooks and the clinker factor in cement.

Source: Adapted from IEA, 2023 and SNIC; ABCP, 2019.

Among the partial clinker substitutions in low-emission cements, supplementary cementitious materials (SCMs) such as pozzolans, slag, fly ash, and carbonate materials stand out, as they have well-established technical performance and are widely used commercially (H. Chen and Yang 2023; Z. Li et al. 2024; Scrivener, John, and Gartner 2018). In parallel, research on new SCMs and alternative binders, such as construction and demolition waste (CDW), biomass ash, as well as low-emission geopolymer cements, supersulfated cements, and LC3 (limestone calcined clay cement), for example, has demonstrated significant potential for mitigating atmospheric emissions, reaching up to 40% when compared to PC (Z. Lei and Pavia 2024; Snellings, Suraneni, and Skibsted 2023; Barbhuiya et al. 2025). Conversely, despite scientific advances associated with such materials, their global market penetration remains limited. Recent studies have expanded the discussion to also consider emissions associated with the maintenance and rehabilitation of concrete structures and the use of alternative materials, such as natural fibers (Kasuga 2023; Helaili and Chafra 2023).

The incorporation of SCMs modifies the material's physicochemical characteristics and, consequently, its chemical reactions (kinetics), resulting in a product with distinct properties for application in cement-based materials (Aïtcin, Wilson, and Mindess 2018; Kipkemboi et al. 2020; Bramha Chari and Ranga Rao 2022). In many cases, these changes in cement characteristics can yield benefits, such as promoting void reduction (pore structure refinement) through the addition of finer materials, thereby increasing the concrete's initial strength (Oliveira et al. 2023). On the other hand, a reduction in the most reactive phases, primarily C_3S and

C_3A, is observed. When the added SCM is silica-rich, changes in hydration kinetics, C-S-H formation, and portlandite consumption may result in lower alkali content and reduced concrete pH, directly influencing the durability of construction (Lothenbach, Scrivener, and Hooton 2011; Mehta and Monteiro 2006; K. Zhang et al. 2024).

Regarding the large-scale application of low-carbon cements and binders under development, the barriers to be overcome include the scarcity of clinker substitutes, logistics, adaptations in industrial processes, and the fact that many scientific studies are conducted in isolation, making it difficult to understand the full scope of the studied material's applicability (Biernacki et al. 2017; Possan, Dal Molin, and Andrade 2018). Additionally, other challenges to be overcome include associated costs, potential difficulties in use and application due to the chemical changes the materials present, and evidence regarding durability and the product's life cycle (Hafez et al. 2022; K. Zhang et al. 2024).

Durability can be defined as the structure's capacity to resist physical, chemical, and mechanical degradation mechanisms, thereby maintaining performance throughout its service life (Mehta and Monteiro 2006; Dyer 2014). The traditional model for this purpose consists of standardized laboratory tests such as carbonation, permeability, sulfate attack, freeze-thaw cycles, chloride penetration, and, in some cases, accelerated tests that simulate long-term use (Ali, Naganathan, and Mahalingam 2021; ASTM 2022). Additionally, compliance monitoring is conducted through longitudinal data collection spanning decades. Both types of information enable the development of predictive models that, in addition to serving as a reference for the structure under study, also support standards published by respected regulatory bodies (Van Deventer et al. 2015; Possan, Dal Molin, and Andrade 2018). Increased concrete durability is associated with adjustments in the formulation of cementitious materials and structural elements (C. Li et al. 2023; Huang et al. 2025); this may be a direction for concentrating efforts aimed at updating current standards, including those focused on alternative binders (Perez Villa et al. 2021; Provis 2025) and to understand if the proposed tests and modeling still meet the products currently offered to the market.

In reinforced concrete structures, corrosion of steel reinforcement corrosion is the most common cause of structural deterioration (Soldado et al. 2021; Ranasinghe and De Silva 2022; Bras et al. 2021; J. J. O. Andrade, Possan, and Dal Molin 2017). Simplistically, this occurs because the concrete covering the reinforcement fails to fulfill its function of adequately protecting it from corrosion-promoting elements, allowing the entry of aggressive agents present in the environment that penetrate and diffuse through the cement paste (C. Li et al. 2023; Soldado et al. 2021; J. Shi et al. 2018; J. J. O. Andrade, Possan, and Dal Molin 2017). The number and size of pores and the chemistry composing the cement matrix structure, associated with the building's exposure environment, are examples of factors linked to material durability (X.-Y. Wang 2019; Dyer 2014) that are not yet fully understood in concretes made with low-emission cements (Doussang 2023; Rathnarajan and Pillai 2025).

Cracking and shrinkage are also common problems in concrete, often caused by delayed ettringite formation (DEF), alkali-aggregate reaction (AAR), or sulfate attack. DEF is associated with high curing temperatures, which can be exacerbated by the type or fineness of the clinker substitute material (Franke Portella et al. 2021; Gu et al. 2020; Dyer 2014). AAR is characterized by the formation of an alkali gel that, due to its expansive properties, exerts internal stress on the concrete, leading to cracks (Pan et al. 2012), which can be even more common in concrete with a high water/cement ratio (Dyer 2014). In low-emission cements, alkali-rich SCMs in clinker substitution can drive AAR formation, whereas silica fume rich materials can mitigate this phenomenon (Dyer 2014; Mehta and Monteiro 2006). Attacks by the presence of sulfur (sulfates and sulfites) can be favored by a mechanism like AAR: if the material added for decarbonization is sulfur-rich (Johansson et al. 2024), and is aggravated in more permeable concretes (Dyer 2014).

What all potential problems in low-emission cements that could lead to premature structural degradation have in common is that the state of the art for these types of materials has not yet been reached, and the recovery of structures with these pathological manifestations is usually difficult, often costly, and may limit the acceptance of new products (Barbhuiya et al. 2025). In research on various types of low-carbon cements, in general, not all durability tests associated with traditional PC are performed (Escalante-Garcia, Cabrera-

Luna, and Castillo-Sanchez 2024; Doussang 2023; Hasheminezhad et al. 2024; Robalo et al. 2020). In other cases, it is questioned whether traditional methodology can be applied to low-emission cements (Ali, Naganathan, and Mahalingam 2021; Doussang 2023; Liang et al. 2024), and there are still situations where the product under study shows excellent results in some aspects but does not meet the minimum requirements in others, especially depending on the clinker substitution percentage (Barbhuiya et al. 2025; Hasheminezhad et al. 2024; Robalo et al. 2020).

Recognizing the need for technological advances to decarbonize the PC chain and considering that the service life of concrete structures is a central premise of sustainability, this article presents a systematic literature review that correlates these variables and investigates how building durability has guided the development of low-carbon cements.

2. Methodology

The systematic literature review was based on the *Methodi Ordinatio* framework, which consists of selecting and classifying articles based on their scientific relevance, measured by the result of an *InOrdinatio* equation. This equation combines the journal's impact factor, the number of citations, and the year of publication (Pagani, Kovaleski, and Resende 2015). The research was conducted across the indexed scientific databases Scopus and Web of Science (WoS), which were selected for their large number of publications in engineering, construction technologies, materials science, and sustainability. A series of keyword combinations was used, with the inclusion of new terms at each refinement step, supplemented by Boolean operators "OR" and "AND" and the wildcard character "*" to retrieve the maximum number of publications on the subject. The timeframe was delimited to 2014-2025, which received the maximum weight of 10 in the *InOrdinatio* equation, since technological advancement is a critical factor for this research. The search focused on English-language scientific journal articles. Finally, the terms combined in each stage of the search, along with the number of returned publications, were required to appear in the title, keywords, or abstract of the publication. Regarding the number of publications associated with the year, the information is correlated in **Figure 1a**, while the most frequently occurring words (a minimum of three times) are grouped in **Figure 1b**.

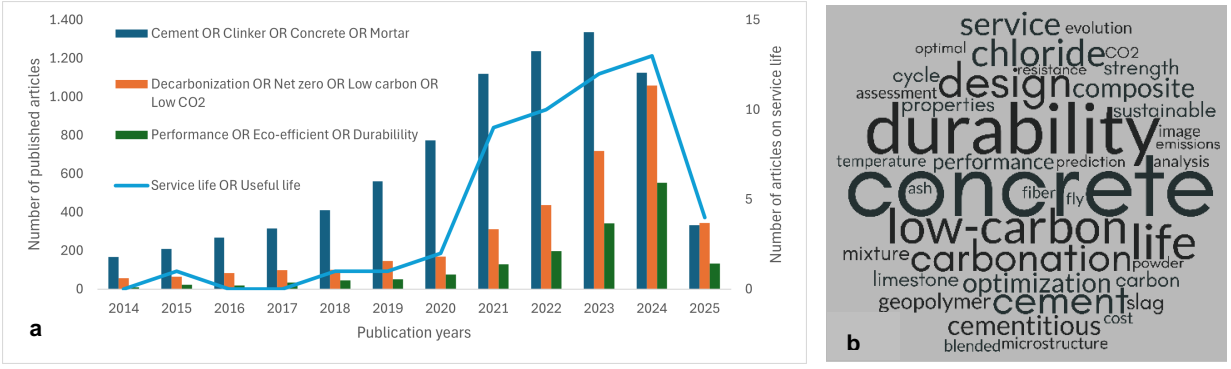

Figure 1: a) Comparison of the number of publications and year as a function of keyword refinement; **b)** word cloud.

In accordance with the eligibility criteria, it was essential that the terms used appeared in all articles. The initial strategy yielded 95 articles, which were added to the Mendeley free reference manager and reduced to 51 after duplicates were removed. Upon implementing a new screening for thematic relevance, the count was further reduced to 48 articles. The *InOrdinatio* equation was applied to these remaining articles using an Excel spreadsheet that considers each journal's impact factor, the year of publication, and the number of citations (Pagani, Kovaleski, and Resende 2015) obtained from Google Scholar. At the end of this process, the 48 selected articles were ranked according to their relevance, based on the established premises and the

method used. In addition to the references obtained through this methodology, other relevant publications on the subject were used during the review to inform the approach and exploration of the topic.

3. Results and discussion

Among the selected articles, it can be observed that, rather than evaluating the durability of existing low-emission PC-based materials, the primary focus of the publications is on assessing the durability of low-carbon materials under development (new materials), particularly under aggressive environmental conditions. Regarding the methods for obtaining results, the main division lies between simulations, models, and/or applied testing. The possibilities for decarbonizing the cement industry range from cement manufacturing to concrete use, as detailed below.

3.1 Geopolymers

In the analyzed publications, the focus is primarily on evaluating mechanical performance and resistance to aggressive environments. While one group of researchers (Cheng et al. 2024) focused on structural improvement through the incorporation of steel fibers (0.5%), another (Liu et al. 2024) considered the reuse of geopolymer concretes as coarse aggregates in environments subject to freeze-thaw cycles. The evidence pertains to the influence of the precursor type and curing conditions on mechanical strength and durability; aggregates derived from fly ash concrete did not perform well in the evaluation, whereas the best results were found in the recyclability of concretes made with metakaolin, red mud, and slag, which was associated with the density and chemical properties of these materials. Two other groups focused on the effects of corrosive environments on geopolymer concrete. In one study involving steel-reinforced geopolymer concrete, the applied tests, modeling, and neural network algorithms led to the conclusion that when observing chloride content, humidity, and temperature, the latter was the most relevant factor in inducing reinforcement corrosion, followed by humidity and chloride content (Wasim, Ngo, and Law 2021). The other study reported positive results on the use of fibers and nanomaterials to enhance the mechanical resistance of geopolymer concrete to chloride attack, thereby increasing its durability (H. Li et al. 2024).

The full replacement of PC with geopolymer binders has been explored in coating applications, focusing on contact angle, surface energy, mechanical properties, and microstructure (A. Wang et al. 2022). The results indicate that the substituents under study have hydrophilic properties like PC and that the test results were positive regarding material porosity, with the advantage of reducing environmental impacts by 50% to 80% in the highest-impact categories, according to the Life Cycle Assessment (LCA) performed (A. Wang et al. 2022). Although this research is relevant to the development and application of technology, none of the studies systematically observe the use and service life of the construction.

3.2 Limestone Calcined Clay Cement (LC3)

As an alternative to PC, ternary cement, also known as LC3, is named for the addition of two other components - generally blast furnace slag and fly ash. Reported benefits include a reduction in atmospheric emissions by replacing a portion of the clinker (Tsivilis et al. 2002; Kim et al. 2018), a decrease in concrete porosity (Kim et al. 2018; Thorne et al. 2024; Du et al. 2023), a reduction in carbonation depth, and consequently, reinforcement protection (Tsivilis et al. 2002), as well as improved clinker reactivity (Tsivilis et al. 2002). Due to these positive characteristics, it has been a subject of study, with results demonstrating a delay in the development of expected compressive strength and greater carbonation depth, which can be detrimental to reinforced concrete due to the increased risk of reinforcement corrosion (Rivera et al. 2021). However, since carbonation is a naturally occurring reaction in concrete, it also contributes to the carbon neutrality goal, provided it does not impair the structure's service life. Therefore, concrete produced with the cements reported in this article can be highly useful in applications where initial strength is not a primary requirement or where there is low exposure to air, such as foundations, pipelines, and similar structures.

Additional research has sought to determine the optimal clinker substitution level in LC3 systems, balancing mechanical performance and carbonation control (Thorne et al. 2024; X.-Y. Wang 2020). Findings indicate that the criteria for using LC3 differ between low-strength concretes (25 MPa), where carbonation must be considered, and high-strength concretes (45 MPa), where mechanical strength predominates (X.-Y. Wang 2020). Mixtures combining PC with fly ash showed strength increments of approximately 20.5% and a 21.1% reduction in CO_2 emissions compared to concrete produced with PC and filler (Thorne et al. 2024). Complementary strategies, such as the incorporation of microcapsules for self-healing, demonstrated the potential for sealing surface cracks with widths exceeding 0.4 mm within 72 hours (Du et al. 2023). However, in studies with high-strength concrete, results indicated that, even after healing, the hydration products formed were brittle, making them prone to re-cracking under load (L. Wang et al. 2023).

3.3 Cements with pozzolanic additions

The use of SCMs, specifically off-specification fly ash and glass spheres, for lightweight concrete, was evaluated in high-performance concrete under flexural load tests to assess mechanical behavior and LCA (Ghahsareh et al. 2025). The mechanical test results were satisfactory, with crack widths remaining below standardized limits. Atmospheric emissions were reduced by up to 20%, the largest fraction of which stems from clinker substitution (Thorne et al. 2024), and by up to 58% due to reduced maintenance requirements (Ghahsareh et al. 2025). However, the LCA is limited to concrete production and does not account for the service life or maintenance requirements of a construction project using this low-carbon cement.

Nanosilica is another SCM that has been explored, particularly because small additions can significantly improve concrete's mechanical properties, especially in aggressive environments, due to its high resistance to sulfate attack (L. Zhang et al. 2023; Xu et al. 2023). Beyond environmental sustainability benefits, some properties of nanosilica are analogous to those of limestone powder: reducing concrete pores through particle packing and assisting reinforcement preservation. Regarding the challenges for large-scale application of this material, the lack of long-term durability studies, dosage standardization, and application systematization stand out (L. Zhang et al. 2023). For the full range of SCMs, microstructure and macroscopic properties need to be evaluated in detail, including extreme situations such as high temperatures (Y. Li, Liu, and Jiang 2024). Natural pozzolans are emerging as an alternative SCM to fly ash, with satisfactory results in workability, strength, water absorption, and chloride diffusion (Robalo et al. 2021).

Focusing on material durability, studies on concrete made with low-carbon cement incorporating 30% fly ash or 50% slag found that resistance to chloride attack is higher than in PC concrete at the same water/cement ratio (Sirivivatnanon, Xue, and Khatri 2022). Although the research focus is on the durability of low-emission cements, there is a stated concern regarding the lack of standardization in codes for certain types of potential clinker substitutes, especially construction waste rich in compounds that remain poorly understood (Liang et al. 2024; Sirivivatnanon, Xue, and Khatri 2022).

3.4 Other solutions

In the line of new product development, studies were conducted to improve the freeze-thaw performance of expanded polystyrene (EPS) concrete, which possesses excellent thermal insulation but unsatisfactory freeze-thaw performance. In this regard, EPS beads were coated with different materials; testing and modeling found that EPS concrete with beads coated with water-based polyurethane and high-performance concrete showed a 60% increase in freeze-thaw resistance compared to uncoated EPS (Yuan et al. 2022). Although the authors cite its use in low-rise buildings and certain engineering applications, they also note that studies on its durability are scarce (Yuan et al. 2022), which may act as a strong deterrent to the popularization of this low-carbon material.

Low-heat expansive cement (LHEC) is presented as a material with the potential for wide use in humid environments, such as dams, as a replacement for PC. Beyond lower CO_2 emissions, since it is primarily composed of granulated blast-furnace slag, its main advantages include high strength, low heat of hydration, and micro-expansion performance (Jin et al. 2024). A challenge still to be overcome with this

material is delayed ettringite formation (DEF), which can cause structural cracking (Dyer 2014); gypsum was added to address this. Promising results indicate the need to not only add gypsum but also to control curing temperatures to minimize DEF formation (Jin et al. 2024).

The use of carbon fiber reinforcement to enhance mechanical performance in low-emission concretes was conducted by two research groups (Diao et al. 2024; Cecen, Aktas, and Ozbayrak 2023). In the first study, the focus was on cement paste with an extremely low water/cement ratio, leading to the conclusion that compressive and tensile strength, freeze-thaw resistance, and drying shrinkage were increased, while freeze-thaw resistance was reduced. Based on these findings, an increase in the service life of structures with these characteristics was inferred (Diao et al. 2024). In a specific application for railway sleeper production, a niche market requiring high early strength, prestressing, and mandatory reinforcement, pieces were produced using low-emission concretes. These were evaluated for both partial PC replacement and reinforcement with polyurethane and carbon fiber (Cecen, Aktas, and Ozbayrak 2023). The highly detailed decarbonization potential assessment indicates that good mechanical performance can be achieved with cements featuring up to 50% clinker substitution by natural pozzolans, resulting in up to 54% fewer atmospheric emissions in the sleepers. However, this reduction will only be achieved if the production of carbon fibers and polyurethane also follows a decarbonization trend; otherwise, the environmental benefits of cement substitution may be progressively lost (Cecen, Aktas, and Ozbayrak 2023). Although this application is focused on the railway market, the author's conclusion addresses a point seldom discussed in other articles: the evaluation of real reduction potential must be comprehensive.

Regarding coarse aggregates but within the decarbonization line, one study indicates the use of bamboo as an aggregate and focuses on mechanisms to overcome material segregation in concrete (X. Chen et al. 2024). While the research is relevant, it brings little contribution regarding zeroing emissions or observing product service life. Similarly, a study was retrieved on grouting materials with additives that increase durability in aggressive environments, with an average carbon emission of 84.86 kg/ton, compared with 280-767 kg/ton in similar studies, significantly reducing atmospheric emissions (Y. Chen et al. 2025).

Also focusing on durability and, in a very particular report, on accelerated carbonation caused by leaked stored CO_2 (Xue et al. 2022), which, with the advent of CCUS technology, may become commonplace. The study was motivated by an incident recorded during tunnel construction in China. A CO_2 leak was detected, and it was observed that the high gas concentration, coupled with elevated pressure, caused rapid and deep carbonation of the concrete, resulting in structural damage and loss of strength due to reinforcement corrosion (Xue et al. 2022). The research focused on evaluating concrete under various CO_2 concentrations and pressures, with different relative humidities. Results showed that although a carbonation front can be beneficial to concrete's compressive strength (Dyer 2014), when the CO_2 partial pressure reaches 1,000 kPa, severe structural damage can occur due to induced carbonation (Xue et al. 2022). The approach in this article points toward an issue surrounding the advancement of CCUS and its potential leaks.

In this stage of the analysis, it was observed that there is a lack of standardization for minimum criteria in conducting research, which often makes literary comparison impractical. Although authors strive for durability in their research, in most cases, it is not possible to compare measurements between the conventional product and the one under study. This is a point of attention that must be addressed for the integration of low-carbon cements into the market, as integrating decarbonization and durability is strategic for all stakeholders in the PC chain, from production to application (Possan 2026).

3.5 Predictive Modeling and Simulation

Although the development of modeling is not new for predicting the durability of cementitious materials (W. Shi, Yu, and Kuang 2012; Zheng, Miao, and Zheng 2023), the subject has been extensively explored by research groups, especially with the advent of Artificial Intelligence algorithms and the use of varied and combined SCMs. However, one question is whether traditional durability models remain applicable to cements with reduced clinker content (Doussang 2023; Liang et al. 2024). Conversely, the use of digital tools and neural networks can accelerate the development of decarbonized products.

Selected publications report simulations for the strength of concrete produced with low-carbon cement (using different SCMs) based on carbonation time (X.-Y. Wang 2022; X. Wang 2022; X.-Y. Wang 2023). The conclusions indicate that for concretes with strength up to 40 MPa, carbonation durability is the criterion for service life, whereas compressive strength is the decisive factor in concretes with strength exceeding 50 MPa (X.-Y. Wang 2022, 2023). In simulations where metakaolin was the SCM used, establishing premises for concrete strength and carbonation service life, alongside optimal mix criteria combining emission reduction and product cost, it was concluded that to meet the requirements, SCM use was minimal because the cost of metakaolin is higher than that of PC (X. Wang 2022). In turn, simulations combining SCMs (metakaolin, fly ash, limestone powder) indicate that a blend of these SCMs can lead to better outcomes in controlling maximum atmospheric emissions, maximum heat of hydration, and concrete electrical resistivity (Lin, Han, and Wang 2021).

In other research, a modeling study aimed to identify the optimal SCM use and water/cement ratio, using compressive strength, additive use, and atmospheric emissions as parameters (Yang, Dong, and Wang 2025). The results indicate that a lower water/cement ratio with fly ash addition increases compressive strength and CO_2 emissions; the application of the models enabled a detailed combination of these variables (Yang, Dong, and Wang 2025).

With a more integrated perspective, one simulation simultaneously considered economic, environmental, mechanical, and durability factors (DeRousseau, Kasprzyk, and Srubar III 2021). The authors highlight a gap in most published models, to the rigidity of input parameters such as costs, availability, and the environmental sustainability of materials. The presented case studies indicate that the most relevant factors in achieving concretes with optimal characteristics are the cost of each component, including SCMs, and the environmental aggressiveness class of the application (DeRousseau, Kasprzyk, and Srubar III 2021). Furthermore, the proposed simulations appear highly useful, particularly by enabling regionalized solutions, an extremely important factor for SCMs.

The proposal for hybrid steel-concrete prefabricated modular buildings was the starting point for a study that modeled the service life of such construction, using PC with partial clinker replacement by SCMs, ultra-lightweight cement, and foam concrete (L. Chen et al. 2024). In addition to evaluating the behavior of the construction material itself, the authors advocate for design-related concepts, such as using concrete with thermal performance that reduces users' electricity consumption during the building's occupancy. This concern is highly relevant and has been noted by other researchers who support the application of engineering concepts as mechanisms for decarbonization (Miller et al. 2025; Watari et al. 2022), given that data indicates that up to 38% of energy-associated CO_2 emissions stem from the built environment (UNEP 2024). Thus, the prefabricated modular structure was studied with respect to cost requirements, carbon emissions, and energy consumption throughout its service life, alongside the effects of extending service life and overall performance. The authors provided comprehensive and important conclusions on atmospheric emission reductions, circular economy, and construction efficiency (L. Chen et al. 2024). One aspect not clearly addressed in other studies but defended as a premise in this one is that durability is key to the circular economy; in this regard, researchers further simulated scenarios to extend the service life of buildings to 100 and 150 years. The main findings include reductions of up to 17% in energy consumption during occupancy and up to 14% in CO_2 emissions, with a service life extended to 150 years (L. Chen et al. 2024).

Regarding concrete durability requirements, there is the concept of "designed concrete," which features a defined standard for minimum strength class, required consistency, water/cement ratio limits, minimum content, and permitted cement types, linked to chemical aspects, in addition to factors such as aggregates, additives, and concrete curing (Dyer 2014). Assuming these truths, modeling or propositional scenarios should, at a minimum, consider these variables to evaluate product quality.

3.6 Life Cycle Assessment (LCA) and Durability

Although LCA constitutes a central tool for measuring environmental impacts throughout the life cycle of products from a sustainability perspective (Rocha and Caldeira-Pires 2019), until the last decade, the influence of the durability of low-carbon concrete structures on the results of this type of analysis was not clear (C. Li et al. 2023). The primary effect has been the development of divergent assessment approaches, which consequently yield very distinct results, ranging from 84 to 612 kg of CO_2 equivalent per m^3 of low-emission concrete (Hafez et al. 2019; D. Lei et al. 2025).

The main durability indicators of a structure stem from the project acceptance requirements, either prescriptive or associated with verified performance (C. Li et al. 2023), and both are governed by relevant standards (Müller, Haist, and Vogel 2014). Prescriptive requirements are linked to the type of environment, or exposure class, for which there are indications regarding materials and concrete cover thickness; for example, it is assumed that meeting these prescriptions will achieve the design service life. In contrast, performance requirements focus on meeting given conditions before reaching a limit state, such as carbonation depth, resistance to chemical attacks, and the natural chemical reactions of concrete. For these, testing and modeling are typically conducted to predict the service life of materials (C. Li et al. 2023; Juenger, Snellings, and Bernal 2019).

Among the analyzed articles, 27 involved testing related to the durability and performance of concrete or mortar (**Table 1**). In six of these, only one parameter was measured, usually a mechanical property. In five others, mechanical, chemical, and microstructural property tests were conducted simultaneously, representing a more comprehensive analysis. Furthermore, among the analyzed article, only three evaluated the studied parameters for more than one year. In thirteen studies, the analysis period was up to 28 days, which is considered a short timeframe when addressing durability. This information highlights the insufficient data to correlate LCA studies with the durability perspective of materials and structures made with low-carbon cement, underscoring the need for further progress in this direction.

Table 1 - Summary of the tests performed, and properties observed in the literature studies analyzed

Material used	Properties				Test time	Ref.
	Physical and Rheologycal	Mechanical	Chemical	Microstructural		

Reinforced concrete (PC with pozzolan and slag)	-	-	Chloride resistance	-	9 Years	(Sirivivatnanon, Xue, and Khatri 2022)
Mortar (PC and Low-heat expansive cement)	-	Compressive Strength Deformation	-	Hydration morphology Hydration products Crystalline structure	120 Days	(Jin et al. 2024)
Reinforced concrete (PC with pozzolan)	Density Water absorption Electrical resistivity Workability	Compressive Strength Deformation Tensile	Carbonation Chloride resistance	-	90 Days	(Robalo et al. 2021)
Ternary Portland cements and Mortar	-	Compressive Strength	Carbonation	-	20 Months	(Rivera et al. 2021)
Reinforced waste-based geopolymer foam concrete	-	Tensile	-	-	90 Days	(Wasim, Ngo, and Law 2021)
Concrete (PC)	-	Compressive Strength	Carbonation	Hydration morphology	28 Days	(Xue et al. 2022)
Mortar (LC3)	-	Compressive Strength	Chloride resistance	Pore size	28 Days	(Du et al. 2023)
Expanded polystyrene (EPS) concrete	-	Compressive Strength Freeze–thaw	-	Pore structure	275 freeze-thaw cycles	(Yuan et al. 2022)
Fiber-reinforced (CP) and LC3 concrete	-	Freeze–thaw	-	Hydration products Pore size	48 Days	(L. Wang et al. 2023)
Pastes and mortar (PC with fly ash and slag)	-	-	Carbonation	Depth and direction of carbonation	3 Months	(K. Zhang et al. 2024)
Reinforced concrete (PC with fly ash and slag)	Humidity	-	-	-	10 Months	(Huang et al. 2025)

Cement Pastes (PC with fly ash, limestone and metakaolin)	Electrical resistivity	Compressive Strength	Heat of hydration CO_2 emission	Crystalline structure	28 Days	(Lin, Han, and Wang 2021)
Concrete (PC)	-	-	-	Phase distribution	28 Days	(X. Chen et al. 2024)
Cement Paste (PC with Colloidal nano-silica)	Workability	Compressive Strength	-	Hydration morphology Hydration products Pore structure	28 Days	(Xu et al. 2023)
Geopolymer Paste (with Steel fiber and ceramsite)	-	Compressive Strength Deformation	-	-	28 Days	(Cheng et al. 2024)
Cement Paste (PC with limestone powder)	Workability	Compressive Strength	Carbonation	-	540 Days	(X.-Y. Wang 2020)
Cement Paste (PC with slag)	Workability	Compressive Strength Freeze–thaw	-	-	28 Days	(X.-Y. Wang and Lee 2021)
Cement Paste (Coal slag and steel slag)	Workability Setting time	Compressive Strength Deformation	-	Phase distribution Hydration products	28 Days	(Y. Chen et al. 2025)
Geopolymer concrete (with fly ash, red mud and slag)	-	Compressive Strength Freeze–thaw	-	Phase distribution Pore structure	28 Days	(Liu et al. 2024)
Geopolymer mortars (with slag, red mud, metakaolin and fly ash)	-	Interfacial adhesive strength	Hardness	Functional Group	1 Year	(A. Wang et al. 2022)
Reinforced concrete (PC with pozzolan)	-	Compressive Strength Deformation Tensile	-	-	28 Days	(Cecen, Aktas, and Ozbayrak 2023)
Cement Paste (PC) reinforced with carbon fiber	Density Water absorption	Compressive Strength Deformation Tensile Freeze–thaw	Drying shrinkage	-	150 Days	(Diao et al. 2024)

Ultra-high-performance concrete (PC with slag) reinforced with fibers	-	Deformation	-	-	28 Days	(Ghahsareh et al. 2025)
Natural fibers in epoxy base	-	Tensile	-	-	1 Day	(Helaili and Chafra 2023)
Mortars (PC with fly ash, limetone filler, pozzolan and slag)	Water absorption Electrical resistivity	Compressive Strength Deformation	Chloride resistance Carbonation	-	90 Days	(Soldado et al. 2021)
Concretes (PC with fly ash and slag)	Water absorption	Compressive Strength	Chloride resistance	Crystalline structure Hydration products Hydration morphology	90 Days	(Van Deventer et al. 2015)
Concretes (PC with silica, calcined clay and limestone)	Density	Compressive Strength Deformation	Carbonation Thermal conductivity	-	28 Days	(L. Chen et al. 2024)

The lack of standardization for LCAs that collectively encompass concrete structures, combined with the fact that current standards do not necessarily cover low-carbon cements, underscores the existing gap in the field. Furthermore, the absence of a clear approach connecting durability with the LCA of low-carbon concretes can lead to contradictory and biased conclusions (D. Lei et al. 2025; C. Li et al. 2023; Hasheminezhad et al. 2024). In the research conducted by (Jiang et al. 2024), the authors report on the difficulties in obtaining experimental data to account for the increased mechanical strength and durability of alternative materials compared to PC concrete. This raises doubts about real decarbonization, as the environmental and economic performance of materials is directly linked to the properties that determine the structure's service life (Jiang et al. 2024).

4. Trends, research gaps and perspectives

The main pathways of the cement sector, whether currently implemented or under implementation to reach Net Zero, include plant energy efficiency, co-processing, the replacement of fossil fuels, and the reduction of clinker content in cement. However, due to issues inherent to the raw material, especially the limestone decarbonation process, the cement industry will depend on carbon capture actions to achieve the neutrality goal. Estimates across various Roadmaps (SNIC and ABCP 2019; IEA, WBCSD, and CSI 2018) suggest that approximately 40% of the decarbonization target is linked to CCUS; however, implementing the necessary carbon capture technologies poses a significant challenge due to associated costs.

Portland cement undergoes decarbonization showing trends in its physicochemical characteristics, particularly increases in fineness, C_3S, and C_3A, and a reduction in alkaline reserve, consequences of

alterations in clinker and cement production. Published works primarily focus on new cementitious materials and alternative binders, such as LC3 and geopolymers, and lack studies on Portland cement with lower clinker content, particularly regarding its effects on the durability of cement-based materials.

The current outlook demands innovation, scientific-technological development, stakeholder training across in the cement and concrete chain, financial investment in research and companies, and local and global regulatory standards and public policies to support the achievement of the sector's zero-emission objective. Significant progress is required in conducting systemic and networked research focused on the durability and service life of products derived from decarbonized Portland cement (**Figure 3**). The use of Machine Learning tools and computational intelligence is of great interest for data analysis, correlation, and system modeling.

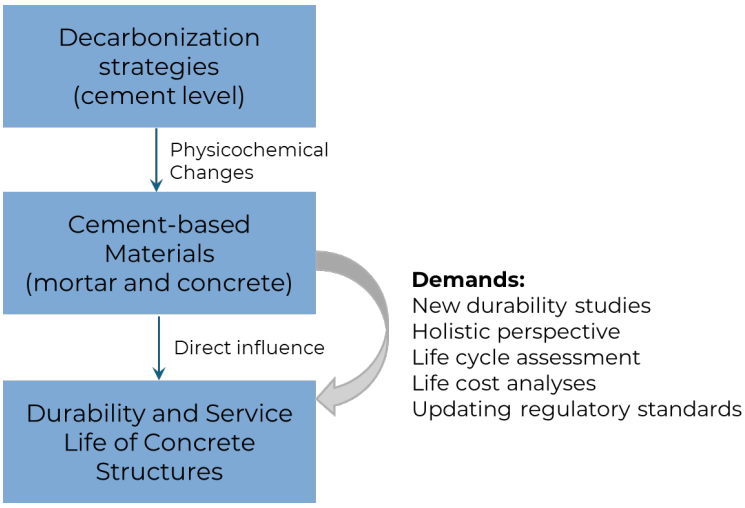

Figure 3 - Summary of the implications of decarbonization in cement and the demands generated.

The main decarbonization pathways focus on cement, the basic raw material of the construction chain, but pay little attention to potential implications in the material's application processes, such as optimizing cement consumption in concrete manufacturing and extending the service life of elements and structures (Watari et al. 2022; GCCA 2021; C. Li et al. 2023; Müller, Haist, and Vogel 2014). Some studies demonstrate that extending the service life of construction can contribute to meeting the sector's global emission targets by 4%-15% (C. Li et al. 2023; Watari et al. 2022); this is a vital agenda for the effective decarbonization of Portland cement sector. Systematic studies are needed to address the trade-off between CO2 reduction and durability throughout the life cycle of concrete structures (Possan 2026), to avoid shifting the problem from cement to concrete, which would result in indirect emissions associated with frequent maintenance or premature reconstruction.

5. Conclusions

The considered literature predominantly addresses the reduction of emissions associated with cement production, yet it comprehensively quantifies, in a comprehensive manner, the actual contribution of materials to decarbonization throughout their life cycle. Methodological fragmentation is evident, with isolated assessments of mechanical or environmental performance failing to consistently correlate with durability, service life, and commercial-scale viability. This gap compromises the robustness of conclusions and limits a safe transition to cement with lower clinker content. Part of this scenario stems from experimental constraints, high costs, and pressure to deliver rapid, novel results.

For the expected environmental gains to be effectively achieved, the implementation of low-carbon cements must be deepened, with durability requirements integrated into the process through holistic Life Cycle Assessment (cradle-to-cradle) studies. Otherwise, the undeclared systemic risk to the chain is a "trade-off": a low-carbon cement that may compromise the durability of the elements and structures produced.

For these reasons, conducting comprehensive interlaboratory studies is recommended to re-evaluate the durability implications of elements and structures manufactured with cement undergoing decarbonization. The results of this process will serve as a basis for updating regulatory standards for low-emission materials, which have direct implications for the carbon market. In parallel, technical qualifications, guidance, and monitoring for professionals working in the cement-based materials and construction chain are fundamental to ensuring specifications, applications, and controls that are compatible with the new performance requirements.

Abstract: 3D Concrete Printing (3DCP) is an Industry 4.0 technology with the potential to improve productivity and reduce costs in the construction sector. However, the rheological and early-age mechanical requirements imposed by extrusion-based printing systems often necessitate mixtures with high Portland cement content to ensure pumpability, extrudability, and buildability. In this study, an alternative strategy is proposed by assessing the combined use of limestone filler (LF), metakaolin (MK), and polypropylene fibers (PF) as partial cement replacements, aiming to reduce cement consumption while preserving essential fresh-state performance. Binary and ternary mixtures containing up to 50% LF and 10% MK were evaluated through viscosity, flowability, consistency, and buildability tests tailored to the printing system.

The results show that LF improves fluidity but may reduce printing stability, whereas MK increases viscosity and promotes structural build-up. When used together, LF and MK produced mixtures with enhanced performance, especially the FC30MK10 composition, which exhibited an optimal balance between viscosity, spread, and layer stability. In contrast, the inclusion of 1% polypropylene fibers sharply increased viscosity and consistency, rendering the mixture unsuitable for extrusion. These findings help establish a performance window for printable cementitious mixtures and demonstrate that LF and MK are effective, sustainable alternatives for reducing cement usage in 3DCP applications.

Keywords: 3D printing; limestone filler; metakaolin; viscosity; flowability; buildability.

1. Introduction

3D Concrete Printing (3DCP) is a rapidly developing technology that has the potential to transform conventional construction practices through automation and digital fabrication. The main advantages of 3DCP are the architectural design flexibility, higher productivity, reduced material consumption, and the elimination of conventional formwork (Akhlaghi *et al*., 2017; Paul *et al*., 2018; Zhang *et al*., 2019; Olsson *et al*., 2021). Additionally, it can reduce labour costs (50–80%), construction waste (30–60%), and production time (50–70%) (Zhang *et al*., 2019).

However, the successful application of this construction method requires the control of several interdependent parameters—both rheological and equipment-related—particularly the development of mixtures that can be easily extruded while maintaining their geometry after deposition. The ability of the mixtures to retain their shape is related to the buildability of the 3DCP, defined as the capacity of freshly

printed layers to resist vertical and lateral deformation during stacking without collapse (ISO/ASTM 52939, 2023).

The rheological properties of 3DCP mixtures in the fresh state that most strongly influence printing performanceare viscosity, flowability, and buildability, and they are related to the dosage of the compositions, as well as the morphology and gradation of aggregates, water-to-cement ratio, the presence of admixtures, and the incorporation of Supplementary Cementitious Materials (SCMs) (Marchon *et al*., 2018; Chen *et al*., 2020).

For a mixture to be considered pumpable and extrudable, it must have sufficiently low plastic viscosity and adequate flow stress to allow uninterrupted transport through hoses and uniform material delivery at the nozzle. At the same time, the lower layers must exhibit enough structural build-up to support the weight of subsequent layers without excessive deformation (Zhang *et al*., 2021).

Due to the mixture for 3D printing sufficient structuration and rapid gain of early-age stiffness, many studies employ high cement contents. According to Wangler *et al*. (2019), the incorporation of this high cement content is mainly required to satisfy the strict rheological criteria associated with pumping, extrusion stability and buildability.

However, Portland cement is a widely used construction material whose production is responsible for approximately 5–7% of global CO_2 emissions (Shanks *et al*., 2019). Since 3DCP printing has a greater focus on sustainability, it is essential to adopt measures to reduce cement consumption and develop mixtures that are both printable and environmentally sustainable (Chen *et al*., 2019).

According to Chen *et al*. (2019) and Shanks *et al*. (2019), one measure to make 3DCP printing more sustainable is the partial replacement of Portland cement with SCMs such as silica fume, metakaolin, limestone filler, fly ash and blast furnace slag. However, some of these materials have limitations for use, as active silica and slag are scarce worldwide and cannot be used on a large scale (Bhattacherjee *et al*., 2021). Therefore, it is necessary to use other materials, such as limestone filler and metakaolin, in the mixes, because they are regionally accessible and calcined clays have a lower carbon footprint compared to Portland cement (Chen *et al*., 2019). Additionally, a study conducted in the United Kingdom showed that replacing cement with calcined clays and limestone can reduce cement consumption by 13–40% and CO_2 emissions by 10–27% (Shanks *et al*., 2019).

Thus, although research on 3DCP has grown significantly over the last two decades, important knowledge gaps remain, particularly regarding how SCMs and fibers influence fresh-state properties across different printing systems (Bos *et al*., 2016). Therefore, this research aims to examine the effects of varying contents of limestone filler and metakaolin, with and without polypropylene fibers, on the rheological behavior and buildability of cementitious mixtures for extrusion-based 3DCP.

2. Materials and Methods

2.1 Materials

For the production of the 3DCP mixtures, Portland cement CP-V ARI (equivalent to ASTM C150 Type III OPC and CEM I from EN 197-1) was used, a high-early-strength cement without mineral additions. The mixtures also incorporated screened natural river sand passing through a 2.36 mm sieve, metakaolin (MK), limestone filler (LF), 12 mm polypropylene fibers (PF), and laboratory-supplied water. A polycarboxylate-based superplasticizer (SP) and a hydroxypropyl methylcellulose (HPMC) viscosity-modifying agent were also included. Table 1 summarises the physical properties of the materials, and Figure 1 presents the morphology of the fine constituents.

Table 1 – Constituents raw materials characterisation

Propriety	Material	Value
Density (kg/m³)	CP-V	3040
	LF	2710
	MK	2490
	Sand	2610
Compact unit mass (kg/m³)	Sand	1,71
Loose unit mass (kg/m³)	Sand	1,58
Maximum characteristic diameter (mm)	Sand	1,18
Fineness module	Sand	1,42
Maximum particle diameter (µm)	CP-V	8,04
	MK	11,69
	LF	27,71
Specific Surface area – BET (m²/g)	CP-V	1,70
	MK	10,93
	LF	2,75
Total pore volume (cm³/g)	CP-V	$0{,}35 \times 10^{-2}$
	MK	$3{,}22 \times 10^{-2}$
	LF	$4{,}24 \times 10^{-3}$

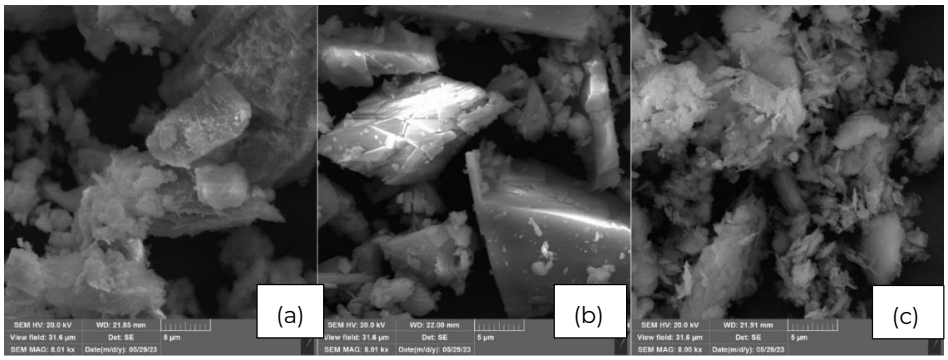

Figure 1 - Scanning Electron Microscopy (SEM) photos of, in secondary electrons mode: (a) CP-V, (b) LF, and (c) MK

2.2 Dosage of the mixtures and printing process

For the preparation of the 3DCP mixtures, a cement-to-sand mass ratio of 1:2 was adopted as the reference proportion. Portland cement was partially replaced by limestone filler and metakaolin in order to reduce cement consumption while maintaining suitable fresh-state performance. The water-to-total-dry-materials ratio was kept constant at 12% for all mixtures. The compositions evaluated in this study are presented in Table 3.

Table 3 – Mix design of 3DCP mixtures developed in the current study

Mixture	CP-V (kg/m³)	LF (kg/m³)	MK (kg/m³)	Sand (kg/m³)	SP (%)	HPMC (%)	w/c (kg/kg)	FP (%)
REF	689,94	-	-	1379,88	0,79	0,15	0,36	-
FC30	478,50	205,75	-	1368,51	0,79	0,15	0,51	-
FC40	409,77	272,91	-	1364,54	0,79	0,15	0,60	-
FC50	340,27	340,27	-	1361,07	0,75	0,15	0,72	-
FC30MK10	408,52	204,26	69,45	1360,36	1,30	0,15	0,60	-

FC30MK10-0,5%FP	350	175	59,5	1165,5	1,30	0,15	0,60	0,5
FC30MK10-1%FP	350	175	59,5	1165,5	1,30	0,15	0,60	1,0
MK10	615,39	-	68,38	1367,52	1,15	0,15	0,36	-
*w/c = water/cement (water to cement mass ratio)								

For the mixing process, the materials were first weighed using a precision scale with 0.1-gram accuracy. The components were then mixed following a defined sequence: homogenization of the dry materials, addition of 75% of the mixing water, incorporation of the superplasticizer, addition of the remaining 25% of water, and finally the introduction of the viscosity-modifying agent. Each mixing stage lasted 2 minutes and was conducted in an inclined-shaft mixer.

To produce the elements used in the buildability assessment, a 3D printer assembled by students from the LABIMACC laboratory (UFPB/IFPB) was employed. The printer features a portal-type structure and is capable of manufacturing components with a volume of up to 1.0 m³ using an extrusion-based system. The printing process consisted of producing block-shaped parts measuring 180 mm × 440 mm × 190 mm (width, length, and height, respectively), using a 25 mm-diameter extrusion nozzle with a deposition height of 20 mm. Printing was performed at a constant speed of 2500 mm/min and an extrusion rate of 1.69 L/min.

2.3 Properties in the fresh state

2.3.1 Viscosity

The viscosity of the compositions was analyzed using a rotational viscometer (model Rotavisc hi-vi I, IKA®). For the test, a spindle (104 mm long) with a geometry composed of 4 blades (25.4 mm long and 12.7 mm in diameter) was used, along with a 600 ml beaker in which the mixture was placed. The angular velocity values were first varied in increasing order and then decreasing, in the following sequence: 8 rpm, 12 rpm, 15 rpm, 17 rpm, 20 rpm, 30 rpm, 40 rpm, 50 rpm, 84 rpm (Nunes *et al*., 2023).

2.3.2 Flowability

The flowability of the mixtures was analyzed through the consistency table test, according to standard NBR 13276 (ABNT, 2016). For this test, a cone-shaped mold and the consistency table were used, and the test was conducted in accordance with the standard's procedures.

2.3.3 Consistency

To measure the consistency of 3DCP compositions, the procedure described in NBR 16606 (ABNT, 2018) was followed, which establishes a method for determining the normal consistency of Portland cement paste using the Vicat apparatus in conjunction with the Tetmajer needle. The analysis of consistency through this test is based on the weight of the needle that penetrates the mixture at rest.

2.3.4 Buildability

ISO/ASTM 52939 (2023) specifies that buildability is evaluated based on the layers' ability to remain stable without collapsing or significant deformation of the printed element. The test was evaluated according to the methodology adapted from Nunes *et al*. (2023), which considered the number of layers needed to print a 3DCP block approximately 190 mm in height. This involved approximately 16 overlapping layers. The buildability was analyzed only for fiber-free mixtures, and its calculation was performed using Equation 1.

$$B = \frac{H_a}{H_P} \qquad \text{(Equation 1)}$$

Where:

B = buildability;

H_a = actual height, in mm;

H_p = total predicted height, in mm (Equation 2).

Where:

H_1 = height of the first layer, in mm;

n = number of stacked layers.

$$H_P = H_1 \times n \qquad \text{(Equation 2)}$$

3. Results and discussion

3.1 Viscosity

Viscosity is a key rheological property for 3D concrete printing, as it reflects the resistance of the mixture to flow under the action of shear stress. Lower viscosity values indicate reduced resistance and greater ease of flow. Figure 2 illustrates the relationship between viscosity and angular velocity for 3DPC mixtures developed (see Table 3), showing that all 3DCP mixtures display pseudoplastic and thixotropic behaviour: viscosity decreases with increasing shear rate, and the mixtures gradually recover their viscosity when left at rest.

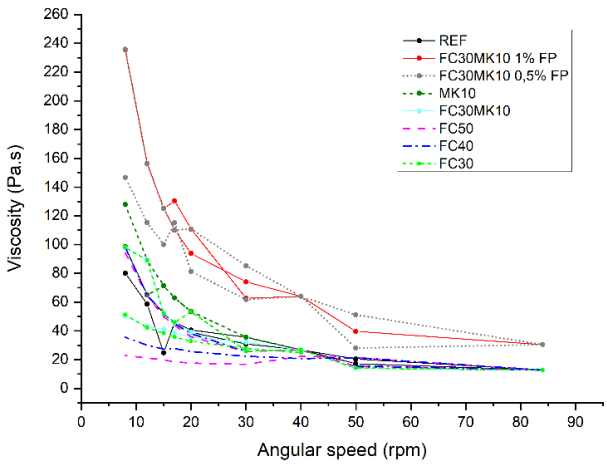

Figure 2 - Viscosity of 3DCP compositions under study

High viscosity implies greater resistance to deformation, limiting the mixture's ability to move smoothly through the pumping system and be extruded without interruption. For this reason, viscosity values at 30 rpm—where the measurements were most stable—were used for comparison, as shown in Figure 3.

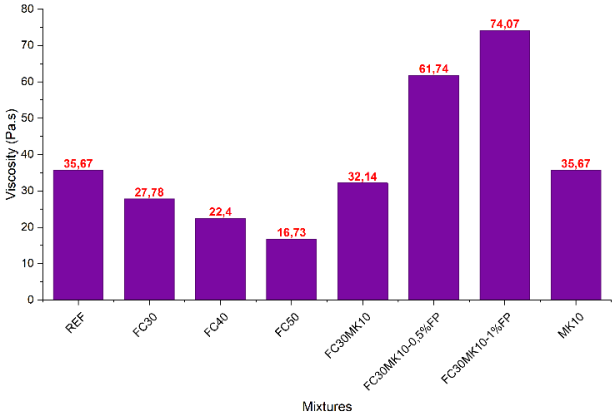

Figure 3 - Viscosity of 3DCP compositions under study

The progressive incorporation of limestone filler (LF) reduced the viscosity of the mixtures, as observed in FC30, FC40 and FC50. This reduction is consistent with the rounded and smooth particle morphology of LF, which decreases flocculation and facilitates internal lubrication, thereby improving flowability. In contrast, the addition of metakaolin (MK) led to an increase in viscosity in the MK10 mixture. This behaviour is attributed to the irregular, plate-like morphology and higher surface area of MK, which increases water demand and enhances resistance to the breakdown of particle agglomerates during shear. These microstructural characteristics are supported by the pore structure and BET surface area data presented in Table 1 and the morphologies observed in Figure 1. (Rojo-López *et al*., 2022).

Viscosity values obtained in this study are comparable to those reported in the literature. Kondepudi *et al*. (2022) documented viscosity ranges of 16–38 Pa·s, while Nunes *et al*. (2023) using the same printing system as in this work, reported values between 21.8 and 53.5 Pa·s. All mixtures in the present study fall within these ranges, except FC30MK10-0.5%FP and FC30MK10-1%FP, which exhibited substantially higher viscosities. These elevated values result from the combined effects of MK—whose high surface area offsets the fluidifying effect of LF—and the presence of polypropylene fibres, which increase internal friction and act as flow barriers, thereby restricting particle movement and raising shear resistance (Rojo-López *et al*., 2022).

3.2 Flowability

Flowability was evaluated using the flow table test in accordance with NBR 13276 (ABNT, 2016), immediately after mixing. Figure 4 presents the spread values obtained for each mix composition presented in Table 3. As can be perceived, values obtained in this research range from 153.3 mm to 257 mm. Previous studies of Ma *et al*. (2018), Kaszyńska *et al*. (2020), and Barbosa *et al*. (2022) suggest that spread diameters between 160 mm and 210 mm generally indicate adequate extrudability for 3D printing systems.

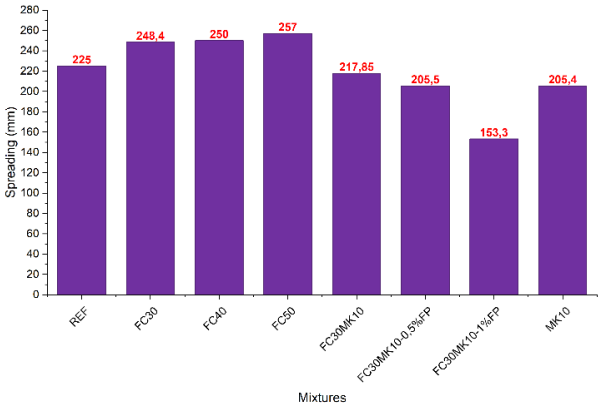

Figure 4 - Spreading of 3DCP compositions

Mixtures FC30, FC40, and FC50 exhibited increases in spread of 10.4%, 11.1%, and 14.2%, respectively, relative to the reference (REF) mixture. This behaviour is consistent with the limestone filler incorporation, whose smooth particle morphology enhances lubrication and reduces internal friction, thereby increasing flowability. Conversely, the MK10 mixture showed an 8.7% reduction in spread compared to REF. This reduction is attributed to the porous microstructure and higher water demand of metakaolin, which increases viscosity and limits the mixture's ability to deform under its own weight (Duan *et al*., 2022).

The FC30MK10-1%FP mixture presented the lowest spread value among the compositions, falling outside the range typically associated with printable mixtures. Although buildability was not evaluated for fibre-containing mixtures, the combination of high viscosity and restricted spread suggests that this mixture would likely present extrusion difficulties. Its rheological behaviour is consistent with the increased resistance induced by fibres, which may compromise particle rearrangement and decrease flowability.

The mixtures that successfully produced printed elements showed spread values between 205.4 mm and 257 mm, reinforcing the idea that both the intrinsic rheological behaviour and the characteristics of the printing system influence the necessary flowability window for extrusion-based 3D concrete printing.

3.3 Consistency

Consistency was assessed using the Tetmajer probe method in accordance with NBR 16606 (ABNT, 2018). The results are presented in Figure 5. Overall, mixtures containing metakaolin (MK) or polypropylene fibres (PF) exhibited greater resistance to penetration, indicating higher stiffness in the fresh state. This increased resistance is associated with the higher surface area and water demand of MK, as well as the internal friction generated by fibres (Tran *et al*., 2021).

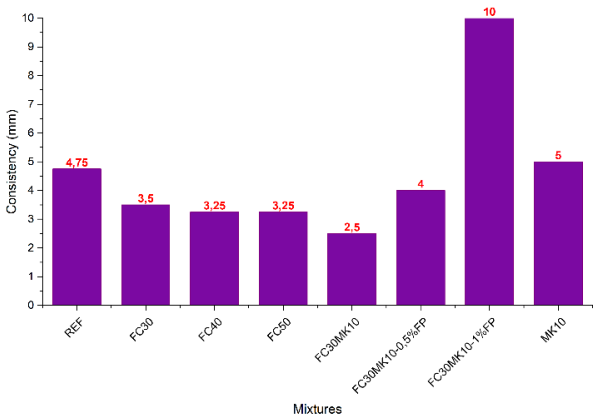

Figure 5 - Consistency of 3DCP compositions

The FC30MK10-1%FP mixture displayed the highest consistency among all formulations. The presence of 1% fibres contributes to a denser internal network, increasing interparticle friction and restricting deformation under the applied load. This behaviour aligns with the role of fibres as micro-reinforcing elements that impede the movement of the paste and aggregate particles, thereby increasing penetration resistance.

In contrast, mixtures containing increasing proportions of limestone filler showed substantial reductions in consistency relative to the reference mixture (REF). The FC30, FC40, and FC50 mixtures exhibited decreases of 26.3%, 31.6%, and 31.6%, respectively. These reductions can be attributed to the fluidifying effect of LF, whose smoother particle morphology reduces mechanical interlocking and allows the probe to penetrate more easily. The behaviour of the FC30MK10 mixture is noteworthy. Despite its higher superplasticizer demand, the mixture exhibited lower penetration resistance than expected for MK-containing systems. This may result from decreased interparticle forces associated with superplasticizer action, which promotes laminar flow and reduces resistance to localized deformation. Similar observations were reported by Gu and Khayat (2024) who found that higher superplasticizer dosages increase fluidity and reduce consistency measurements.

It is worth mentioning that consistency measured with the Tetmajer probe does not fully replicate the structural build-up that occurs during layer deposition in 3D printing. While the probe measures local resistance to penetration under shear, printed layers undergo thixotropic recovery when at rest, allowing viscosity to rebuild and support the weight of subsequent layers. Thus, consistency data should be interpreted alongside viscosity and buildability measurements to fully assess printability.

3.4 Buildability

Buildability was evaluated by printing block-shaped elements and comparing the actual height achieved with the theoretical height predicted by Equation 1, following the methodology adapted from Nunes et al. (2023) and aligned with ISO/ASTM 52939 (2023). This assessment reflects the ability of freshly deposited layers to maintain their geometry without excessive deformation or collapse. Only fibre-free mixtures were considered for this test, as fibre-containing mixtures exhibited viscosity and flowability values outside the printable range and were therefore excluded from extrusion trials.

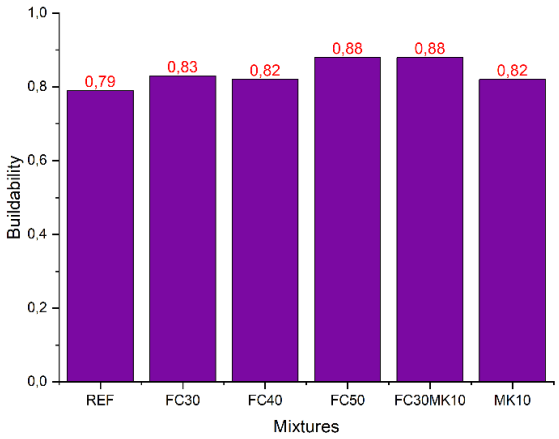

Figure 6 - Buildability of 3DCP compositions

Buildability was evaluated by printing block-shaped elements and comparing the actual height achieved with the theoretical height predicted by Equation 1, following the methodology adapted from Nunes et al. (2023) and aligned with ISO/ASTM 52939 (2023). This assessment reflects the ability of freshly deposited layers to maintain their geometry without excessive deformation or collapse. Only fibre-free mixtures were

considered for this test, as fibre-containing mixtures exhibited viscosity and flowability values outside the printable range and were therefore excluded from extrusion trials.

Although some mixtures achieved similar numerical buildability values, their printed quality differed significantly when visually inspected. The mixtures FC40 and FC50, which contain higher proportions of limestone filler (LF), showed pronounced deformation—particularly on external faces not supported by the internal truss. This behaviour is attributed to the increased flowability induced by LF, which, while beneficial for extrusion, can compromise geometric stability after deposition. By contrast, the MK10 mixture presented improved printing characteristics, with more uniform layer stacking and reduced lateral deformation. This effect is associated with the higher viscosity and structural build-up promoted by metakaolin.

Among all evaluated formulations, the FC30MK10 mixture delivered the most favourable performance, combining adequate viscosity, controlled flowability, and high layer stability. Its printed blocks exhibited minimal deformation and clean stratification. While the FC50 mixture attained one of the highest buildability indices numerically, achieving this required reducing the superplasticizer dosage. Despite the adjustment, the printed element remained more susceptible to deformation compared to MK-containing formulations. This suggests that buildability is influenced not only by viscosity and flowability but also by the restructuring kinetics associated with admixture content (Harbouz et al., 2022).

Overall, the results demonstrate that mixtures incorporating MK tend to enhance buildability and print quality, while excessive LF content increases the likelihood of deformation despite favourable flow properties. This highlights the need for balancing fluidity and structural build-up to achieve stable multi-layer deposition in extrusion-based 3D printing.

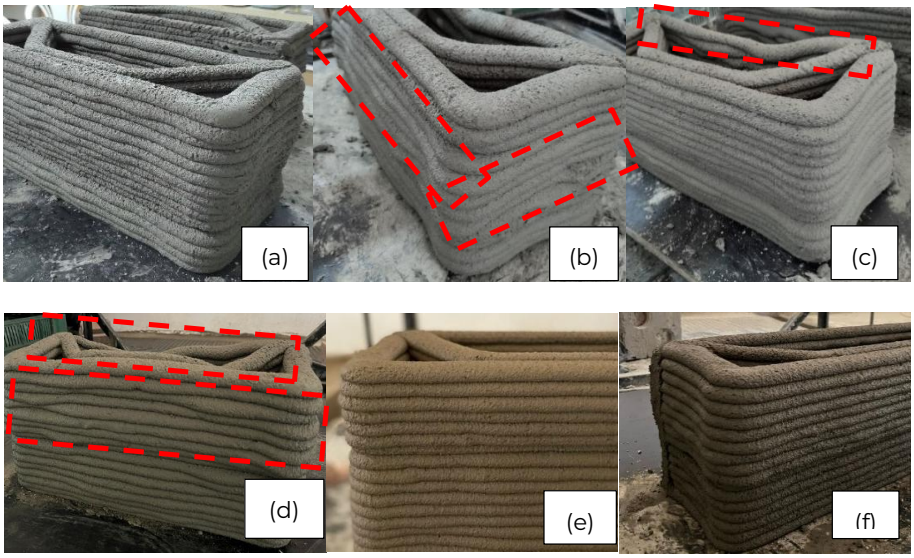

Figure 7 - 3DCP Blocks with mixes under study: (a) REF, (b) FC30, (c) FC40, (d) FC50, (e) FC30MK10, (f) MK10

3.5 Results summary, main trends and interactions

Figure 8 summarizes the fresh properties of the mixtures, highlighting an increase in viscosity, which is correlated with lower fluidity and greater consistency. Notably, in Figure 8, the dotted lines represent the printed mixtures. It is observed that the FC30, FC40, and FC50 mixtures are more deformable, which is attributed to the higher fluidity imparted by the limestone filler. Conversely, mixtures with MK tend to reduce deformation. Therefore, there is an indication that mixtures with viscosities between 32 and 36 Pa·s, spreads between 205 and 225 mm, and Tetmajer probe consistencies between 2.5 and 5 mm can be considered as ideal printing parameters. These are the properties of the REF, MK10, and FC30MK10 mixtures, which demonstrated the best printing capability.

From the combined rheological assessment, mixtures with viscosities between 32 and 36 Pa·s, spreads between 205 and 225 mm, and Tetmajer consistency values between 2.5 and 5 mm can be considered optimal for extrusion-based printing. These ranges correspond to the REF, MK10 and FC30MK10 mixtures, all of which demonstrated the most favourable printing performance and produced elements with superior geometric stability.

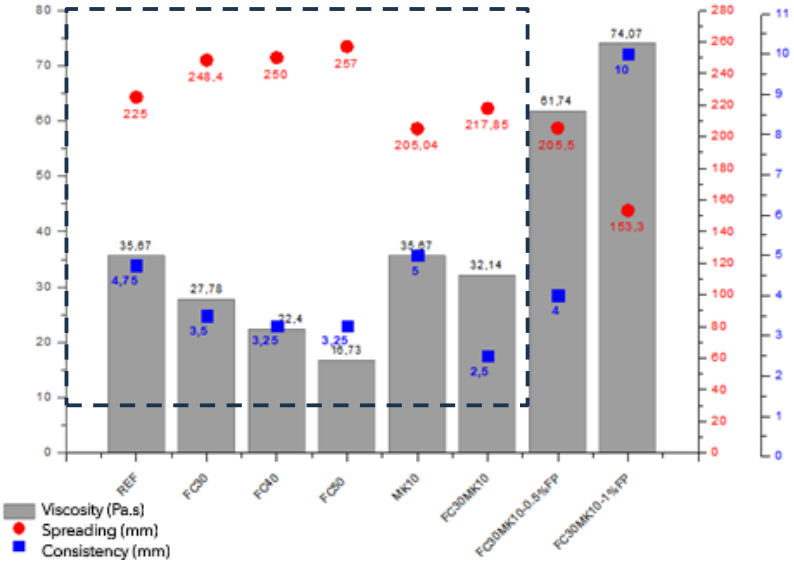

Figure 8 – Fresh properties results overview of the 3DCP compositions under study

4. Conclusions

Based on the experimental results and the adopted methodology, it was possible to develop and evaluate 3D-printable cementitious mixtures incorporating different proportions of limestone filler (LF), metakaolin (MK) and polypropylene fibres (PF). The study enabled a systematic assessment of how these additions influence fresh-state behaviour and printability. The main conclusions are as follows:

- Cement consumption between 340.27 kg/m³ and 478.50 kg/m³ was achieved through binary mixtures containing cement and LF (FC30, FC40 and FC50) and ternary mixtures incorporating cement, LF and MK (FC30MK10 and FC30MK10 with fibres).
- Regarding the reference mixture, the incorporation of limestone filler reduced viscosity by 22.1%, 37.2% and 53.1% in the FC30, FC40 and FC50 mixtures, respectively. In contrast, the MK10 mixture exhibited higher viscosity due to the greater specific surface area and porosity of MK.
- The FC30MK10-1%FP mixture presented the highest viscosity and lowest spread, resulting from the combined effects of MK and polypropylene fibres, which increase internal friction and restrict flow.
- Optimal fresh-state properties for printing in the employed system were associated with spreads between 205 mm and 250 mm, viscosities between 22.5 and 35.67 Pa·s, and Tetmajer probe consistencies between 3.25 mm and 5 mm. Mixtures within these ranges achieved stable layer deposition.
- The FC30MK10-1%FP mixture showed a 100% increase in consistency compared with MK10, attributed to the significant rise in internal friction and shear resistance caused by fibre incorporation.
- Among all evaluated mixtures, FC30MK10 demonstrated the best balance between viscosity, flowability and buildability, meeting the printing criteria and producing high-quality printed elements.

Overall, the results indicate that the combined use of limestone filler and metakaolin can effectively tailor the rheological behaviour required for extrusion-based 3D concrete printing and may therefore represent a technically viable solution for achieving significant partial replacement of Portland cement in printable mixtures.

Abstract: The contemporary concept aims at decarbonization in the Brazilian civil construction industry, emphasizing the importance of using waste materials as supplementary cementitious materials, since cement-based inputs represent a significant fraction of greenhouse gas emissions. Therefore, the objective of this study is to identify, considering the diversity of the Brazilian territory, which waste materials offer the best balance between mechanical performance and environmental benefit at cost-effective levels in cementitious mixtures. The methodology is organized into three stages: a systematic literature review on the use of waste materials as SCMs, covering the period from 2015 to 2025, identifying their origin and application in cementitious matrices. Subsequently, a standardized data extraction was carried out, including technical and economic indicators; the selection criteria were based on the availability of consistent data that allow effective comparison between studies. Thus, studies presenting the following were considered: minimum compressive strength of 20 MPa at 28 days, material consumption (kg/m³), or, when not directly available, values estimated from mix proportions and material densities, as well as concrete density. Finally, embodied CO_2 emissions were estimated for each mixture. The results provided a national overview of the use of waste as SCMs for the development of eco-efficient materials, integrating economic, environmental, and technical aspects related to performance and durability. However, many studies lacked essential information for the proposed analysis, and a concentration of research in the Southeast region of Brazil was observed. Among the analyzed materials, São Tomé stone waste, mining tailings sand, and recycled glass powder showed the best overall performance, combining mechanical adequacy with reductions in embodied CO_2.

Keywords: Low-carbon concrete. Waste. Supplementary cementitious materials. Performance. Structural recovery.

1. Introduction

Decarbonization strategies in the construction industry are part of a broader process aimed at mitigating the effects of climate change and achieving the Sustainable Development Goals (SDGs) (Hafez et al., 2024). The production of traditional structural materials used in Brazil, i.e., reinforced concrete, is associated with significant CO_2 emissions, estimated at approximately 7% of global emissions. (Sbahieh *et al.* (2023)).

Therefore, efforts towards the structural sustainability of buildings have focused on two dimensions: their efficiency, associated with project design, and the reduction of the carbon emissions of the materials produced and marketed. In the first case, the focus is on rationalizing the use of resources, with emphasis on choosing more efficient structural systems that are better suited to the required performance. Recent research shows that design decisions can reduce CO_2 emissions up to 76%, through the appropriate

selection of parameters such as the concrete mechanical strength and the reinforcement ratio. (Olsson *et al.* (2023)).

The second dimension, which refers to decarbonization, focuses on technological innovation, since optimized projects are still dependent on composites with lower carbon intensity, highlighting: the partial replacement of clinker with supplementary cementitious materials (SCMs), such as LC_3 cement, and the development of alternative binders, such as geopolymers (Sbahieh *et al.* (2023); Hafez *et al.,* (2024)), whose potential varies with the regional availability of raw materials.

In line with the circular economy, recent research demonstrates the potential to transform high-impact environmental waste into solutions for the built environment. A notable example is the recycling of marine plastics, such as high-density polyethylene (HDPE) recovered from the oceans, to create new composites with thermal insulation and mechanical strength properties, mitigating the disposal problem and adding value to these materials (Almeida *et al*., 2025).

However, decarbonizing the sector is not limited to new buildings. A significant part of the challenge lies in increasing the life cycle and providing sustainable maintenance services for existing infrastructure, which represents a huge embodied carbon liability (EKN Engineering (2023)). In the case of reinforced concrete structures, deterioration shows itself progressively, compromising integrity and safety. This process results from multiple factors, such as the natural aging of materials, changes in the function or use of buildings (changed loads), design or execution errors, as well as exposure to aggressive environments or extreme events.

Experimentals research demonstrates that the use of combined reinforcement systems in reinforced concrete elements is capable of restoring, and in some cases increasing, the structural capacity and extending the building life cycle (Attia *et al*., (2023)). Researchers indicate that sustainable strategies for the preservation and retrofit of structural systems include techniques such as the use of hypocarbon binders, fiber-reinforced polymer (FRP) systems, self-repair techniques, and the use of computational tools for optimizing the proportioning of cementitious mixtures (Rusnak (2025)). Although promising, these solutions face challenges regarding performance variability, economic viability, and regulatory standardization, which requires joint efforts from researchers, the productive sector, and regulatory sectors.

Given the above, this paper proposes the identification and analysis of the main waste and by-products used in Brazil as supplementary cementitious materials in composites intended for the structural repair of reinforced concrete elements. Aspects related to regional availability, compliance with standards, mechanical performance, and environmental impacts are examined, aiming to support the selection of technically viable, environmentally efficient solutions with an adequate cost-benefit ratio.

1.1 Motivations and paper contributions

Brazil, due to its continental size and socioeconomic diversity, presents significant disparities in the generation, management, and utilization of construction waste (Doussolin and Bittencourt, 2022). In this context, the transition to practices combined with the circular economy, which value the reuse of byproducts and waste as a partial replacement for conventional inputs, becomes strategic for the decarbonization of the Brazilian building industry. Therefore, central motivation of this work lies in the need to understand how different regions of the country, with varying waste generation profiles, can adopt the incorporation of supplementary materials in cementitious matrices. Territorial heterogeneity demands adapted approaches capable of reconciling cost, performance, and environmental impact, ensuring greater practical viability, and local relevance.

The highlight of this study can be summarized as follows:

i. Mapping of waste and by-products currently available in each region of Brazil for use in concrete as additions/supplementary materials;
ii. Comparative evaluation of the technical properties of cementitious mixtures, as well as the carbon footprint of these materials in association with costs and availability, promoting a sustainability analysis;
iii. Identification of the inputs with the best cost-benefit ratio in the Brazilian context, considering technical, economic and environmental viability;

iv. Provision of technical and scientific subsidies to support public policies, standardization and engineering practices aimed at the circular economy and increasing the lifespan of buildings.

1.2 Brazilian territory

Brazil has a territory of 8,515,758.7 km² and is divided into 27 Federative Units, 26 States and the Federal District, grouped into five major Geographic Regions: North, Northeast, Southeast, South and Midwest, considered for planning and management purposes (Figure 1) (EMBRAPA (2020); IBGE (2021)).

.**Figure 1 -** Regions and states of Brazil.

The Brazilian territory presents striking contrasts in its physical and productive space, a direct reflection of its territorial vastness, bioclimatic diversity, and the distribution of industrial and agro-extractive chains (EMBRAPA (2020)). This configuration defines the profile of solid waste generated in each macro-region, determining its potential for reuse as supplementary cementitious admixtures (SCMs). It is observed that the country encompasses macro-territories with distinct productive vocations, which are reflected in the nature and volume of by-products that can be integrated into the low-carbon construction chain

Table 1 presents, by region, the biomes, the main production chains and the generating activities, and summarizes the national scenario, highlighting the regional availability of waste that can guide strategies for decarbonization, circularity and optimization of cementitious matrices.

Table 1 – Summary about macroregion and main characteristics.

Macroregion	Characteristics	Main economics activities	Reference
North	Amazon Florest; equatorial climate (hot and wet)	Plant extration (açaí); bauxite, iron, manganese, gold	IBGE (2024a); IBGE (2023); ANM (2023); MMA (2023); Rocha *et al.* (2022)
Northeast	Caatinga e Atlantica forest; semi-arid and tropical wet climate	Agroindustry; plaster; ceramics; ornamental rocks	IBGE (2024b); ANM (2023); IBGE (2024a); Cruz *et al.* (2023); SEBRAE (2024)
Midweast	Tropical savana climate	Agroindustry; biofuels; mining	MME (2024); MAPA (2024); IBGE (2024b); IBGE (2023); MME/EPE (2024)

South	Atlantica forest and Pampa; subtropical climate	Agroindustry; coal; pape rand cellulose	MME/EPE (2024); ANM (2023); IBGE (2024a); Tashima *et al.* (2012)

2. Experimental procedure

The study is based on a systematic literature review and systematic data extraction, focusing on the application of supplementary cementitious materials (SCMs) in concrete and mortars intended for structural repair in the Brazilian macro-regional context. The research protocol is shown in Figure 2.

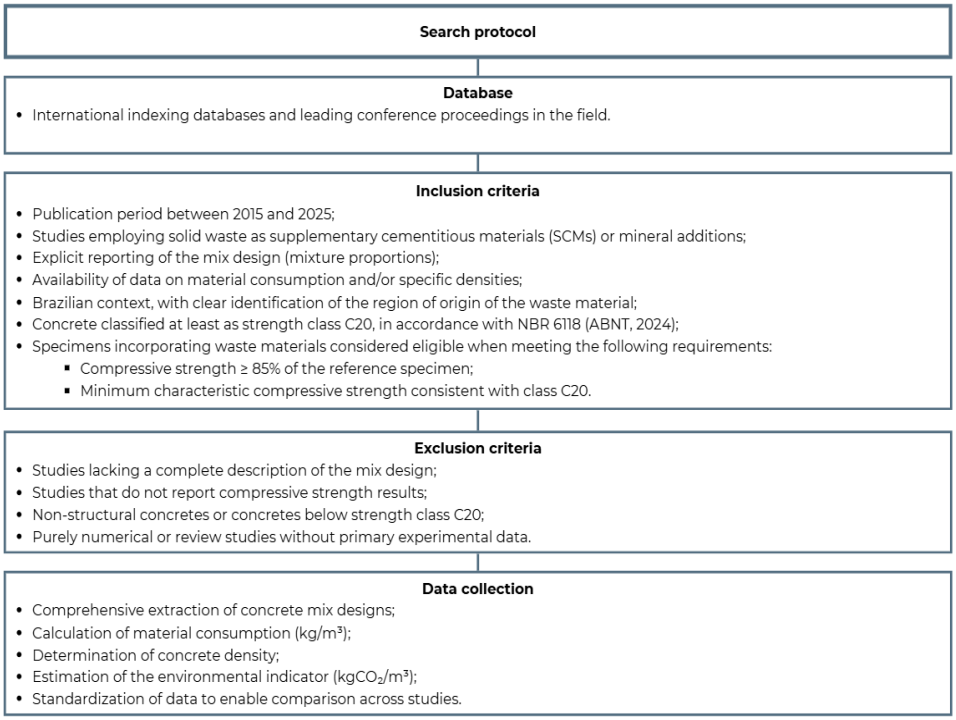

Figure 2 - Search protocol.

2.1 Database

A survey was conducted of the main waste and by-products used as supplementary cementitious materials/additives in cement-based composites with structural characteristics in each Brazil macro-region (Figure 1). For each identified waste, information was compiled regarding its main physical, chemical, and mechanical properties.

2.2 Environmental impact: Calculation method

The environmental impact was determined from the estimation of embodied carbon dioxide (embodied CO_2), adopting the principles of Life Cycle Assessment (LCA), as established by NBR ISO 14040 (ABNT, 2009a) and the requirements defined in NBR ISO 14040 (ABNT, 2009b), as well as the methodological guidelines of the Technical Bulletin "Quantification of embodied CO_2 emission

s in cementitious materials and concrete structures" (ABCP (2023))

To determine the amount of embodied CO_2, attributional LCA was used (IBRACON (2023)), adopting stages A1–A3 (cradle to gate) as the main boundary. The functional unit adopted is 1 m^3 of concrete or mortar, with the inventory modeled from the unit mix. Embodied CO_2 is calculated by summing the emissions associated with each constituent material, obtained by multiplying the unit consumption by the respective emission factor. Emission data are obtained from technical literature and national databases (SIDAC (2026); IBRACON (2023); Ecoinvent (2026)).

The procedure adopted compares the incorporated CO_2, expressed in $kgCO_2/m^3$, between conventional mixtures and mixtures with residues or SCM with equivalent mechanical performance, according to Equation (1).

$$CO_{2,inc} = \sum_{i=1}^{n}(q_i \times FE_i) \quad (1)$$

Being:

$CO_{2,inc}$: CO_2 emissions incorporated from concrete or mortar ($\frac{kgCO_2}{m^3}$);

q_i: consumption of material i in the unit mix ($\frac{kg}{m^3}$);

FE_i: CO_2 emission factor of material i, considering the A1-A3 boundary ($kg\ CO_2/kg$);

i: constituent materials of the mix design (cement, aggregates, water, mineral additions, SCM, additives).

The emission factor for conventional materials:

$$FEi\ =\ FE_{i_{A1-A3}} \quad (2)$$

The emission factor for waste SCM;

$$FEi\ =\ FE_{processing\ +\ transport} \quad (3)$$

3. Results and discussions

3.1 Characterization of SCM materials by macroregion

After applying the methodological selection protocol, the waste materials were organized according to the Brazilian macro-regions (Table 2), considering their origin, regional availability, physicochemical characteristics, and required processing stages. This regional approach highlights the dependence between local productive chains and the availability of supplementary cementitious materials (SCMs), reinforcing the importance of territorial context in the development of low-carbon strategies.

Most residues present high silica contents (SiO_2), either in amorphous or crystalline form, which directly influences their behavior as pozzolanic materials or inert fillers. Agro-industrial ashes (e.g., rice husk ash and sugarcane bagasse ash) exhibit pronounced pozzolanic activity, whereas mining and ornamental rock

residues tend to act predominantly through filler effects, contributing to particle packing and matrix densification.

Table 2 - Compilation of residues used as SCM by region.

Waste	Highlights	Performance
North		
CA: Acai seed ash (Cordeiro *et al*., 2019).	% SiO_2 ≈ 88–92%; pozzolanic activity. Processing: sieving and grinding.	Reduction of porosity. Optimal content ≈ 10%.
BP: Pal Biomas (Percy *et al*., 2021)	% SiO ≈ 63–71%; filler effect. Processing: sieving and grinding.	Reduction of porosity. 7.5% ≤ optimal contente ≤ 15%.
MU: Murumuru bark ash (Souza *et al*., 2024).	% SiO_2 ≈ 66%; partially amorphous. Processing: grinding and calcining.	Reduction of porosity. Optimal content ≈ 6%.
Northeast		
CT: Thermoelectric mineral coal ash (Jacinto, Oliveira e Oliveira, 2025).	% SiO_2≈ 80%; pozzolanic activity. Processing: grinding and sieving (< 75 µm).	Reduction of porosity. Optimal content ≈ 30%.
LV: Red mud (Degen *et al*. 2013).	% SiO_2≈ 74,4–77,7%; amorphous, filler effect + low pozzolanic activity. Processing: grinding	Reduction of porosity. Optimal content ≈ 5 a 15 %.
CB: Biomass ash from ceramic kilns (Mendonça *et al*. 2025).	Variable composition depending on the type of wood; filler effect. Processing: drying and sieving.	Reduction of porosity. Optimal content ≈ 5 a 10%.
Southeast		
CB: Sugarcane bagasse ash (Dias *et al*., 2025; Siqueira e Cordeiro, 2022).	% SiO_2 ≈ 70 - 80%; pozzolanic activity. Processing: grinding.	Reduction of porosity. 7% ≤ optimal contente ≤ 14%.
PV: Glass powder (Soares *et al*., 2022; Sales *et al*., 2017)	% SiO_2 ≈ 70%; filler effect + low pozzolanic activity. Processing: grinding.	Reduction of porosity 10% ≤ optimal contente ≤ 20%.
AR: Mining waste sand and ornamental rock waste (Figueiredo *et al*., 2024).	% SiO_2 ≈ 78%; filler effect. Processing: sieving.	Reduction of porosity 5% ≤ optimal contente ≤ 10%.
PS: São Tomé rock waste (Scalabrini *et al*., 2025).	% SiO_2 ≈ 90–95%;. filler effect Processing: sieving.	Reduction of porosity 10% ≤ optimal contente ≤ 15%.
South		
CZ: Rice Husk Ash (Mourão *et al*., 2025).	% SiO_2 ≈ 85–95%; pozzolanic activity Processing: burning and grinding.	Redução da porosidade. Optimal content ≈ 10%

Nevertheless, this approach represents a simplification, particularly in the context of structural repair, where additional parameters such as durability, compatibility with the existing substrate, shrinkage, and long-term performance are critical. The absence of these indicators in a significant portion of the reviewed literature limits a more comprehensive assessment and should be addressed in future studies.

Figure 3 shows that ornamental rock waste (AS), used primarily as a filler (Figueiredo et al. (2024)), when incorporated into cementitious mixtures, results in an increase in compressive strength of approximately 10% to 25% compared to reference mixtures, with absolute values reaching 52 MPa, while enabling reductions of up to approximately 45% in $kgCO_2/m^3$. São Tomé stone residue (PS) shows even more significant behavior, with a strength increase of approximately 29%, from 52 to 67 MPa, associated with a reduction of about 6% in CO_2 emissions (Scalabrini et al., 2025).

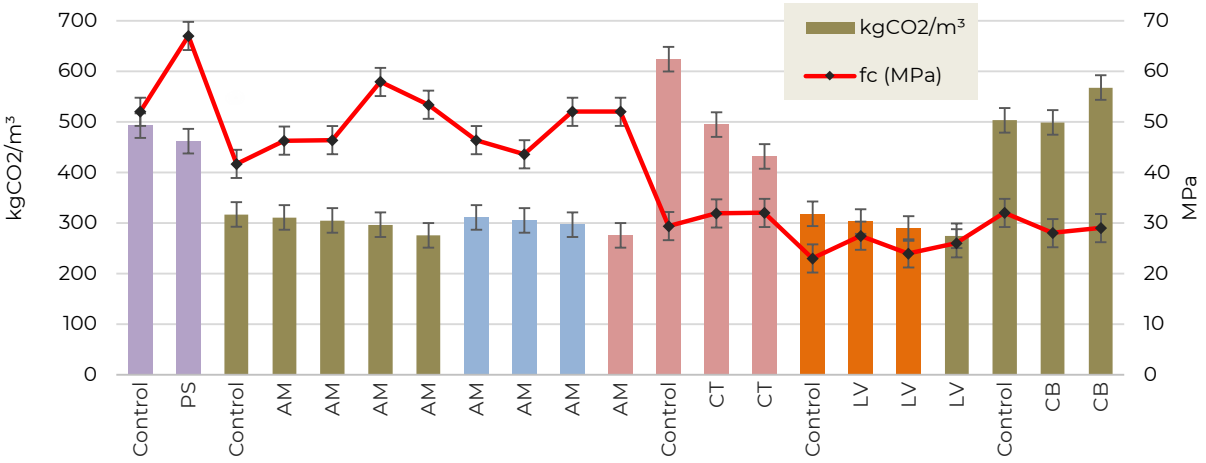

Figure 3 - $kgCO_2/m^3$ versus fc (MPa) graph for reference samples and residues incorporated without processing.

Regarding thermoeletric mineral coal ash (CT) and red mud (LV) (Jacinto, Oliveira and Oliveira (2025); Degen *et al.* (2013)), an intermediate behavior is observed, in which physical and chemical effects act in a complementary way, such as:

i) CT showed low increases in compressive strength, on the order of 2% to 9%, concomitantly with emission reductions ranging from 21% to 31% when compared to reference concretes. This performance is consistent with the composition rich in SiO_2, Al_2O_3 and Fe_2O_3, which confers pozzolanic potential with a more pronounced manifestation at later ages.

ii) LV showed strength gains of approximately 4% to 20% in moderate substitutions, associated with reductions of 5% to 14% in $kgCO_2/m^3$, resulting from its high fineness, high specific surface area, and residual alkalinity, which favor its action as an active filler and the densification of the matrix.

In the case of waste that undergoes grinding (Figure 4), the results indicate that the fineness achieved in processing plays a decisive role in mechanical performance and emission reduction. Recycled glass powder stands out, showing strength increases of around 5% to 10% in conventional concretes and maintenance in high-strength concretes, associated with reductions of up to approximately 20% in incorporated CO_2, depending on the substitution rate (Costa et al. (2026); Soares et al. (2022); Sales et al. (2017)). This behavior is associated with the amorphous vitreous nature of the material, rich in SiO_2, which favors slow pozzolanic reactivity combined with a pronounced filler effect.

Despite these advantages, grinding represents an additional energy demand, and its environmental benefit depends on the balance between improved performance and the emissions associated with comminution processes. This trade-off is not consistently quantified in the literature and represents an important gap for future research.

For calcined residues (CB and MU) (Figure 5) (Souza et al. (2024); Siqueira and Cordeiro (2022)), a compensatory relationship is pointed between the thermal activation of the material and the increased environmental impact associated with processing. Although additional calcination promotes increased fineness, partial amorphization of silica, and improved granular packing, the increases in compressive

strength at 28 days are low, on the order of 1% and 5% when compared to the reference mixtures. This behavior indicates that the mechanical gains resulting from thermal activation should be evaluated in light of the increased energy and the potential increase in CO_2 incorporated into the material.

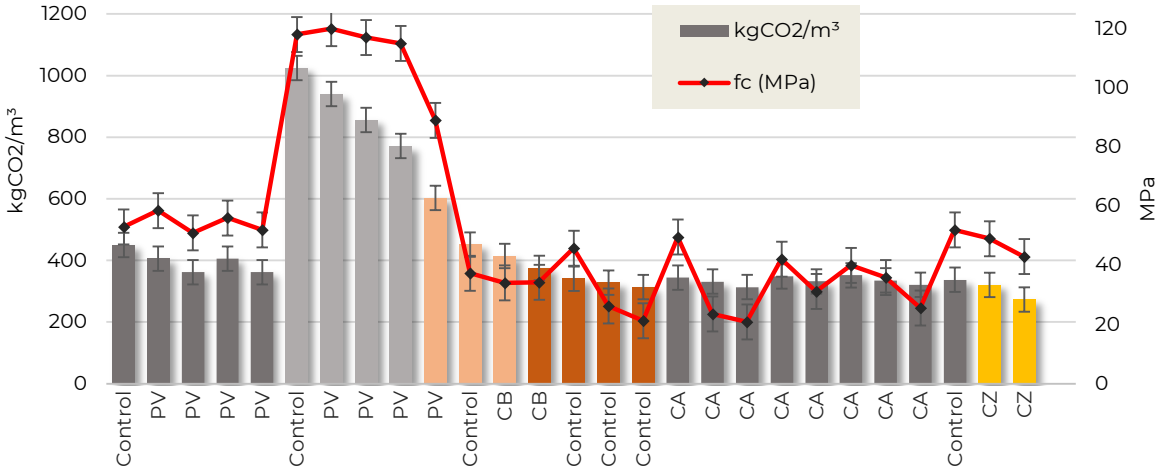

Figure 4 - $kgCO_2/m^3$ versus fc (MPa) graph for reference samples and residues incorporated without processing.

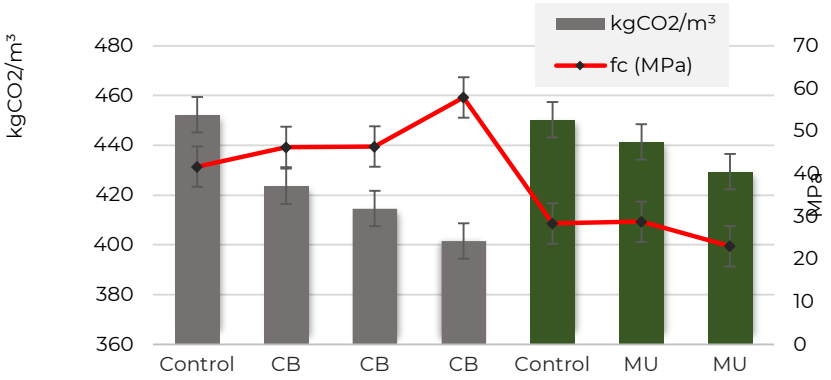

Figure 5 - $kgCO_2/m^3$ versus fc (MPa) graph for reference samples and residues incorporated after calcination.

In summary, Figure 6 correlates the variation in compressive strength at 28 days with the variation in emboidied CO_2, relative to the control of its respective study, for all mixtures analyzed, allowing the identification of the alternatives with the best technical-environmental performance. It can be observed that the most optimized solution corresponds to the São Tomé Stone residue, which combines a significant increase in strength, on the order of 29%, with a reduction of approximately 6% in incorporated CO_2, positioning itself more favorably in the quadrant of greatest mechanical gain associated with reduced emissions.

From a critical perspective, three main trends can be identified: (i) SCMs requiring little or no processing tend to present the best balance between mechanical performance and emission reduction; (ii) highly processed materials, particularly calcined ones, tend to show diminishing environmental returns; and (iii) the relationship between compressive strength gain and CO_2 reduction is not linear, indicating the presence of trade-offs that must be considered in material selection.

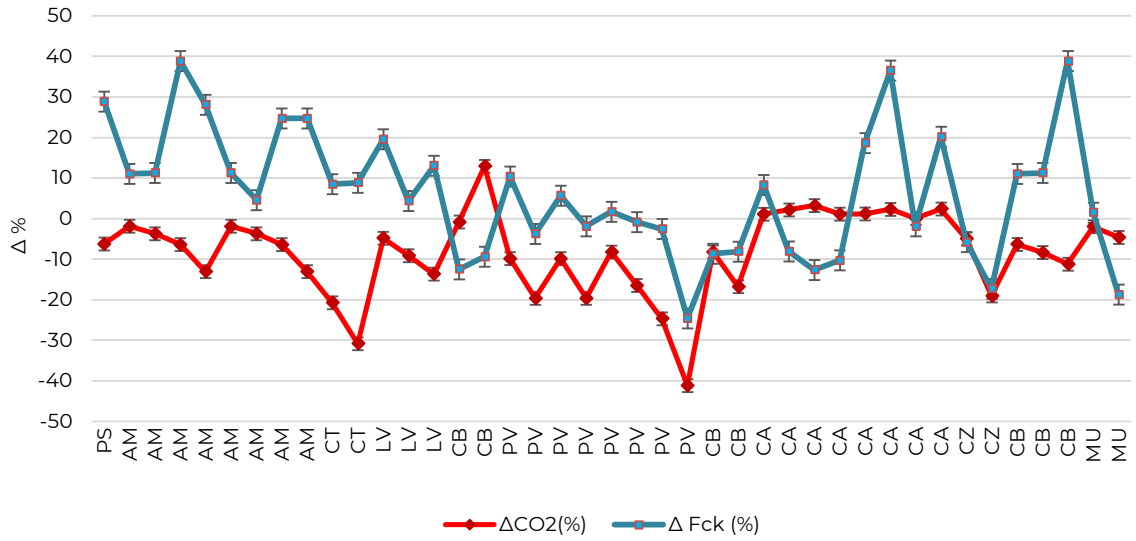

Figure 6 - Graph of variation in compressive strength and embodied CO_2.

3.2 Critical analysis and trade-offs

The combined interpretation of Figures 3 to 6 reveals that the best-performing SCMs are not necessarily those with the highest reactivity, but those that achieve a balance between processing requirements, mechanical performance, and environmental impact. Materials requiring minimal processing (Figure 3) consistently occupy the most favorable regions of the graphs, demonstrating that low-energy strategies can simultaneously enhance strength and reduce embodied CO_2. In contrast, SCMs subjected to grinding (Figure 4) or calcination (Figure 5) tend to shift this balance, often achieving either environmental gains or mechanical improvements, but rarely both. An important aspect emerging from this analysis is the behavior of SCMs that preserve, rather than significantly increase, compressive strength while still reducing CO_2 emissions. This trend is particularly evident for recycled glass powder (PV), which shows a predominantly horizontal shift in Figure 4 and clusters near the region of $\Delta fck \approx 0$ and $\Delta CO_2 < 0$ in Figure 6. From an engineering perspective, this response is especially relevant in structural repair contexts, where maintaining mechanical performance is often more critical than increasing strength. These findings highlight a fundamental trade-off: although increased processing enhances reactivity, it also raises embodied CO_2, potentially offsetting environmental benefits. Therefore, SCM selection should be based on a multi-criteria evaluation that considers not only strength but also processing intensity, regional availability, and overall environmental efficiency.

3.3 Limitations and implications for structural repair

The results should be interpreted considering the limitations inherent to the adopted methodology. The analyzed studies present significant heterogeneity in mix design, curing conditions, and characterization methods, which affects the comparability of results and contributes to the dispersion observed in Figure 6. Furthermore, the estimation of embodied CO_2 is based on emission factors obtained from the literature and national databases, which may not fully capture regional variations in production processes and logistics. This limitation is consistent with broader challenges in national data production, as highlighted by IBGE (2025), which emphasizes the need for standardized, disaggregated, and regionally representative datasets to support reliable indicator development. The strict inclusion criteria adopted in this study, although necessary to ensure consistency, reduced the number of eligible studies and may have affected the representativeness of the dataset.

Moreover, although compressive strength was adopted as the primary comparison parameter, it does not fully represent the performance of materials used in structural repair. Durability-related properties, such as permeability, shrinkage, and compatibility with existing substrates, are critical for long-term performance and were not consistently reported in the analyzed studies. This limitation restricts a more comprehensive assessment and highlights the need for future research integrating mechanical, environmental, and durability indicators to support more robust and application-oriented decision-making.

4. Conclusion

This study aimed to identify the main waste materials that were studied as supplementary cementitious materials for cementitious mixtures between 2015 and 2025, considering the macro-regions of the Brazilian territory and their potential.

In the literature review procedure on the subject, the following criteria were adopted: minimum compressive strength of the mixture of 20 MPa, the specific mass of the constituent materials of the mixtures, the complete description of the mixtures studied (experimental program), the consumption of materials used in the mixtures (kg/m^3), and the determination of the density of the concrete.

In this sense, the literature analysis reveals, however, recurring limitations related to the absence of fundamental information, such as specific mass, detailed granulometric characterization, and complete data on the proportioning of cementitious mixtures, which compromises the thorough comparison between the studies and the consistent evaluation of the environmental impact per unit volume of concrete. Research was found to be concentrated in the Southeast region of Brazil, in contrast to the limited number of studies in other regions. This imbalance reflects broader structural disparities in data production and availability across the country, as highlighted by IBGE (2025), reinforcing the need for regionally disaggregated studies and the valorization of locally available residues.However, the results obtained demonstrate that the incorporation of waste as supplementary cementitious materials can result in structurally adequate and environmentally more efficient concretes, even when the materials have a chemically inert character. In these cases, the microstructural improvement associated with the filler effect and granular packing proved sufficient to maintain or increase compressive strength, as well as to promote gains in the properties analyzed in the studies described in this work. The waste from São Tomé Stone (PS), certain compositions with mining tailings sand (AM), coal ash from thermal power plants (CT), and recycled glass powder (PV) stand out as solutions with the best overall performance, which combined relevant mechanical increases with significant reductions in incorporated CO_2, especially when used without additional processing or subjected only to grinding. In this context, the integration of technical, environmental, and regionally disaggregated data is essential to support more consistent decision-making and to provide technical and scientific basis for public policies, regulatory improvements, and engineering practices aligned with circular economy principles, CO_2 emission reduction, and the extension of the service life of concrete structures.

Resumo: O estudo analisou a origem dos elevados teores de cálcio (Ca) identificados em fragmentos de azulejos históricos portugueses presentes em uma edificação religiosa de Pernambuco, datados da primeira metade do século XVIII. Os valores encontrados foram considerados elevados quando comparados a parâmetros ideais para desempenho mecânico. Situações semelhantes foram observadas em outros estudos sugerindo tanto a utilização de argilas calcárias na fabricação quanto possíveis alterações pós-produção. Diante disso, investigou-se a hipótese de contribuição externa de cálcio por meio da percolação de compostos provenientes das argamassas de assentamento à base de cal. As análises de FRX dessas argamassas indicaram teores superiores a 40% de Ca, evidenciando um potencial significativo de migração. A análise petrográfica por microscopia de luz polarizada confirmou a presença de material esbranquiçado preenchendo microfissuras na matriz cerâmica, indicando processos de infiltração. Para validar experimentalmente essa hipótese, amostras cerâmicas com baixo teor de cálcio foram submetidas à imersão em solução de hidróxido de cálcio. Após o ensaio, verificou-se aumento significativo no teor de Ca, além da deposição do elemento em microfissuras, observada por microscopia eletrônica de varredura (MEV) e análise EDS. Os resultados indicam que os elevados teores de cálcio nos azulejos históricos são decorrentes de uma combinação entre a composição original da matéria-prima e processos de percolação ao longo do tempo. Além disso, a presença de cálcio contribui para a fissuração e degradação das peças, sugerindo que os valores atuais são superiores aos originais de fabricação.

Palavras-chave: Azulejos históricos portugueses; Microscopia; Índice de cálcio, Argamassa.

Abstract: *The study analyzed the origin of the high calcium (Ca) contents identified in fragments of historical Portuguese tiles from a religious building in Pernambuco, dating to the first half of the 18th century. The values found were considered high when compared to ideal parameters for mechanical performance. Similar situations have been reported in other studies, suggesting both the use of calcareous clays in manufacturing and possible post-production alterations. In this context, the hypothesis of external calcium contribution through the percolation of compounds from lime-based setting mortars was investigated. X-ray fluorescence (XRF) analyses of these mortars indicated Ca contents exceeding 40%, highlighting a significant potential for migration. Petrographic analysis*

using polarized light microscopy confirmed the presence of whitish material filling microcracks in the ceramic matrix, indicating infiltration processes. To experimentally validate this hypothesis, ceramic samples with low calcium content were immersed in a calcium hydroxide solution. After the test, a significant increase in Ca content was observed, along with the deposition of the element in microcracks, as evidenced by scanning electron microscopy (SEM) and EDS analysis. The results indicate that the high calcium contents in historical tiles result from a combination of the original raw material composition and long-term percolation processes. Furthermore, the presence of calcium contributes to cracking and degradation of the pieces, suggesting that current values are higher than those at the time of manufacture

1. Introdução

Uma das diversas utilizações de materiais cerâmicos é na produção de azulejos para o revestimento de fachadas em edificações. No Brasil colonial os interiores de algumas capelas, igrejas e conventos, costumavam ser revestidos com azulejos importados de Portugal.

A documentação sobre a importação de azulejos no período colonial é escassa. Em função dessa circunstância uma das formas para se definir o período de importação é através dos padrões estéticos.

Nesse contexto, os azulejos importados existentes em 18 edificações religiosas em Pernambuco são classificados cronologicamente a partir dos padrões estéticos em três fases: A primeira, do final do século XVII ao início século XVIII, corresponde a azulejos com temas geométricos e policrômicos produzidos em oficinas, mais por artífices de formação prática do que artística (Santos, 1957) e (Simões, 1965). A segunda, da 1ª metade do século XVIII, a temática concentra-se em cenas religiosas com as cores azul e branco e foram produzidos por artífices organizados em corporações de ofícios (Pileggi, 1958). A terceira, que corresponde a 2ª metade e Século XVIII, foi um período em que, após o terremoto que abalou Lisboa em 1755, a produção tornou-se mais seriada, principalmente associada à Fábrica Real de Cerâmica do Rato, criada em 1767, em resposta a um crescimento da demanda, (Terol, 2021).

Foram coletadas 7 amostras de fragmentos azulejares do Convento e Igreja de Santo Antônio, em Igarassu da 1ª metade do século XVIII, Figura 1. A análise de fluorescência de raio X (FRX) do material chamou atenção o fato de que os fragmentos históricos apresentaram altos teores de cálcio (Ca). Os valores encontrados nas amostras analisadas variam de 24,53% até 29,36% conforme a Tabela 1.

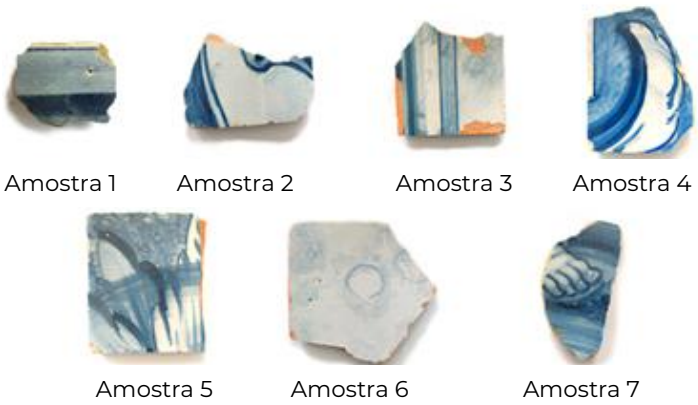

Figura 1 – Fragmentos azulejares da primeira metade do século XVIII, recolhidos do Convento e Igreja de Santo Antônio, em Igarassu.

Tabela 1 – Fluorescência por raio X das amostras da primeira metade do século XVIII, provenientes do Convento de Santo Antônio.

Amostra	Ca	Si	Al	Fe	K	Ti	Pb	Sr	Mn	Zr	Rb	Sn	Zn
Amostra 1	24,53%	45,20%	17,41%	8,81%	2,42%	1,07%	0,40%	0,07%	0,00%	0,04%	0,03%	0,00%	0,01%

Amostra 3	25,16%	42,87%	17,63%	8,11%	4,91%	0,99%	0,16%	0,09%	0,00%	0,04%	0,03%	0,00%	0,01%
Amostra 4	26,15%	42,72%	16,75%	8,23%	4,99%	0,99%	0,00%	0,07%	0,00%	0,04%	0,04%	0,03%	0,00%
Amostra 5	27,08%	43,16%	16,96%	7,97%	3,49%	0,95%	0,25%	0,06%	0,00%	0,04%	0,03%	0,00%	0,01%
Amostra 6	29,00%	42,14%	15,40%	7,63%	4,30%	0,95%	0,28%	0,21%	0,00%	0,04%	0,03%	0,03%	0,00%
Amostra 7	29,36%	40,74%	16,23%	8,38%	3,56%	0,99%	0,50%	0,09%	0,03%	0,04%	0,03%	0,04%	0,01%

Porém, estes altos valores em peças cerâmicas históricas não são um caso isolado. Em uma pesquisa realizada em 50 amostras de diversos tipos de materiais cerâmicos históricos italianos, fabricados entre os séculos XIII e o início do século XVII d.C., as peças estudadas apresentaram altos teores de cálcio, sendo constituídas de argilas calcárias com teores de cal entre 14% e 25% (CaO) (M.S. Tite, 2009). Outro caso foi a análise realizada em azulejos do monastério de San Lorenzo, na Espanha, provenientes do Escorial, e que também apresentou percentuais altos de cal, que variaram entre 22% e 25.5 % de CaO (Agua *et al.*, 2022).

Com base nos dados obtidos nas análises dos fragmentos de azulejos históricos de Pernambuco e, a partir desses dois estudo citados anteriormente, debruçou-se sobre quais as causas desse alto teor de cálcio nos materiais cerâmicos, uma vez que é conhecida sua interferência na modelagem de peças cerâmicas. Além do mais questionou-se que parte dos índices de cálcio dos biscoitos azulejares históricos poderiam ser provenientes das argamassas de assentamento.

Cabe advertir que o teor de cal pode ser proveniente da própria matéria prima utilizada na fabricação das peças cerâmicas. As composições de silício, cálcio e magnésio nas cerâmicas portuguesas estudadas indicaram a utilização de argilas ricas em carbonatos, ou mesmo a adição de materiais carbonáticos à pasta cerâmica. Tais materiais, durante o processo de queima, podem ser responsáveis pela formação de poros ou vazios na placa cerâmica, uma vez que durante a queima ocorre a liberação do CO_2 (Costa *et al*., 2013).

Porém a presença de produtos cálcicos também pode ser originada de mecanismos externos ao azulejo. É possível que certos minerais, como a calcita, podem se formar a partir do processo de carbonatação do hidróxido de cálcio existente nas argamassas de cal utilizadas no assentamento dos azulejos, que podem migrar para o biscoito cerâmico através dos poros existentes no material (Sanjad *et al*., 2004).

Também é possível que ao longo do tempo os ciclos contínuos de umedecimento pelas chuvas e pela umidade do solo, que é absorvida pelas alvenarias, e posterior secagem provoquem a dissolução e precipitação do carbonato de cálcio presente na argamassa, que se deposita nas microfissuras da estrutura interna dos materiais e atua na sua recristalização, produzindo um material rico em cal (Kanan, 2008).

As indústrias cerâmicas tendem a evitar o uso de carbonatos e resíduos de mármore, (calcita ou dolomita), como aditivo para a massa cerâmica, pois esse material pode apresentar grãos isolados de carbonato e que durante a queima se transformam em óxidos de cálcio e magnésio. Além do mais esses óxidos podem sofrer hidratação e expansão com a presença da umidade, provocando fissuração na cerâmica (Alexandre *et al*., 2004). Baixos teores de carbonatos na massa de conformação da cerâmica podem induzir a bons resultados mecânicos. Isso indica que baixos teores de calcita, ou de cal, implicam em maiores percentuais de módulos de rupturas formando peças azulejares mais resistentes (Darweesh, 2000) (Oliveira *et al*., 2001) (Goulart *et al*., 2000).

Assim, indagou-se que o teor de cálcio, identificado através da FRX, nos fragmentos históricos poderia não ser o original totalmente da produção das peças do século XVIII.

2. Questionamentos sobre o cálcio

Como as análises de FRX identificaram um alto teor de cálcio nos azulejos históricos surgiu o questionamento se esses os altos teores de cálcio seriam ou não provenientes da matéria prima utilizada na fabricação azulejos históricos, conforme também visto em outros estudos (Sanjad *et al*., 2004) e (Kanan, 2008).

Entretanto, ao considerar que os azulejos estudados foram assentados com argamassas a base da cal com espessuras que variam entre 0,50 e 1 cm em paredes com tijolos maciços, porosos e que absorvem muita umidade, (com características de elevada higroscopicidade), questionou-se se o cálcio encontrado nas amostras históricas era proveniente da percolação do contato entre a peça e o substrato onde ela se encontrava assentada. Sendo assim, foi realizada a análise da lâmina delgada, juntamente com a FRX da argamassa de assentamento.

Alguns dos fragmentos de azulejos possuía argamassa de assentamento encrustadas nas faces posteriores dos azulejos, essa argamassa foi analisada através de FRX e identificaram-se os percentuais do cálcio. E de fato, os teores identificados foram maiores de 40%, Tabela 2 e Figura 2 . Se considerarmos as paredes das igrejas com espessura que variam ente 0,5 e 1 metro de espessura e úmidas ao longo de mais de 200 anos é factível a existência de processos de percolação do substrato nos biscoitos históricos.

Tabela 2 – FRX das argamassas de assentamento do painel azulejar na qual se identificou altos teores de cálcio, conforme 0.

Ca	Si	Al	Fe	K	Ti	Pb	Sr	Zr	Rb	Ba
43,85%	35,08%	11,98%	5,54%	1,87%	0,73%	0,65%	0,25%	0,04%	0,02%	0,00%
67,38%	17,55%	4,08%	1,79%	3,31%	0,36%	4,99%	0,42%	0,05%	0,05%	0,00%
66,38%	20,16%	4,19%	1,86%	3,44%	0,35%	3,01%	0,46%	0,08%	0,07%	0,00%
53,21%	36,22%	4,88%	2,00%	1,86%	1,46%	0,00%	0,12%	0,03%	0,01%	0,19%

Figura 2 – Face posterior de biscoitos azulejares com fragmentos da argamassa de assentamento de origem histórica e das quais se obtiveram os índices de cálcio, através da FRX.

Uma vez constatado os altos teores de cal da argamassa de assentamento pesquisaram-se quais os efeitos na chacota. Para isso preparou-se uma seção delgada, para análise por microscopia por luz polarizada (MLP), e registrou-se um material argiloso de coloração esbranquiçada envolto pela matriz argilosa avermelhada. A porção esbranquiçada preenche as áreas de fissuras que se prolongam por toda a matriz. Isso é um indício que corrobora os altos teores de cálcio identificados nas análises por FRX como consequência da percolação de hidróxido de cálcio oriundo dos substratos de assentamento na chacota histórica 0.

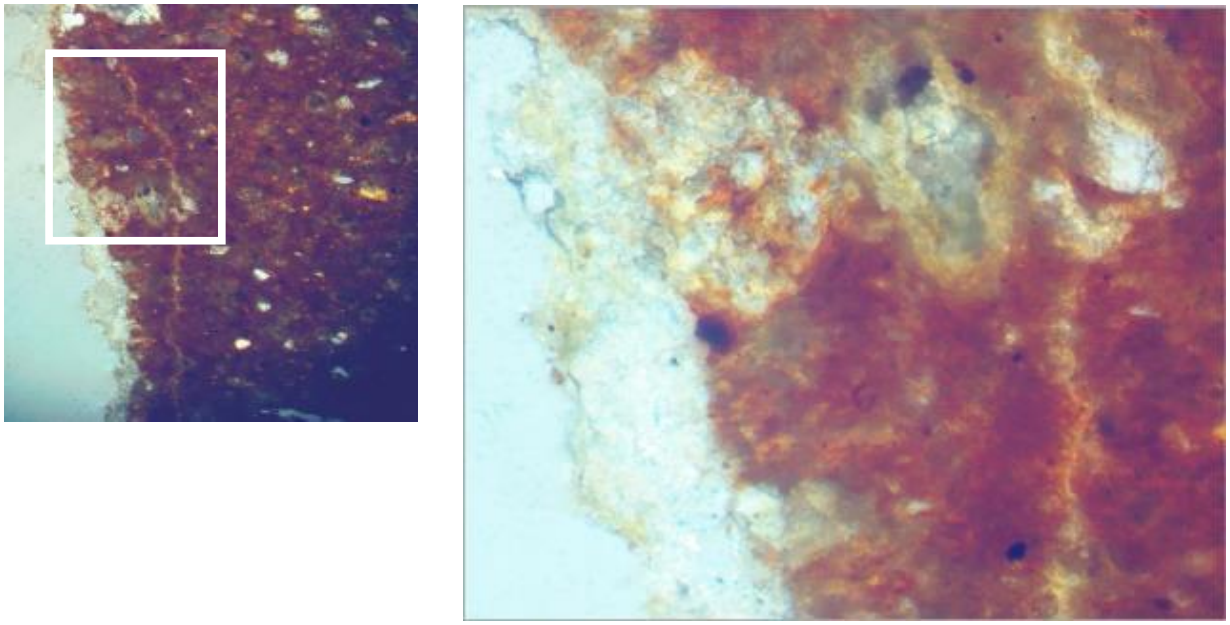

Figura 3 – Identificação do processo de percolação de cal no substrato de assentamento do biscoito do fragmento histórico através das microfissuras. A direita da imagem, no detalhe, a face posterior do biscoito azulejar e que estava em contato com a argamassa na qual ocorreu o processo percolação pelo cálcio da argamassa através de fissura.

Em relação aos teores de cálcio, a análise petrográfica mostrou A percolação através das microfissuras existentes nos fragmentos dos azulejos portugueses. Esta hipótese pode ser corroborada a partir da análise da lâmina delgada obtida na amostra histórica, 0.

A fim de comprovar o processo de percolação do óxido de cálcio da argamassa de assentamento na cerâmica, foram selecionadas amostras cerâmicas com baixo teor de cálcio. Essas amostras foram colocadas em uma solução de cal hidratada [$Ca(OH)_2$]. Após essa exposição selecionou-se uma amostra com maior evidência de percolação, através da observação em uma lupa binocular.

Da amostra selecionada, foram realizadas as FRX, antes e após a imersão, para confirmar o aumento para 9,77 do teor de Ca. Com essa comprovação da contaminação pela Ca foi então preparado um corpo de prova e levado a um microscópio eletrônico de varredura (MEV) onde foram produzidas imagens em escala de ampliação de 1000 vezes. A região selecionada para análise apresentava uma microfissura onde foi verificada a deposição de óxido de cálcio nas regiões de fissura 0 a 0.

Esse processo pode ser desencadeado devido a presença de umidade, sais solúveis e variações térmicas. A água, seja através da chuva, umidade ascendente ou condensação, pode atuar como um meio de transporte para íons dissolvidos. Os íons Ca^{2+} presentes em materiais adjacentes (como uma argamassa rica em cal) pode migrar para zonas de menor concentração como os azulejos. Ao longo

de décadas ou séculos essas exposições podem promover substituição iônica parcial dos íons Fe^{2+}/Fe^{3+} por Ca^{2+}, ou seja, a precipitação de compostos de cálcio nas áreas originalmente ricas em ferro. Nesse processo a composição original dos azulejos é lentamente alterada, e pode comprometer sua integridade estrutural bem como suas propriedades físicas e químicas.

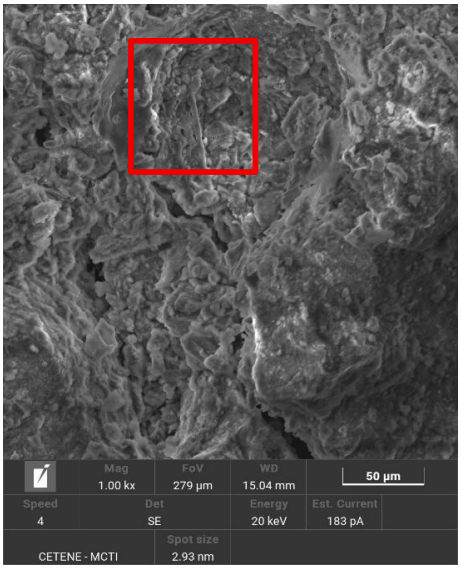

Figura 4 – Detalhe com ampliação x 1000 da região onde a fissura apresenta a deposição de partículas de Ca (partículas brancas) nas microfissuras presentes na amostra da chacota cerâmica produzida em laboratório e submersa em uma solução com 10% de hidróxido de cal (CaOH) durante dois anos a temperatura ambiente (30°). Em vermelho a área onde se realizou o mapeamento dos elementos químicos através de EDS.

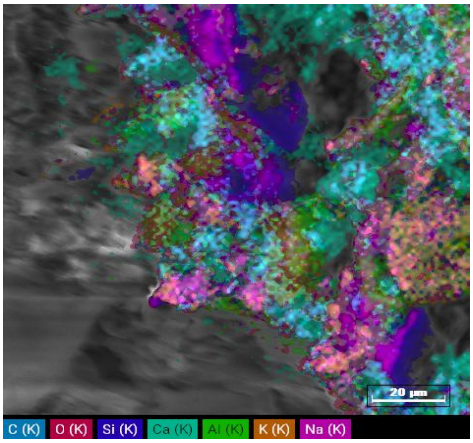

Figura 5 – Mapa de elementos químicos (x 3000) da amostra de chacota cerâmica produzida em laboratório e submersa em uma solução com 10% de hidróxido de cal (CaOH) durante dois anos a temperatura ambiente (30°). Foram detectados carbono (C) na área azul claro, sílica (Si) na área azul escura, oxigênio (O) na área rosa, alumínio (Al) na área verde escuro, cálcio (Ca) na área verde claro, potássio (K) na área marrom e sódio (Na) na área roxa. Para o estudo em questão identificou-se grande quantidade de Ca (0) sem a presença de Fe na região das fissuras.

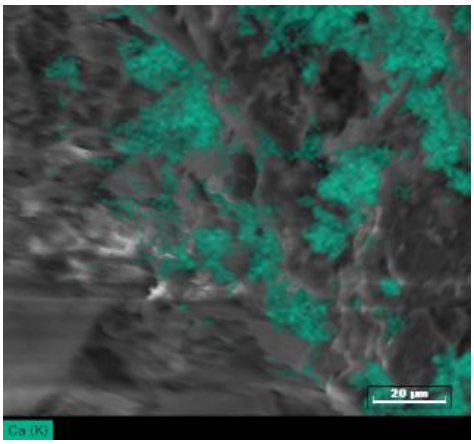

Figura 6 – Mapa de elementos químicos (x 3000) da amostra de chacota cerâmica produzida em laboratório e submersa em uma solução com 10% de hidróxido de cal (CaOH) durante dois anos a temperatura ambiente (30°). Em destaque (verde) da presença de cal nas regiões com microfissuras e poros. Não foi registrada a presença de Fe nessa região de microfissura.

Os dados desse experimento, em conjunto as FRX realizadas nos fragmentos históricos, indicam que os altos teores de cálcio das amostras históricas são provenientes de uma combinação entre a matéria prima, (argila rica em calcita), e a percolação da argamassa de assentamento a base de cal. Cabe destacar que a cal atua na fissuração dos biscoitos históricos, fundamentalmente aquela porção que percola e acelera a degradação dos azulejos. Isso indica que os teores de cálcio identificados atualmente nos azulejos históricos importados de Portugal para o Brasil são superiores aos de quando os biscoitos foram produzidos.

3. Conclusões

Os resultados obtidos permitem concluir que os elevados teores de cálcio (Ca) identificados em algumas amostras de azulejos históricos podem não ser condizentes com as proporções de matéria prima empregada originalmente nas suas manufaturas. Ao considerarmos que esses azulejos estão assentados em paredes com tijolos maciços, em um modelo construtivo com alta higroscopicidade, a análise petrográfica confirmou a presença de material esbranquiçado preenchendo microfissuras na matriz cerâmica, indicando a migração e deposição de cálcio ao longo do tempo.

Esse comportamento foi corroborado experimentalmente por meio da imersão de amostras cerâmicas em solução de hidróxido de cálcio, que resultou no aumento do teor de Ca e na sua deposição preferencial em regiões fissuradas, conforme observado em análises por MEV e EDS.

Dessa forma, conclui-se que os teores atuais de cálcio nos azulejos históricos são resultado de um processo combinado: a composição original da pasta cerâmica e a incorporação progressiva de cálcio ao longo dos séculos, favorecida por condições ambientais como umidade, presença de sais solúveis e variações térmicas. Esse processo implica alterações na composição química original das peças, com possível substituição iônica e recristalização em zonas fragilizadas.

Além disso, a presença e migração de cálcio desempenham papel relevante na degradação dos azulejos, contribuindo para a formação e propagação de fissuras, o que compromete sua integridade estrutural e durabilidade. Assim, os resultados indicam que os valores atualmente medidos podem ser superiores aos originais de fabricação, aspecto fundamental a ser considerado em estudos de caracterização, conservação e restauro de revestimentos azulejares históricos.

Os resultados obtidos neste estudo embora pertencente a uma pequena quantidade de amostras pode servir de ponto de partida para a análise em outros conjuntos azulejares maiores, especialmente aqueles assentados com argamassas à base de cal e submetidos, ao longo de séculos, a condições de elevada umidade e intensa interação com substratos porosos. As constatações desse estudo podem ser relevantes para trabalhos na área de conservação, uma vez que interpretações composicionais baseadas apenas nas análises químicas podem superestimar o teor original de Ca das peças e levar a conclusões equivocadas sobre a tecnologia de fabricação, procedência ou qualidade das argilas utilizadas. Dessa forma, o estudo reforça a necessidade de considerar as interações entre os azulejos, a argamassa e ambiente nas estratégias de preservação, sobretudo em edificações históricas sujeitas à umidade ascendente, infiltrações e ciclos de dissolução e precipitação de sais.

Agradecimentos

Gostaríamos de expressar nossos agradecimentos ao INAPAS (Instituto Nacional de Arqueologia, Paleontologia e Ambiente do Semiárido) pelo financiamento deste projeto, sem o qual esta pesquisa não teria sido possível. Agradecemos também a UFPE (Universidade Federal de Pernambuco) pela disponibilidade da utilização dos laboratórios e equipamentos utilizados nesta pesquisa, cuja contribuição foi essencial para o desenvolvimento e a conclusão deste estudo.

Resumo: O estudo avaliou a substituição parcial de cimento por pó reciclado (PRH) em pastas cimentícias, focando na resistência à compressão aos 7 e 56 dias de cura. Foram produzidas 13 misturas, sendo uma de referência e 12 com substituição parcial do cimento por pó reciclado híbrido (PRH), nos teores de 10%, 20% e 30%, e com diferentes níveis de finura obtidos por moagem. O PRH foi caracterizado quanto à composição química, granulometria, morfologia e mineralogia, evidenciando predominância de SiO_2, além de partículas irregulares e angulosas com ampla faixa granulométrica. Ensaios de resistência à compressão foram realizados aos 7 e 56 dias. Os resultados mostraram que a finura do PRH não influenciou significativamente a resistência, mas o aumento do teor de substituição reduziu a resistência mecânica. Substituições de 10%, 20% e 30% apresentaram quedas progressivas na resistência, sendo mais acentuadas aos 56 dias. Substituições acima de 30% foram desfavoráveis, comprometendo a hidratação. Embora baixas proporções possam melhorar a microestrutura, a eficácia do PRH como substituto se limita a teores reduzidos.

Palavras-chave: Pastas cimentícias, Pó reciclado, Reutilização de resíduos de construção.

Abstract: *The study evaluated the partial replacement of cement with recycled powder (HRP) in cementitious pastes, focusing on compressive strength at 7 and 56 days of curing. A total of 13 mixtures were produced, including one reference mixture and 12 with partial replacement of cement by hybrid recycled powder (HRP) at levels of 10%, 20%, and 30%, with different fineness levels obtained through grinding. The HRP was characterized in terms of chemical composition, particle size distribution, morphology, and mineralogy, showing a predominance of SiO_2, as well as irregular and angular particles with a wide granulometric range. Compressive strength tests were carried out at 7 and 56 days. The results showed that the fineness of HRP did not significantly influence strength; however, increasing the replacement level reduced mechanical strength. Substitutions of 10%, 20%, and 30% resulted in progressive decreases in strength, more pronounced at 56 days. Replacement levels above 30% were unfavorable, impairing hydration. Although low replacement levels may improve the microstructure, the effectiveness of HRP as a cement substitute is limited to reduced proportions.*

Keywords: *Cementitious pastes, Recycled powder, Reuse of construction waste.*

.1. Introdução

A reciclagem de resíduos da construção e demolição (RCD) pode reduzir a quantidade de resíduos destinados a aterros sanitários, diminuindo os impactos ambientais causados e promovendo uma gestão mais sustentável dos recursos naturais. Segundo a Associação Brasileira de Empresas de Limpeza Pública e Resíduos Especiais (ABRELPE), foram geradas mais de 81 milhões de toneladas de resíduos sólidos no Brasil em 2024. A Secretaria Nacional de Saneamento Ambiental estima que os RCD correspondem a 51% a 70% dos resíduos sólidos urbanos gerados no país.

A disposição inadequada desses resíduos causa problemas socioambientais, como ocupação irregular de áreas urbanas, esgotamento da capacidade dos aterros sanitários, assoreamento de córregos e rios, obstrução das redes de drenagem, proliferação de vetores de doenças e degradação das paisagens rurais e urbanas (Oliveira, 2007).

Um levantamento realizado em cidades brasileiras entre 2010 e 2019 indicou que a geração de RCD aumentou 25%, passando de 33,4 milhões de toneladas/ano em 2010 para 44,5 milhões de toneladas/ano em 2019. A produção per capita aumentou de 174,3 kg/ano em 2010 para 213,5 kg/ano em 2019 (Hendges, 2021).

A produção de agregados reciclados é uma boa alternativa para a destinação dos RCD. Contudo, esse processo gera uma quantidade considerável de partículas finas, que podem apresentar até 35% do volume total de agregados produzidos. Segundo Heinz e Schubert (2007), o tamanho das partículas geradas varia da escala submicrométrica até a milimétrica.

Essas partículas finas geralmente apresentam uma distribuição granulométrica contínua, porém o tamanho médio das partículas varia consideravelmente de acordo com a origem do resíduo, conforme indicado em diversos estudos. Por exemplo, Zhu et al. (2016) estudaram resíduos de tijolos cerâmicos e cimento e encontraram um tamanho médio de partícula de 31,40 μm, enquanto Topic et al. (2017) e Sun et al. (2017) analisaram resíduos de concreto e determinaram tamanhos médios de 12,00 μm e 14,38 μm, respectivamente. Em geral, essas partículas apresentam formato irregular e bordas angulosas (Liu et al., 2014; Zhu et al., 2016).

Com base no tamanho e na composição granulométrica desse material, uma possível aplicação é como adição do tipo fíler. Materiais fíler podem reduzir a porosidade do concreto, minimizando o consumo de pasta de cimento (De Larrard, 2010). Esse efeito resulta do empacotamento das partículas, no qual vazios maiores no concreto podem ser preenchidos pela seleção adequada da proporção e do tamanho das partículas de resíduo (Hunger, 2010), deixando um espaço mínimo para a água, o que é conhecido como efeito microfíler.

Os fíleres são partículas inertes, ou seja, não interagem quimicamente com os produtos de hidratação, embora formem núcleos que favorecem a hidratação do silicato tricálcico (C_3S) e do silicato dicálcico (C_2S) (Ye et al., 2007).

Os materiais fíler comumente utilizados para substituição parcial do cimento são predominantemente de origem calcária. Diversos estudos têm se concentrado na influência de fíleres naturais na hidratação do cimento. Wolf (2010) avaliou o efeito do calcário calcítico no cimento branco. Jordani (2020) analisou a hidratação do cimento Portland com elevados teores de fíler dolomítico com diferentes finuras. No entanto, ainda existem lacunas quanto ao uso de fíleres provenientes de materiais alternativos, como os finos gerados durante a reciclagem de RCD.

Diante da necessidade de melhor compreender o efeito dos finos de RCD em pastas cimentícias e na hidratação do cimento, este estudo teve como objetivo analisar a influência desse material, em diferentes proporções e valores de finura, nas reações de hidratação do cimento.

2. Materiais e métodos

Para os experimentos, foram produzidas 13 combinações: uma pasta de cimento de referência e 12 pastas com substituição do cimento por pó reciclado híbrido (PRH), em volume, nos teores de 10%, 20% e 30%, e com diferentes valores de finura. A nomenclatura utilizada foi M1H10, em que 1H se refere ao tempo de moagem e 10 corresponde ao percentual de substituição empregado. As proporções das pastas produzidas estão detalhadas na Tabela 1.

Tabela 1 – Proporções das pastas produzidas.

Combinações	Cimento (%)	PRH (%)	Tempo de moagem	D50 do PRH
Referência	100	0	–	–
M1H10	90	10	1 h	18.39
M1H20	80	20		
M1H30	70	30		
M2H10	90	10	2 h	15.70
M2H20	80	20		
M2H30	70	30		
M4H10	90	10	4 h	15.27
M4H20	80	20		
M4H30	70	30		
M8H10	90	10	8 h	10.16
M8H20	80	20		
M8H30	70	30		

Para todas as análises realizadas, amostras foram moldadas em corpos de prova cilíndricos de 5 × 10 cm, produzidos com pastas de cimento e de cimento + HRP. Em seguida, as amostras foram preparadas de acordo com cada ensaio.

2.1 Caracterização dos materiais

O cimento utilizado foi o CPV-ARI – alta resistência inicial (equivalente ao cimento Tipo III especificado pela norma ASTM C150/C150M). Esse cimento foi empregado devido à menor quantidade de adições normalmente presentes nos cimentos comerciais, permitindo melhor compreensão da influência dos resíduos da construção e demolição (RCD) nas pastas cimentícias.

O pó reciclado híbrido (PRH) foi obtido como subproduto do processo de produção de agregados reciclados em uma usina de reciclagem. Durante a britagem dos RCD, as partículas finas geradas são separadas por aspiração no britador. O pó reciclado coletado na usina foi peneirado em peneira com abertura de 2,4 mm, a fim de remover partículas maiores e impurezas, como folhas e fragmentos plásticos. Em seguida, realizou-se a moagem em moinho de bolas rotativo por períodos de 1 h, 2 h, 4 h e 8 h. A carga de esferas de alumina, em três diferentes diâmetros, foi de 7900 g. A rotação do moinho foi de 50 rpm, e o tempo de moagem variou de 1 a 8 h. Em cada moagem, foram utilizados 1,5 kg de PRH.

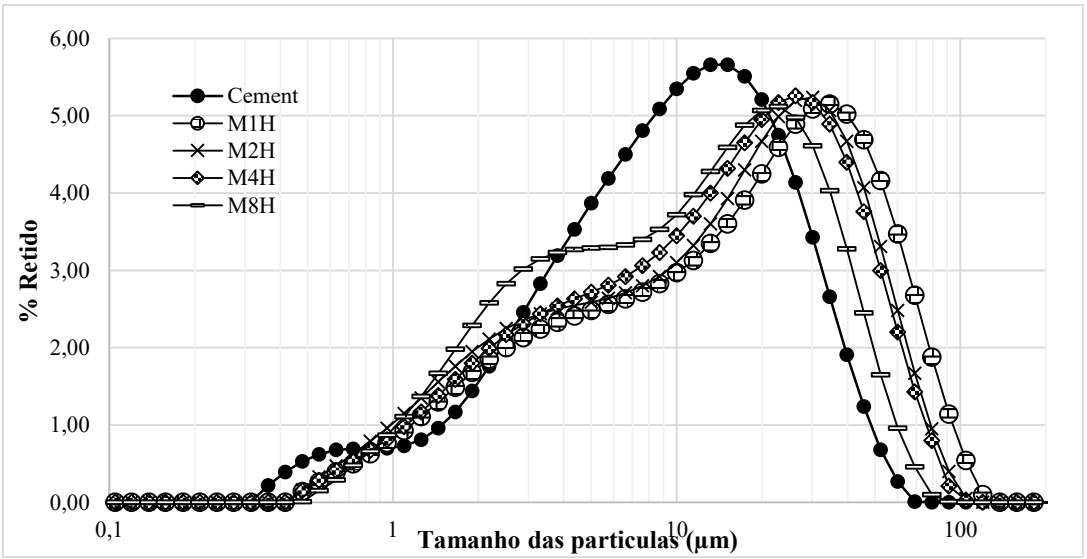
As composições químicas do cimento, fornecidas pelo fabricante, e do PRH estão apresentadas na Tabela 2.

Tabela 2 – Caracterização química do cimento e do PRH.

Óxidos	Cimento	PRH
CaO	59.97	3.28
SiO_2	18.66	80.86
Na_2O	0.17	0.92
Al_2O_3	4.34	5.95
MgO	5.73	0.50
K_2O	0.88	1.05
Fe_2O_3	2.37	1.80
SO_3	4.28	0.28
TiO_2	–	0.30
Insolúvel resíduo	0.79	–
Perda ao fogo (LOI)	3.59	5.06

Com base na caracterização química, os componentes do PRH são semelhantes aos encontrados em materiais de construção usuais, como concreto, argamassa e tijolos, com exceção do TiO_2, comumente utilizado como pigmento branco presente em revestimentos, tintas e azulejos. Além disso, SiO_2, Al_2O_3 e CaO representam cerca de 90% da composição do PRH, sendo o SiO_2 provavelmente proveniente da areia presente no concreto e nas argamassas.

As distribuições granulométricas das partículas de cimento e do PRH são apresentadas na Figura 1. O diâmetro característico das partículas de cimento (D_{50}) foi de 10,5 µm, e a área superficial específica foi de 1250 m²/kg.



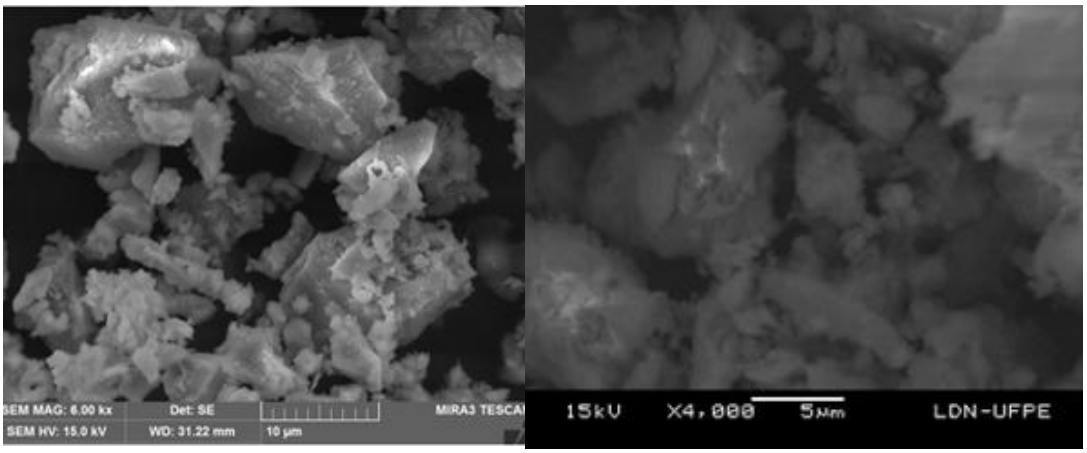


Figura 1 – Distribuição granulométrica das partículas de cimento.

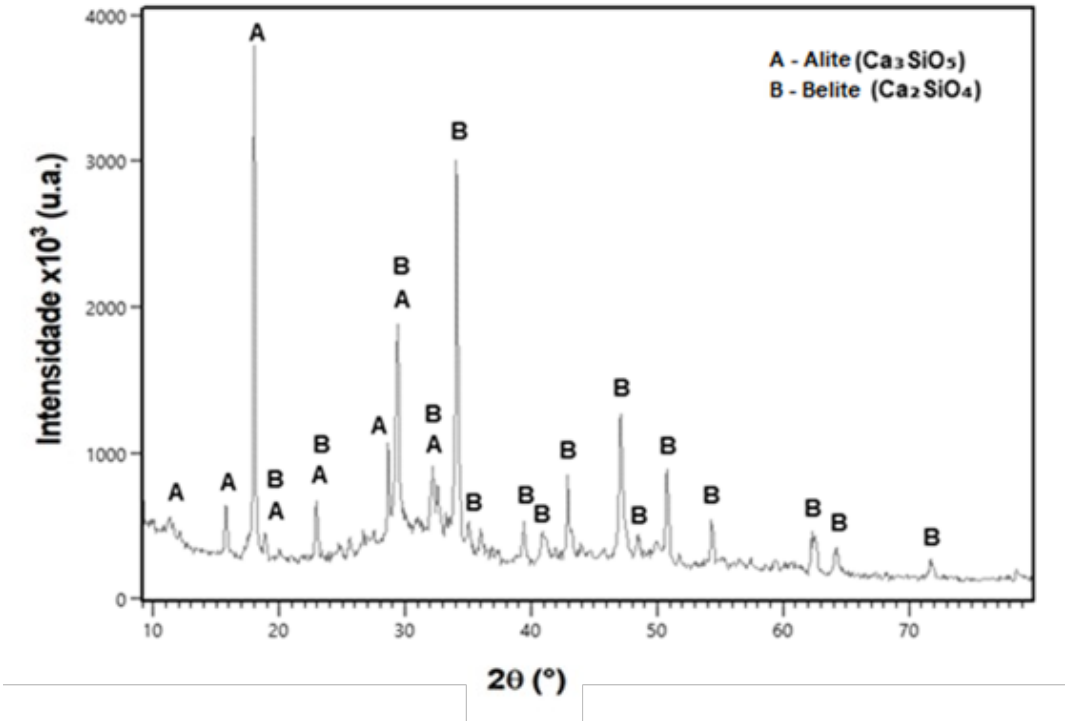
Conforme observado, a distribuição granulométrica do PRH é bem graduada e contínua. O PRH moído por 1 h apresenta partículas de maiores dimensões quando comparado ao material moído por

8 h. Além disso, as dimensões das partículas de PRH variam entre 0,5 e 100 μm, concentrando-se majoritariamente na faixa entre 5 e 50 μm.

As Figuras 2(a) e 2(b) apresentam as micrografias obtidas por microscopia eletrônica de varredura (MEV) do cimento e do PRH, respectivamente.



(a) (b)

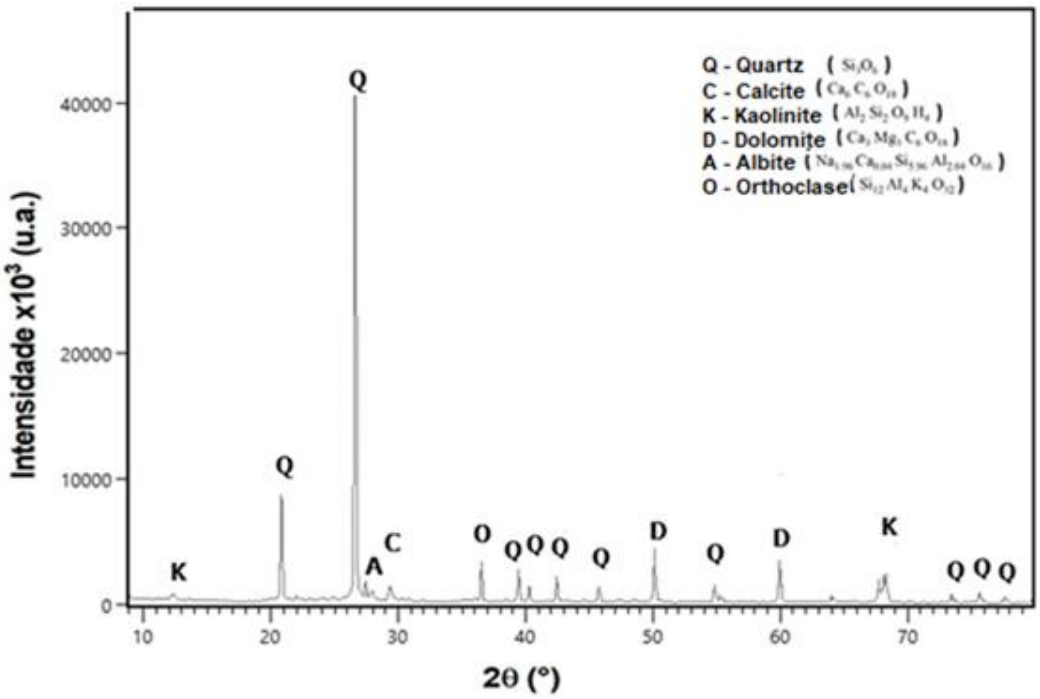


Figura 2 – MEV imagens do (a) cimento (× 6000) e (b) PRH partículas (× 4000).

A imagem de MEV do cimento indica a predominância de partículas angulares e de tamanhos variados. Quanto ao PRH, a imagem mostra algumas partículas de quartzo recobertas por resíduos de materiais cimentícios que aderiram à sua superfície. Conforme observado, as partículas de PRH apresentam bordas afiadas e irregulares, que formam reentrâncias em formato de V. A forma irregular das partículas também foi observada em outros estudos, como o de Liu *et al*. (2014).

Figuras 3(a) e (b) apresentam os difratogramas de DRX do cimento e das partículas de PRH, respectivamente.

(a)

(b)

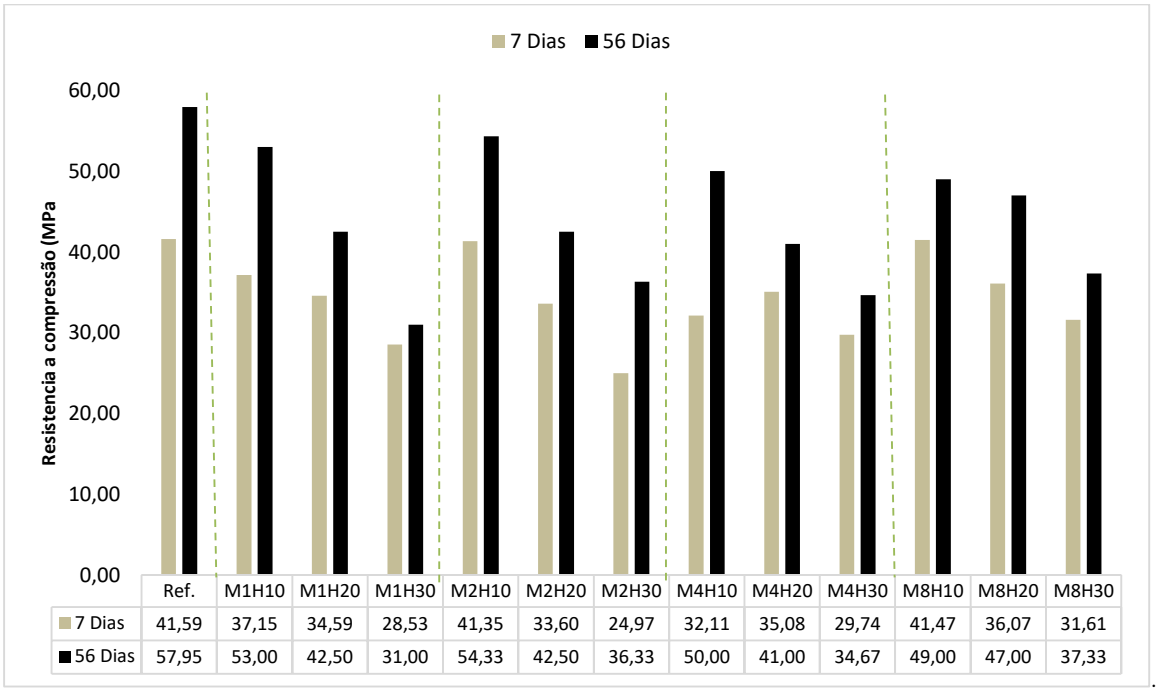

Figura 3 – DRX difratogramas de (a) cimento e (b) partículas de PRH.

O difratograma do cimento apresenta picos característicos de alita e belita, com intensidades variadas. O difratograma do HRP exibe diversos picos, uma vez que se trata de um material de composição bastante heterogênea. A composição química do HRP indica que ele é majoritariamente composto por SiO_2, o que também foi confirmado pelos picos de quartzo, possivelmente provenientes da areia presente no concreto e na argamassa que deram origem ao HRP.

Os demais picos identificados foram determinados com base nas fichas do sistema JCPDS, registradas no International Center for Diffraction Data, sendo eles: quartzo (Si_3O_6), calcita ($Ca_6C_6O_{18}$), caulinita ($Al_2Si_2O_9H_4$), dolomita ($Ca_3Mg_3C_6O_{18}$), albita ($Na_{1.96}Ca_{0.04}Si_{5.96}Al_{2.04}O_{16}$) e ortoclásio ($Si_{12}Al_4K_4O_{32}$), minerais presentes na cal (calcita), no cimento (calcita, caulinita, dolomita e albita), nos agregados e em outros materiais utilizados na construção civil. Além disso, não foi observado halo amorfo.

3. Resultados

Os resultados de resistência à compressão das pastas aos 7 e 56 dias são apresentados na Figura 4.

	Ref.	M1H10	M1H20	M1H30	M2H10	M2H20	M2H30	M4H10	M4H20	M4H30	M8H10	M8H20	M8H30
7 Dias	41,59	37,15	34,59	28,53	41,35	33,60	24,97	32,11	35,08	29,74	41,47	36,07	31,61
56 Dias	57,95	53,00	42,50	31,00	54,33	42,50	36,33	50,00	41,00	34,67	49,00	47,00	37,33

Figura 4 – Resistência à compressão aos 7 e 56 dias das pastas produzidas

Conforme observado na Figura 4, não foi verificada uma tendência clara em relação à redução do tamanho das partículas do PRH e os resultados de resistência à compressão. Em contrapartida, a redução do teor de cimento exerceu influência significativa nos resultados obtidos.

As pastas aos 7 dias, com 10% de substituição do cimento por PRH, apresentaram valores de resistência à compressão variando entre 32,11 e 41,47 MPa, com reduções de 10,7%, 0,58%, 22,8% e 0,29% para M1H10, M2H10, M4H10 e M8H10, respectivamente.

Para a substituição de 20%, os valores variaram entre 24,97 e 35,08 MPa, com reduções de 16,8%, 19,2%, 15,6% e 13,3%. Para 30% de substituição, os valores ficaram entre 24,97 e 31,61 MPa, com reduções de 31,4%, 40,0%, 28,5% e 24,0%.

Aos 56 dias, as pastas com 10% de substituição apresentaram resistências entre 49,00 e 54,33 MPa, com reduções entre 6,2% e 15,4%. Para 20% de substituição, as reduções variaram entre 18,9% e 29,2%, enquanto para 30% variaram entre 35,6% e 46,5%.

Os resultados indicam que a substituição de 30% do cimento por PRH não é vantajosa, resultando em perda significativa da resistência à compressão. A substituição do ligante por um material inerte em baixos teores pode trazer benefícios, como refinamento da porosidade, modificação microestrutural da zona de transição interfacial (redução da espessura da ZTI e interferência no crescimento cristalino), redução da exsudação e aumento da densidade da mistura devido ao preenchimento dos vazios por partículas finas (Fonseca, 2010).

Entretanto, em teores elevados, a redução significativa do ligante afeta negativamente a formação de produtos de hidratação. Na versão anterior da norma brasileira para cimentos comerciais, o limite de fíler calcário no cimento CP II-F era de 10%; a norma atual NBR 16697 (2018) elevou esse limite para 25%. No caso do PRH analisado, a substituição de 30% não se mostrou viável.

Resultado semelhante também foi obtido por Topic *et al.* (2017). Os autores substituíram o cimento por partículas finas provenientes da reciclagem de concreto em proporções de 10%, 20%, 30%, 40% e 50% e verificaram uma redução considerável da resistência à compressão a partir de 30% de substituição, atingindo uma redução de 38% em comparação com a amostra de referência. Além disso, Zhu et al. (2016) também observaram uma diminuição das resistências à compressão e à flexão com o aumento dos teores de substituição. Outro aspecto importante é que, devido ao cimento utilizado, CP V, apresentar elevada resistência inicial, o ganho de resistência entre 7 e 56 dias não foi significativo, permanecendo abaixo de 25%.

4. Conclusão

A resistência à compressão das pastas foi analisada para diferentes teores de substituição do cimento por PRH. Os resultados indicaram que, embora o tamanho de partícula do PRH não tenha influenciado de maneira significativa a resistência das pastas, o percentual de substituição exerceu influência relevante. A partir de 30% de substituição, observou-se uma queda acentuada da resistência à compressão, indicando que elevados teores de substituição podem não ser viáveis, uma vez que afetam negativamente essa propriedade.

Os resultados sugerem que o uso de PRH em substituição ao cimento, em baixos percentuais, pode ser benéfico, contribuindo para a redução da fissuração e para a densificação da matriz cimentícia. Entretanto, teores elevados (a partir de 30%) não são recomendados, pois podem resultar em reduções significativas da resistência à compressão das pastas. Dessa forma, o percentual de PRH a ser utilizado nas misturas deve ser cuidadosamente avaliado, a fim de garantir um desempenho adequado das pastas no estado endurecido.

Agradecimentos

Gostaríamos de expressar nossos agradecimentos ao INAPAS (Instituto Nacional de Arqueologia, Paleontologia e Ambiente do Semiárido) pelo financiamento deste projeto, sem o qual esta pesquisa não teria sido possível. Agradecemos também a UFPE (Universidade Federal de Pernambuco) pela disponibilidade da utilização dos laboratórios e equipamentos utilizados nesta pesquisa, cuja contribuição foi essencial para o desenvolvimento e a conclusão deste estudo.

Abstract: Understanding the fresh-state behavior of cement-based materials is essential for ensuring performance, durability, and efficient resource use in concrete production. As traditional fresh-state tests often provide indirect or delayed information, non-intrusive electrical impedance sensing emerges as a promising alternative for fast-response, quantitative, and non-destructive characterization. This study aims to evaluate how the electrical properties of fresh concrete are influenced by water content, cement content, and water-to-cement ratio (w/c), using non-intrusive impedance measurements to support mixture characterization and composition control. The w/c ratio was intentionally varied from 0.39 to 0.73. The aggregates were characterized and their granulometry determined; the specific mass of the cement was determined and a slump test was performed. For mechanical characterization, 30 compositions were tested to determine their compressive strength at 7 and 28 days. The electrical data were analyzed to assess influence and correlations between impedance behavior and mixture parameters. The results demonstrate the feasibility of using non-intrusive microwave impedance measurements to characterize the dielectric behavior of fresh concrete. Using the custom 2.4 GHz patch antenna, impedance magnitude and phase spectra were acquired between 1 to 3 GHz, revealing that each mixture exhibited a distinct spectral signature closely associated with variations in water content, cement content and w/c ratio. Materials with low moisture content exhibited higher impedance magnitudes and stable phase responses, whereas mortars and fresh concretes showed significantly lower impedance values, ranging from 7.2 to 40.7 ohms along with noticeable phase-shift variations due to the contribution of free water, dissolved ions, and pore connectivity. These differences confirm that spectral responses are governed by water and cement content and, therefore, by w/c ratio, enabling each mixture to be distinguished by a unique dielectric signature. The patch antenna proved its potential for non-intrusive, composition-dependent influence of fresh concrete.

Keywords: Water-to-Cement Ratio (w/c), Fresh Concrete Composition, Microwave Electrical Impedance, Non-intrusive Measurement, Concrete Quality Control.

1. Introduction

Concrete is the most widely used material in civil construction due to its high mechanical strength, durability, and adaptability to different structural applications (Fortulan *et al.*, 2023). However, the final performance of concrete structures is strongly influenced by the properties of concrete in the fresh state. In particular, the water-to-cement ratio (w/c) directly affects compressive strength, porosity, permeability, durability, and service life (Park *et al.*, 2022). Small variations in this parameter can lead to significant changes in both mechanical behavior and long-term performance, especially in high-performance concrete.

Traditionally, the control of concrete properties relies on standardized laboratory tests, such as the slump test (ABNT NBR 16889) and the axial compressive strength test (ABNT NBR 5739). Although widely accepted, these methods present important limitations. The slump test provides only a qualitative indication of workability and is strongly influenced by admixtures, aggregate grading, and mixture composition. Compressive strength testing, in turn, is destructive, time-consuming, and does not allow immediate corrective actions during production or placement (Fortulan *et al.*, 2023). These limitations are particularly critical when rapid decision-making and real-time quality control are required.

In addition to operational constraints, destructive testing methods present intrinsic uncertainties. Compressive strength exhibits significant spatial variability due to concrete heterogeneity, curing conditions, moisture gradients, and compositional variations, making it difficult to obtain representative results from a limited number of specimens or cores (Breysse *et al.*, 2019; Malhotra and Carino, 2003). As a result, conventional approaches may fail to accurately represent in-situ conditions, especially in large or complex structural elements.

In this context, non-destructive testing (NDT) techniques, such as the Schmidt rebound hammer, ultrasonic pulse velocity (UPV), and combined methods, have been extensively investigated for strength estimation both in laboratory conditions and in situ. However, their reliability when used independently remains limited, as results are strongly influenced by surface conditions, degree of saturation, carbonation, age, and environmental exposure (Breysse *et al.*, 2019; Malhotra and Carino, 2003). Consequently, international recommendations, such as RILEM TC 249-ISC, emphasize the need for statistical analysis, local calibration with destructive tests, and appropriate sampling strategies.

Beyond mechanical wave-based methods, the electrical, electromagnetic, and dielectric properties of concrete are highly sensitive to composition, moisture content, pore structure, and hydration degree. Early studies by Gjørv *et al.* (1977) showed that electrical resistivity decreases with increasing water-to-cement ratio, particularly at intermediate saturation levels, highlighting the influence of pore solution and free water. These findings support the use of electrical and electromagnetic parameters as indirect indicators of concrete quality.

Recent studies have expanded this approach by investigating dielectric properties over a wide frequency range, showing strong correlations between dielectric permittivity, water content, pore volume, and compressive strength (Dinh *et al.*, 2021). Measurements in radiofrequency and microwave ranges are particularly sensitive to free and bound water, which dominates the electromagnetic response of cement-based materials. Since water has significantly higher permittivity than solid phases, changes in moisture state and microstructure during hydration directly affect dielectric parameters.

Experimental evidence also indicates that dielectric properties can be used not only to monitor hydration and moisture evolution but also to predict mechanical performance. Studies on early-age concrete show that complex permittivity enables accurate strength prediction models, offering an alternative to traditional curing-time-dependent tests (Gao *et al.*, 2021). Similarly, correlations between dielectric behavior and compressive strength have been reported for different aggregate sizes and mixture proportions (Zhong *et al.*, 2024).

Furthermore, low-cost electrical sensors originally developed for soil moisture monitoring have been successfully adapted to fresh concrete, enabling continuous and non-destructive assessment of water availability during early hydration. These techniques offer advantages in simplicity, speed, and field applicability, making them suitable for real-time quality control and process optimization.

Overall, the demand for improved production efficiency, reduced cement consumption, and enhanced reliability in technological control has driven the development of advanced non-destructive and non-intrusive techniques. The integration of electrical, dielectric, and mechanical methods, combined with proper calibration and data interpretation, represents a promising approach to overcome the limitations of conventional tests and improve the control of concrete properties from the fresh to the hardened state.

2. Theoretical Background

2.1 Basic concepts of electrical impedance and dielectric properties of cementitious materials

Electrical impedance is a complex quantity that describes the overall opposition that a material or system offers to the flow of an alternating electric current. It can be expressed as:

$$Z(\omega)=R(\omega)+jX(\omega), \text{ with } \omega = 2\pi f \quad (1)$$

where R is the resistance (real component, associated with current conduction) and X is the reactance (imaginary component, related to energy storage and phase lag in the electric field). The angular frequency ω defines the excitation regime (Barsoukov and Macdonald, 2005). As shown in Equation 1, impedance is represented as a complex quantity composed of resistive and reactive contributions.

Analyzing impedance as a function of frequency, known as electrical impedance spectroscopy (EIS), makes it possible to distinguish different physical transport and polarization mechanisms occurring within a material. At low frequencies, ionic conduction and interfacial polarization (Maxwell–Wagner) effects dominate. At higher frequencies, the response is increasingly influenced by polarization mechanisms, particularly the dipolar contribution associated with water, in addition to electronic and atomic contributions (Dinh *et al.*, 2021).

The shape and magnitude of these responses depend on the internal structure, composition, and water content of the material, making impedance a sensitive tool for characterizing complex media such as fresh concrete (Hu *et al.*, 2019). At radiofrequency and microwave frequencies, the analysis is commonly expressed in terms of dielectric properties and scattering parameters.

In cementitious materials, alternating current follows heterogeneous paths through solid phases (hydrated cement and aggregates), pores filled with an aqueous solution, and interfaces between these phases. This heterogeneity gives concrete a multiphase electrical response. Electrical resistance is linked to the connectivity and conductivity of the pore solution, while the dielectric response is strongly sensitive to water content and to microstructural evolution during hydration (Gallardo and Provis, 2021; Dinh *et al.*, 2021).

Dielectric behavior can be described by the complex permittivity, which incorporates energy storage and losses:

$$\varepsilon^*(\omega) = \varepsilon'(\omega) - j\varepsilon''(\omega) \quad (2)$$

where ε' is the real part (ability to store energy in the electric field) and ε'' is the imaginary part (dielectric losses, including contributions from relaxation and conduction). A common way to express the conductive contribution is to incorporate it into ε'' via $\sigma/(\omega\varepsilon 0)$ (Nelson, 1991). According to Equation 2, the dielectric response can be interpreted in terms of energy storage and loss mechanisms.

In RF/microwave techniques without direct electrical contact with the sample, electrode–material interface effects observed in contact EIS are avoided. Nevertheless, the conductivity of the pore solution contributes to ε'' (losses), and the dielectric response is strongly influenced by the water present in the pores (Nelson, 1991; Hu *et al.*, 2019; Dinh *et al.*, 2021).

Microwave dielectric characterization studies show that the dielectric properties of concrete vary with moisture content and curing or hydration time, particularly due to the contribution of water to the effective permittivity (Dinh *et al.*, 2021). In parallel, contact electrical measurements indicate that electrical conductivity (or resistivity) evolves with hydration and tends to reflect the loss of connectivity of the liquid phase (depercolation) and changes in ionic strength over time (Gallardo and Provis, 2021).

Therefore, measuring impedance and/or complex permittivity over a frequency range can provide quantitative information about the physicochemical state of the material, including water content and microstructural evolution (Dinh *et al.*, 2021; Hu *et al.*, 2019).

2.2 Comparison between intrusive and non-intrusive methods: limitations due to ionic conduction, electrode polarization, and sample disturbance

Electrical measurements in cementitious materials are generally classified as intrusive or non-intrusive, depending on how the sensor interacts with the material under analysis.

In intrusive methods, metallic electrodes are in direct contact with the sample, establishing an electrode–material interface through which the alternating current flows. In non-intrusive methods, coupling occurs without direct electrical contact, for example via capacitive or inductive coupling, or via RF/microwave techniques based on transmission lines, resonators, or antennas (Hu *et al.*, 2019; Islam *et al.*, 2024).

Fresh concrete contains a conductive liquid phase (pore solution), whose ionic composition results from the dissolution of soluble cement species and evolves with hydration (Gallardo and Provis, 2021). When an alternating electric field is applied between two electrodes in contact with this matrix, charged species can accumulate at the interfaces, forming charge layers (electric double layer). This process, known as electrode polarization, introduces an additional (typically capacitive) component and can distort the measured response at low frequencies (Barsoukov and Macdonald, 2005).

As a first approximation, the total measured impedance (Z_{med}) can be interpreted as the contribution of the material (Z_{med}) in series with an interfacial contribution (Z_{int}):

$$Z_{med} \approx Z_{mat} + Z_{int} \tag{3}$$

where Z_{int} depends on the surface state of the electrodes, the effective contact geometry and area, and local interface conditions, which can compromise reproducibility and comparability between samples (Hu *et al.*, 2019; Park *et al.*, 2022). In this simplified interpretation, Equation 3 highlights that the measured response includes both material and interfacial contributions. In addition, variations in positioning and in contact or immersion conditions between successive measurements can introduce systematic assembly errors and result dispersion (Park *et al.*, 2022; Hu *et al.*, 2019).

Another relevant factor is the physical disturbance of the sample. In fresh concrete, inserting probes may locally rearrange paste and aggregates and alter the local electric field, reducing the representativeness of the measured volume. These effects tend to be more critical as material heterogeneity increases and as the sensing region becomes more localized.

In non-intrusive RF/microwave approaches, coupling can occur through planar structures (e.g., microstrip) or resonant structures (e.g., patch), in which fringing or evanescent fields interact with the material. The response is often analyzed through variations in parameters such as center frequency, return loss, and phase (S-parameters), which are related to the effective complex permittivity of the medium (Pozar, 2012; Balanis, 2016; Islam *et al.*, 2024).

In addition to avoiding electrode polarization typical of contact measurements, non-contact methods can eliminate interfacial elements in equivalent circuit models and increase temporal stability (Hu *et al.*, 2019).

The feasibility of non-intrusive RF/microwave measurements is linked to frequency selection, which simultaneously affects penetration depth and sensitivity. In non-metallic media, electromagnetic penetration is frequency dependent, with lower frequencies tending to penetrate more deeply. This behavior can be described by quantities such as skin depth, which increases with the resistivity of the medium (Islam *et al.*, 2024). At the same time, conductive losses contribute to ε'' and $\tan(\delta)$, and the water present in pores remains a dominant factor in the effective dielectric response (Nelson, 1991; Dinh *et al.*, 2021).

2.3 Microstrip and patch antenna applied to dielectric characterization of cementitious materials

Microstrip lines and patch antennas are widely used in the RF/microwave range to measure dielectric properties and to sense materials. Both structures rely on the propagation of guided electromagnetic waves over a dielectric substrate and are sensitive to variations in the medium interacting with the electric field (Pozar, 2012; Balanis, 2016; Islam *et al.*, 2024).

A microstrip line consists of a metallic conducting strip deposited on a dielectric substrate, with a metallic ground plane on the opposite side (Figure 1). This configuration supports a quasi-TEM propagation mode. The fields are distributed partly in the substrate and partly in the adjacent medium, motivating the use of an effective permittivity (ε_{eff}) to describe propagation (Pozar, 2012).

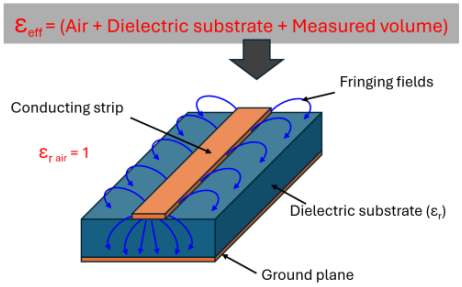

Figure 1 – Conceptual scheme of a microstrip line

However, when applied to the characterization of heterogeneous and conductive materials such as fresh concrete, microstrip lines may present limitations related to the effective interaction depth of fringing fields. Depending on the sensor geometry and material losses, the interaction may be more sensitive to near-surface layers. In general, higher resistivity and lower frequencies favor deeper penetration, whereas lossier materials reduce the effective field reach (Islam *et al.*, 2024).

To increase measurement representativeness and explore a regime with greater spectral selectivity, microstrip patch antennas can be employed. These are resonant structures that share the same construction principle but operate at resonance at a specific frequency.

A patch antenna is composed of a metallic patch over a dielectric substrate and a ground plane under this substrate, forming an open resonant cavity. In this configuration, fringing fields extend beyond the edges and interact with the adjacent medium (Balanis, 2016) (see Figure 2).

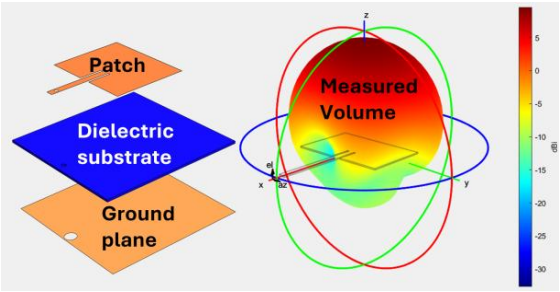

Figure 2 – Microstrip Patch Antenna: schematic (left) and evanescent electric field simulations (right)

The resonance frequency (fundamental mode) can be approximated by:

$$f_r = \frac{c}{2L\sqrt{\varepsilon_{eff}}} \tag{4}$$

Changes in the permittivity and losses of the coupled material modify ε_{eff}, shifting the resonance frequency and the magnitude of the reflection response (S11), or the apparent impedance. As indicated by Equation 4, the resonant response is directly affected by changes in the effective permittivity of the coupled medium. This is the basis of passive antenna sensors, in which sensing is achieved through variations in center frequency, return loss, phase, and reflected or received intensity (Islam *et al.*, 2024).

In the context of this study, the transition from a linear microstrip geometry to a patch antenna was adopted to increase the volumetric representativeness of coupling, reducing the dominance of a very thin surface layer; to reduce sensitivity to micro-roughness and highly localized heterogeneities at the interface, seeking

more stable spectral responses; and to exploit a resonant response (in terms of frequency and return loss) that is easier to track over time for monitoring changes in moisture and composition.

The antenna sensor literature reports high sensitivity to variations in the permittivity of the surrounding medium, with several applications in moisture detection and in diverse dielectric materials (Islam *et al.*, 2024). For cementitious materials, because effective permittivity depends strongly on water content and curing or hydration time, shifts in the resonant response can be exploited for non-intrusive monitoring (Dinh *et al.*, 2021).

According to Islam *et al.* (2024), microstrip antennas are popular for sensing applications because they are conformal, robust, compact, relatively inexpensive, and sensitive to dielectric variations in the substrate or coupled medium. These features are particularly relevant for non-intrusive monitoring of heterogeneous materials. In addition, frequency selection should consider the trade-off between penetration and medium losses. Lower frequencies tend to increase penetration depth in non-metallic materials, while conductive and dielectric losses reduce the effective field reach (Islam *et al.*, 2024; Nelson, 1991).

3. Experimental work

The experimental program was designed to investigate the influence of water content, cement content, and water-to-cement ratio (w/c) on the electrical behavior of fresh concrete using non-intrusive impedance measurements. The methodology combined material characterization, controlled concrete production, fresh-state and hardened-state testing, and the systematic acquisition and processing of electrical data. All experimental procedures were carried out under controlled laboratory conditions and in compliance with applicable Brazilian standards.

3.1 Materials

The cement used in this study was Portland blast-furnace cement CP II. The fine aggregate consisted of medium sand with a maximum particle size (Dmax) of 2 mm, while the coarse aggregate was crushed stone classified as “brita 1”, with a maximum particle size of 19 mm.

The water-to-cement ratio (w/c) was varied over a wide range, from 0.39 to 0.73, to evaluate the influence of mixture composition on the electrical properties of fresh concrete. Aggregate characterization included granulometric analysis and the determination of physical properties, and the specific gravity of the cement was also measured.

Prior to characterization, the aggregates were oven-dried at 110 ± 5 °C for 24 h to eliminate residual moisture. Mixing water was obtained from the local public water supply. All characterization procedures followed relevant Brazilian standards, including ABNT NBR 7211, NBR 17054, NBR 16916, and NBR 16917 for aggregates, and ABNT NBR 16605 for cement specific gravity determination.

3.2 Test Procedure

The experimental methodology was developed and conducted in a university research laboratory at the University of São Paulo (USP), São Carlos campus, specifically at the Laboratory of Industrial Multiphase Flow (LEMI), which operates under a development agreement with the startup coordinating the project. The study was based on planned experimental campaigns aimed at validating a non-intrusive method for measuring the electrical impedance of fresh concrete.

Concrete mixtures were prepared in accordance with ABNT standards, including NBR 12821 for laboratory concrete production and NBR 7212 for batching tolerances. Each mixture was produced in a commercial drum mixer with a nominal capacity of 120 L and a useful batch volume of 30 L. Materials were weighed using digital scales with nominal capacities of 6 kg and 30 kg and respective resolutions of 2 g and 10 g.

Fresh concrete consistency was evaluated using the slump test, in accordance with ABNT NBR 16889. For mechanical characterization, cylindrical specimens were molded and cured in accordance with ABNT NBR 5738, and compressive strength tests were performed at 7 and 28 days following ABNT NBR 5739. A total of 30 different concrete compositions were prepared and electrically characterized. All mixing, molding, and testing procedures were conducted under controlled laboratory conditions to minimize variability between batches and ensure reproducibility.

3.3 Data acquisition and processing

Electrical measurements were performed using a high-precision impedance analyzer, Hioki IM7587-01 (1 MHz–3 GHz), equipped with automatic range control and standard open–short–load calibration. The experimental database was developed exclusively from controlled laboratory measurements.

Impedance measurements were carried out in the frequency range from 1 GHz to 3 GHz, where the electrical behavior of fresh concrete was predominantly dielectric and governed mainly by dipolar polarization mechanisms. The analyzer was configured to record 801 frequency points per sweep, simultaneously acquiring impedance magnitude (Z), phase (PH), resistance (R), and reactance (X).

A microstrip patch antenna designed to resonate at 2.4 GHz was used as the sensing element. This antenna type was selected due to its dielectric sensitivity, non-intrusive operation, design simplicity, and robustness. Its applicability to concrete-related moisture measurements has been demonstrated by Teng *et al.* (2019), and the same physical principle—variations in dielectric permittivity—supports its use for estimating water content, cement content, and the water-to-cement ratio.

The experimental campaign, with the setup shown in Figure 3, generated a dataset from 30 fresh concrete compositions molded into cylindrical specimens with dimensions of 100 × 200 mm, in accordance with ABNT NBR 5738. For each composition, 16 distinct measurements were performed, resulting from the combination of four probe positions on the specimen surface (with 90° rotation between positions), two independent replicas molded from the same batch, and two consecutive measurements at each position to evaluate repeatability.

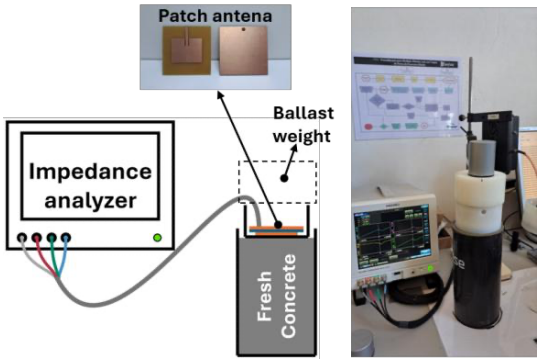

Figure 3 – The experimental setup for data collection: schematic (left) and photographic record (right)

This protocol ensured statistically representative sampling and enabled the assessment of repeatability between replicas, the influence of probe positioning, and the temporal stability of the dielectric response.

The target variables used as outputs for machine learning modeling were the water content (w, kg/m^3), cement content (c, kg/m^3), and water-to-cement ratio (w/c). These parameters were defined from the controlled mixture proportions and served as reference values for training predictive models.

All electrical measurements were conducted within a time window of 30 to 50 minutes after water addition, avoiding the very early hydration stage and remaining sufficiently distant from the initial setting period. The experimental campaign produced approximately 1.54 × 10^6 elementary observations in the raw dataset. For

supervised learning, however, each spectral sweep was treated as a single sample, resulting in 480 complete spectra used for regression modeling.

Data analysis focused on repeatability assessment using the coefficient of variation, sensitivity to changes in mixture parameters, and the ability to discriminate between different concrete compositions. Spectral interpretation emphasized the identification of frequency regions with higher dielectric contrast and improved signal-to-noise ratio, forming the basis for subsequent inverse modeling using machine learning techniques.

4. Results and Discussion

The experiments carried out in this study confirmed the feasibility of non-intrusive microwave measurements for the dielectric characterization of fresh concrete. Measurements were conducted using a patch antenna designed to operate at 2.4 GHz, with acquisition of complete impedance and phase spectra over the 1 GHz to 3 GHz range.

4.1 Spectral Response of Basic Materials

The impedance magnitude and phase responses of basic materials (air, sand, and cement) provide a reference for understanding the dielectric behavior of more complex systems. As shown in Figure 4, these dry materials exhibit high impedance values and stable phase responses across the entire frequency range, indicating predominantly insulating behavior.

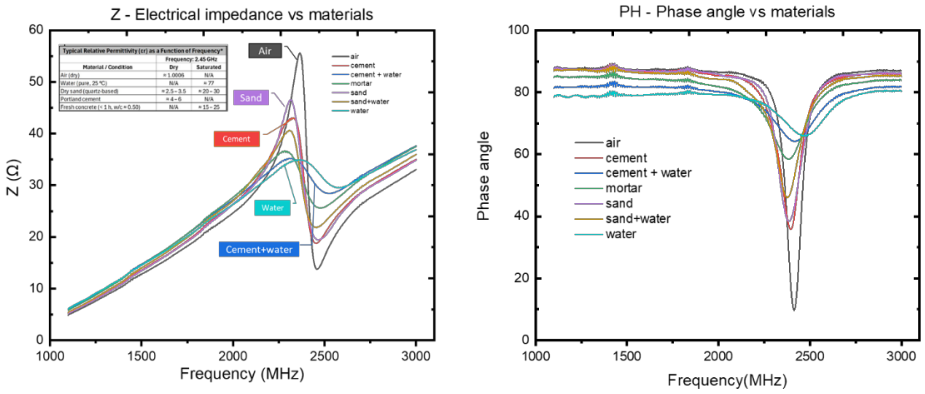

Figure 4 – Impedance spectra measured by Hioki (1–3 GHz) in basic materials, showing sensitivity to water

In contrast, in mortars and fresh concretes, the presence of free water and dissolved ions significantly reduces the impedance magnitude and alters the slope of the phase curve. This behavior evidences the dielectric contribution of the liquid phase and pore connectivity.

These observations confirm that the spectral response is governed by water content, phase distribution, and degree of hydration, establishing the physical basis for interpreting the electrical behavior of fresh concrete.

4.2 Spectral Signature and Material Differentiation

Building on the fundamental behavior of individual materials, the results obtained for concrete mixtures demonstrate that each composition exhibits a distinct spectral signature. Figure 5 shows that the measured dielectric spectrum is sensitive to variations in mixture composition, particularly water content, cement content, and the water-to-cement ratio.

The impedance magnitude and phase curves obtained for different concrete compositions exhibit distinct spectral patterns, confirming the method's ability to differentiate materials with different dielectric

characteristics. The specific spectral signature obtained for each mixture therefore represents a unique dielectric identifier, capable of distinguishing compositions from different mix designs.

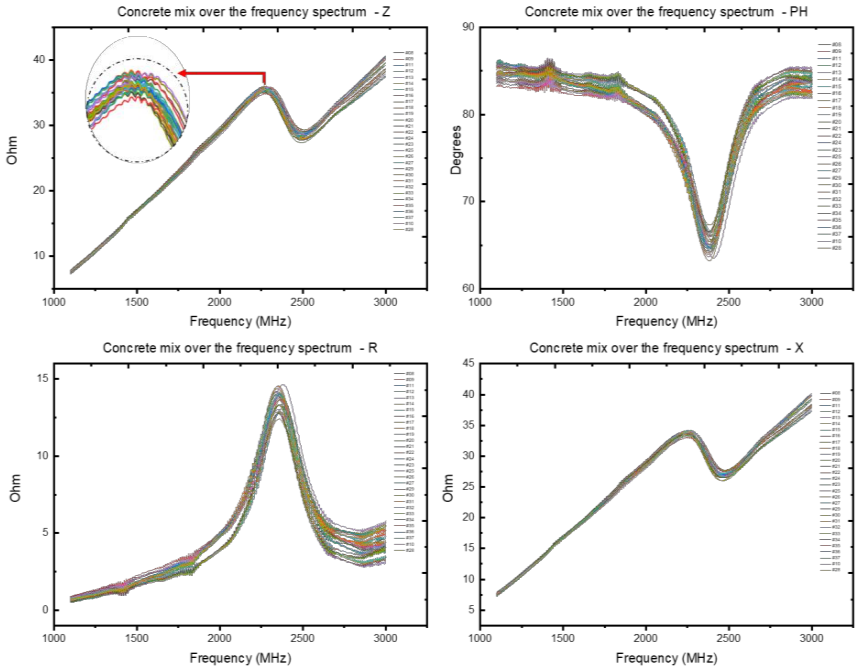

Figure 5 – Z, PH, R, and X spectra obtained with Hioki for the 30 compositions

4.3 Sensitivity of the Patch Antenna to Water Content

The microstrip patch antenna demonstrated high sensitivity to variations in moisture and concrete composition. In measurements where the water content increased, a systematic shift in the resonance frequency and a corresponding change in impedance magnitude were observed.

This behavior results from changes in the effective dielectric permittivity (ε_{eff}) of the medium beneath the antenna: as the water content increases, (ε_{eff}) also increases, modifying the electromagnetic coupling between the patch and the fresh concrete.

This direct relationship between water content and electrical response reinforces the hypothesis that microwave measurements enable non-intrusive characterization of concrete composition, providing a representative volumetric response and minimizing contact-related effects.

4.4 Patch Antenna Structure and Characteristics

Preliminary tests with conventional microstrip lines indicated that the penetration depth of the evanescent field was limited to a few millimeters, restricting sensing to the superficial region of the sample (so-called “wall effect”). To overcome this limitation, a resonant microstrip patch antenna operating around 2.4 GHz was adopted, and its geometry was optimized through electromagnetic simulation.

The final structure consisted of an FR-4 substrate (thickness 1.6 mm; $\varepsilon_r \approx 4.4$), a rectangular metallic patch with dimensions adjusted for resonance at 2.4 GHz (within the ISM band—Industrial, Scientific and Medical), a continuous ground plane on the opposite side, and an insulating dielectric encapsulation in nylon to prevent direct contact between the antenna and the measured material (concrete).

This configuration concentrated the electric field beneath the patch region, generating deeper and more stable fringing fields with greater penetration capability into the sample. The higher volumetric representativeness and lower sensitivity to surface irregularities justified the adoption of the patch antenna as the sensing element for the experimental campaign.

4.5 Future Work

Based on the experimental results obtained in this study, further improvements are proposed for the next stages of methodology development aimed at measuring concrete composition in the fresh state. These include replacing nylon as the probe housing material with a more electrically suitable and preferably hydrophobic material, such as polypropylene (PP) or polytetrafluoroethylene (PTFE), as well as redesigning the patch antenna while explicitly considering the dielectric properties of both the new housing material (PP or PTFE) and the material under test (MUT), with the objective of maximizing electromagnetic coupling and signal transfer.

Additionally, the reflection coefficient S11 is proposed as the primary measurement parameter instead of complex impedance, as it is well established in the literature as the main performance metric for microstrip antennas fed by a 50 Ω line and is widely used for analysis and optimization in recent designs (Galleto and Africa, 2025; Hasan *et al*., 2015; Naidu *et al*., 2023). Further developments include reviewing the sampling procedure to improve repeatability and reproducibility, defined as the ability to obtain similar results for identical compositions produced in different batches, and applying Principal Component Analysis (PCA) to the spectral signatures of new datasets. This approach will be combined with modern machine learning techniques, such as Support Vector Regression (SVR), Random Forest Regression (RFR), XGBoost, and Multilayer Perceptron artificial neural networks (ANN/MLP), aiming to enhance regression performance by exploiting the principal components of each spectral signature.

5. Conclusions

The experimental investigations confirmed the feasibility of non-intrusive microwave electrical impedance spectroscopy for the dielectric characterization of fresh concrete. Measurements performed using a microstrip patch antenna operating around 2.4 GHz, with spectral acquisition over the 1 GHz to 3 GHz range, demonstrated that each concrete mixture exhibits a distinct dielectric signature. This response was shown to be sensitive to variations in water content, cement content, and the water-to-cement (w/c) ratio.

The results demonstrated clear spectral differentiation between materials. Dry materials such as air, sand, and cement exhibited high impedance values and stable phase behavior, consistent with their insulating nature. In contrast, mortars and fresh concrete presented lower impedance magnitudes and altered phase responses due to the presence of free water and dissolved ions. These findings confirm that the dielectric response is primarily governed by water content, phase distribution, and pore connectivity, enabling the association of spectral features with the physical and chemical properties of fresh concrete.

The microstrip patch antenna showed high sensitivity to moisture variations, with increases in water content producing systematic shifts in resonance frequency and corresponding changes in impedance magnitude. This behavior is associated with variations in the effective dielectric permittivity of the medium and the resulting changes in electromagnetic coupling. These results reinforce the potential of microwave-based measurements as a reliable, non-intrusive technique for volumetric characterization of fresh concrete, with reduced sensitivity to contact effects.

From a sensing perspective, the adoption of the resonant patch antenna was essential to overcome the limitations of conventional microstrip lines, particularly the restricted penetration depth of the evanescent field. The optimized antenna configuration enabled deeper electromagnetic field penetration and improved volumetric representativeness, while reducing sensitivity to surface irregularities.

Overall, the results demonstrate that the dielectric spectral signature obtained from microwave impedance measurements can serve as a unique identifier for different concrete mixtures, enabling reliable differentiation between compositions. This capability highlights the potential of the proposed method as a non-destructive and non-intrusive tool for monitoring concrete composition in the fresh state.

Future developments will focus on improving the robustness and accuracy of the methodology. Planned efforts include replacing the nylon probe housing with electrically suitable and hydrophobic materials such

as polypropylene (PP) or polytetrafluoroethylene (PTFE), redesigning the patch antenna considering the dielectric properties of both the housing and the material under test, and adopting the reflection coefficient S11 as the primary measurement parameter. Additional work will address improvements in sampling repeatability and reproducibility, as well as the application of advanced data analysis techniques, including Principal Component Analysis (PCA) combined with machine learning models such as Support Vector Regression, Random Forest Regression, XGBoost, and artificial neural networks (ANN/MLP), to enhance the predictive capability of the spectral data.

Acknowledgments

The authors would like to acknowledge the Laboratory of Industrial Multiphase Flow (LEMI) at the São Carlos School of Engineering, University of São Paulo (EESC-USP), for its valuable support and collaboration in the development of this research. The authors also acknowledge Votorantim Cimentos do Brasil for the provision of materials and technical support.

Abstract: The construction industry remains a major emitter of CO_2 (~37% globally), demanding insulation solutions that reduce embodied carbon while maintaining performance. This work investigates mycelium-based composites (MBCs) grown on birch woodchips and modified through targeted additives (sheep wool, silica) and fabrication scales (block-grown vs. mold-grown). The goal is to identify how these parameters influence key functional properties.

MBCs exhibited densities of 140–200 kg/m³ and thermal conductivities of 0.059–0.066 W/m·K, comparable to conventional insulation. Mechanical tests yielded compressive strengths of 0.13–0.47 MPa, suitable for lightweight, non-structural applications. Fire resistance varied markedly: wool-reinforced composites exceeded 2100 s under direct flame exposure, while silica-modified specimens failed after ~720 s. Microstructural analysis revealed that wool promotes continuous hyphal networks and cohesive char formation, whereas silica disrupts filament interconnectivity.

These results confirm that microstructure—governed by additive type and fabrication method—is central to optimizing performance. MBCs thus represent a regenerative, carbon-storing material class capable of meeting future low-carbon insulation demands.

Keywords: mycelium-based composites; bio-based insulation; fire-resistant biocomposites; microstructure–property relationships

1. Introduction

The building and construction sector is responsible for a substantial share of global greenhouse gas emissions, contributing approximately 37% of total global CO_2 emissions (Dyson, 2023). This combined contribution from operational and embodied energy highlights the urgent need to shift towards materials and systems that reduce both energy consumption and the carbon intensity of construction. Conventional insulation materials—such as expanded and extruded polystyrene (EPS, XPS), polyurethane foams (PUR/PIR), mineral wool, and fiberglass—play an essential role in improving building energy efficiency. However, these products have significant environmental drawbacks: their manufacturing is energy-intensive, relies on non-renewable resources, and often involves chemicals that can lead to toxic emissions during production, use, and end-of-life disposal (Alaneme *et al.*, 2023). Their limited recyclability and long-term persistence in landfills further exacerbate environmental impacts.

In response, there is growing interest in bio-based insulation materials derived from renewable resources, which typically exhibit lower embodied energy and can store biogenic carbon during their service life. Materials such as hemp, straw, sheep wool, cork, and cellulose offer promising thermal properties comparable to mineral wool, while simultaneously valorizing agricultural by-products and reducing environmental burdens) (Hetimy *et al.*, 2025). (Babenko *et al.*, 2024). Beyond thermal performance, natural insulation materials avoid hazardous additives, support healthier indoor environments, and align well with circular-economy principles due to their biodegradability or recyclability. Their performance, however, can be sensitive to moisture content, density, and fiber distribution, requiring careful characterization and standardized production methods (Motamedi et al, 2025).

Among these emerging alternatives, mycelium-based composites (MBCs) have gained increasing attention due to their combination of low density, biodegradability, thermal efficiency, and carbon-negative production potential(Fellah *et al.*, 2024). MBCs are produced through fungal colonization of lignocellulosic substrates—such as agricultural residues or woodchips—resulting in a lightweight, porous network where fungal hyphae act as a natural binder. Reported thermal conductivity values typically fall in the range of 0.036–0.06 W/m·K, placing these composites within the performance range of common insulation materials while requiring minimal energy input during fabrication. The growth process itself takes place at near-ambient conditions and relies on biological mechanisms rather than synthetic binders, substantially reducing embodied energy and environmental impacts (Motamedi et al., 2025; Alaneme *et al.*, 2023). Beyond their insulating capacity, MBCs also demonstrate advantageous fire behavior. A common limitation of many organic insulation materials is their flammability—while materials such as mineral wool and fiberglass are non-combustible (Euroclass A1), most bio-based insulations fall into combustible categories such as Euroclass C, D, or E. Mycelium-based materials, however, tend to char instead of igniting easily (Gezer and Kuştaş, 2024). This charring behavior slows flame propagation and reduces heat release during combustion. Research has shown that fungal mycelia are less flammable than several widely used polymers, including PMMA and PLA, and that applying mycelium layers to organic substrates can enhance their fire resistance (Alaneme *et al.*, 2023). In numerous experimental tests, mycelium composites have demonstrated self-extinguishing behavior after the removal of a flame source, while simultaneously forming a protective char layer that improves their fire performance compared with untreated bio-based materials.

However, like other organic materials, they usually achieve only moderate Euroclass fire ratings. For reference, typical foam insulation panels have thermal conductivities of approximately 0.03–0.04 W/m·K, while glass wool typically ranges from about 0.035 to 0.045 W/m·K. MBCs can achieve thermal performance levels comparable to conventional insulation materials while offering additional benefits, including biodegradability and carbon sequestration (Gezer and Kuştaş, 2024). Nevertheless, because they remain

combustible lignocellulosic materials, their fire classification is typically limited, and improvements in fire safety often require specific additives or post-treatments to enhance flame retardancy.

Recent research has explored the potential benefits of mycelium-based composites (MBCs). For example, Zhang et al. produced fungal fibers with added silica that reduced the peak heat release rate by up to 66% while maintaining structural stability under flame exposure (Zhang *et al.*, 2022). Similarly, Chulikavit et al. studied deacetylated mycelium composites and found improved thermal stability and fire resistance, suggesting their use in fire-resistant cladding (Chulikavit *et al.*, 2023). Although mycelium insulation is still a combustible organic material (typically around Euroclass E), it often self-extinguishes once the ignition source is removed, which improves safety (De *et al.*, 2025). This indicates that mycelium has natural flame-retardant potential, especially when combined with small amounts of inorganic additives or protective coatings. Current research is therefore examining mycelium coatings and hybrid composites to further improve fire performance in sustainable construction (Yang, Park and Qin, 2021).

MBCs also offer environmental advantages. During growth, the fungus stores carbon from its substrate, meaning the final material can temporarily act as a carbon sink. Production typically occurs at ambient temperatures and uses agricultural waste, resulting in low energy demand. Life-cycle studies suggest that mycelium insulation can have a smaller carbon footprint than fiberglass or petroleum-based foams (Motamedi et al, 2025). Despite these environmental and functional benefits, significant knowledge gaps remain regarding the standardization of MBC performance. Reviews note that thermal and fire properties remain insufficiently studied (Jones, Bhat, Kandare, *et al.*, 2018). Most work reports only density and thermal conductivity for a few substrate–fungus combinations. Data on specific heat capacity—critical for understanding thermal inertia and fire development—are still scarce, and comprehensive fire testing (e.g., cone calorimetry or limiting oxygen index) is seldom reported. As a result, standardized formulations and testing methods for MBC insulation have not yet been established (Alaneme *et al.*, 2023).

Given these gaps, this study investigates the combined effects of substrate composition, additive type, and fabrication method on the microstructure, thermal behaviour, mechanical properties, and fire resistance of mycelium-based composites grown on birch woodchips using Ganoderma lucidum. Additives—namely, sheep wool and silica—were selected for their potential to influence porosity, thermal response, and flame retardancy. Two fabrication approaches (block-grown and mold-grown) were compared to examine how growth confinement and specimen scale affect density, surface development, and hyphal network continuity. By systematically evaluating these variables, the study aims to clarify structure–property relationships and identify composite formulations with improved performance for sustainable, low-carbon insulation applications.

2. Materials and Methods

2.1 Mycelium Composite Fabrication

Specimens examined in this study were fabricated using a multi-stage process. First, a lignocellulosic substrate was selected and prepared for colonization. Two different fabrication methods were used to produce specimens for mechanical, thermal, and fire performance testing. All samples were grown using the fungal species *Ganoderma lucidum* on sterilized birch woodchips, a locally available forestry by-product in Iceland.

Three substrate formulations were developed to identify the influence of additives

MBC^{s}: Default substrate with silica additive

MBC^{w}: Default substrate with natural wool additive

MBC: Default substrate with no additive (control group)

The additives (wool and silica) were selected for their potential to modify the porosity, thermal resistance, and fire behavior of the composite. All additives were blended with the sterilized substrate before fungal inoculation. After inoculation, the substrate was incubated under controlled environmental conditions (22–25°C, ~70% RH) for 10–14 days, depending on growth progression.

To ensure compatibility with various standardized testing protocols, two distinct fabrication methods were used for growing the mycelium specimens:

- Method I – Block-Grown Samples (Large Scale)

In this method, the mycelium was cultivated in free-form blocks (about 400 × 300 × 350 mm) without the use of molds. After the material was fully colonized and dried, test specimens were cut to the required sizes for each experiment. This technique was mainly applied for tests needing larger samples, such as stiffness and thermal conductivity measurements. These specimens are referred to as **MBCI**.

- Method II – Mold-Grown Samples (Standardized Scale)

For smaller and more precise tests, particularly fire-related experiments, the mycelium was grown directly inside 3D-printed molds. The molds measured 75 × 75 × 12.3 mm and were designed to match the dimensions specified in international testing standards. This minimized the need for additional cutting and ensured consistent sample geometry. These samples are labeled **MBCII**.

Both fabrication methods used the same fungal species, substrate composition, growth conditions, and post-processing steps, including drying and the inactivation of fungal activity. Using two parallel manufacturing approaches enabled the evaluation of scale-dependent effects, facilitated comparison with previous studies employing standardized specimen sizes, and provided insight into how growth confinement and sample geometry influence the final material properties. This framework supports reproducibility, reliable comparison between tests, and relevance for both laboratory research and potential industrial production. The procedures were developed based on a review of previous studies on mycelium-based composites (Dias, Jayasinghe, and Waldmann, 2021; Pelletier et al., 2013; Fellah et al., 2024; Barta et al., 2024; Aiduang, Suwannarach, et al., 2022).

2.2 Specimen production

In **Method I**, the mycelial mixture was placed directly into sealed plastic bags, where it formed compact, dense blocks. In **Method II**, the same mixture was filled into 3D-printed molds. These molds were designed in Fusion 360 and printed with GreenTEC Pro 160 °C PLA filament, selected for its ability to withstand autoclave sterilization at 120 °C. The fungal inoculation was carried out using *Ganoderma lucidum* (reishi) grain spawn.

Both methods followed the same initial preparation steps. First, the substrate materials were selected and mixed, then the mixture was placed either in molds or sealed plastic bags. When molds were used, they were placed inside sterilization bags so they could be autoclaved while maintaining their shape. After sterilization, the substrate was inoculated with fungal spawn under sterile conditions. Once the mycelium had fully colonized the substrate, all samples were dried under controlled conditions to stop biological growth. The drying process consisted of two 12-hour cycles at 40 °C, followed by a 24-hour light compression step to improve dimensional stability. For Method II, the samples were removed from the molds before drying to ensure even moisture removal. This workflow ensured consistent growth conditions across both

fabrication methods while allowing a systematic evaluation of how mold confinement and sample size influence the structural development and performance of the resulting composites.

a) b)

Figure 1 – Block-grown mycelium composites specimens, Method I.

2.3 Test Methods

2.3.1 Density

In this study, density was measured to describe the physical structure of the composites and to allow comparison with typical insulation materials. The density of each specimen (ρ, kg/m³) was calculated using:

$\rho = m / V$

where **m** represents the dry mass (kg), and **V** is the geometric volume (m³). Before measurement, the samples were oven-dried at 60 °C until a constant mass was reached. All measurements were performed under standard laboratory ambient conditions. This procedure ensured consistent moisture removal before weighing, reducing variability and allowing reliable comparison between formulations and fabrication methods.

2.3.2 Thermal conductivity

In this study, measurements were carried out on two MBCI samples produced using Method I, each measuring 100 × 100 × 350 mm. Testing was performed using a FOX 314 Heat Flow Meter in accordance with ASTM C518 and ISO 8301.

During the test, the specimens were positioned between calibrated hot and cold plates to establish steady-state heat transfer. The thermal conductivity (λ) was then determined from the measured heat flux and the temperature difference across the sample. The obtained λ values were used to assess the insulating capability of the composites and to compare their performance with that of conventional insulation materials. This setup allowed precise quantification of steady-state heat transfer and ensured compliance with widely recognized thermal testing standards.

2.3.3 Compressive strength

The compressive strength of the mycelium-based composites was tested using an Instron 8503 universal testing machine. MBCI specimens measuring 95 × 100 × 350 mm^3 were subjected to uniaxial compression in accordance with ASTM C165-07. A constant crosshead speed of 1.27 mm/min was applied until the samples failed (Figure 4). The recorded stress–strain data were used to characterize the compressive behavior of the composites. This evaluation provides important information on the mechanical stability of mycelium composites, supporting their potential use as non-structural insulation or lightweight panels and offering a biodegradable alternative to conventional polymer foams.

2.3.4 Fire Resistance

The fire performance of the mycelium-based composites was assessed using controlled laboratory flame exposure tests in accordance with EN 13501-2. All sample types—including MBCs, MBC^{W}, and both MBC^{I} and MBC^{II}, produced via Method I and Method II—were tested, with each group containing two to four specimens (Figure 5a). During testing, samples were placed 5–7 cm above a burner fueled with a propanol-based gas mixture, resulting in flame temperatures exceeding 660 °C. Surface temperatures and thermal evolution were monitored using an FLIR T640 thermal camera.

Following the approach adapted from Dias et al. (2021), a Kemper burner was used instead of a standard Bunsen burner to achieve higher and more consistent flame temperatures (Dias, Jayasinghe, and Waldmann, 2021). A layer of cotton wool was positioned atop each specimen to act as a visual ignition indicator. Tests were concluded when the cotton ignited, structural failure occurred (e.g., visible perforation), or the mycelium material itself began to burn.

2.3.5 Microstructural observation

Cross-sectional specimens were manually taken from the interior of representative samples produced by each fabrication method described in Section 3.1. The pieces were mounted on metal stubs using conductive carbon adhesive tape for scanning electron microscopy (SEM) analysis. High-resolution Environmental SEM (ESEM) was performed in backscattered electron (BSE) mode and combined with Energy Dispersive X-ray Spectroscopy (EDS) using a FEI Quanta 400 FEG ESEM/EDAX Genesis X4M system. Before imaging, all samples were sputter-coated with a thin Au/Pd layer to improve signal quality and reduce surface charging effects.

3. Results and Discussion

The findings show that Ganoderma lucidum mycelium composites offer a high-performance, bio-based insulation solution, combining low density with excellent thermal efficiency. Measured thermal conductivities ranged from 0.050 to 0.062 $W \cdot m^{-1} \cdot K^{-1}$, comparable to those of high-end synthetic foams. Wool-reinforced variants (MBCW) demonstrated improved fire resistance, retaining structural integrity at temperatures up to 660 °C, making this hybrid configuration the most promising for flame-retardant applications. With a high biogenic carbon content (62.96–73.68 wt%), these composites also act as carbon sinks, potentially contributing to net-negative emissions over a building's lifecycle. Overall, these combined properties—low density, strong thermal performance, enhanced fire resilience, and intrinsic carbon storage—reinforce the potential of mycelium-based composites as next-generation regenerative materials for low-carbon construction. Table 1 highlights the general results of the study. The following sections examine each result property in detail.

Table 1 –Test results summary

Substrates	Density (kg/m³)	Thermal Conductivity (W/m·K)	Compression (MPa)	Fire Resistance (Seconds)
MBC^{S}	150 kg/m³			720
MBC^{W}	140 kg/m³			>2100
MBC^{I}	200 kg/m³	0.05–0.06W/m.K.	0.13–0.47MPa	1020
MBC^{II} (control group)	140 kg/m³			1200

3.1 Density

Low bulk density is a key feature of insulation materials, reducing structural load, easing handling, and providing good thermal resistance per unit mass, which has historically made synthetic foams popular (EPS: 15–35 kg/m³; PU: 30–50 kg/m³).

In this study, large MBCI samples (Method I) had a density (ρ) of 200 kg/m³, whereas smaller MBCII specimens (Method II) had a density of 140 kg/m³. Wool- and straw-modified composites (MBCW, MBCS) ranged from 140–150 kg/m³, giving an overall range of ~120–210 kg/m³. Notably, wool-reinforced composites attained densities ≤140 kg/m³, comparable to mineral wool insulation (80–150 kg/m³), while offering the added advantages of full biodegradability and intrinsic carbon sequestration. This density envelope validates the potential of mycelium composites as viable drop-in replacements within non-structural insulation systems, balancing mechanical integrity with low embodied mass.

Density affects thermal performance by controlling air entrapment, though conductivity and porosity also play a role. The observed densities align with reported mycelium composites (100–390 kg/m³) (Appels *et al.*, 2019), with heat-pressed samples showing higher values due to pore collapse. Scale effects were clear: large MBCI blocks were denser than small MBCII molds, likely due to edge compaction and preservation of microporosity. Wool additives helped maintain a lower density while optimizing void fraction.

Compared to standard building materials, mycelium composites are over three times lighter than MDF (500–1000 kg/m³) and gypsum board (410–950 kg/m³), slightly denser than rock wool (118 kg/m³) (Rajendran, 2022), and denser than polystyrene foams (11–50 kg/m³). Their porous, fungal-bound structure reduces convective heat transfer, enhancing insulation.

Compressive strength is relatively low, limiting structural use. Still, their density and microstructure make them suitable for non-load-bearing applications such as insulation panels, acoustic tiles, partition walls, door cores, or cladding. Overall, mycelium composites offer a sustainable, low-density alternative for high-performance insulation, reducing reliance on synthetic foams and associated environmental impacts.

3.2 Thermal conductivity

The mycelium-based composites showed strong thermal insulation, with thermal conductivity (λ) values between 0.059 and 0.066 W/m·K, comparable to many conventional insulation materials. For reference, EPS typically ranges from 0.036 to 0.046 W/m·K (Saini *et al.*, 2025).

Literature reports a wide range for mycelium composites: Rejeesh (Rajendran, 2022) noted ~0.070 W/m·K, while Alaneme et al. (Alaneme *et al.*, 2023) observed 0.088–0.104 W/m·K. The improved performance in this study likely reflects the choice of fibers and the fabrication method. Surface roughness may slightly influence measurements, with smoother specimens expected to show lower conductivity.

High porosity, low density, and significant internal air volume give mycelium composites their insulating capability. Values reported here align with prior studies (Yang et al., 2017; Schnabel, 2019) showing 0.05–0.07 W/m·K, like glass wool (0.04 W/m·K), extruded polystyrene (0.03 W/m·K), sheep wool (0.05 W/m·K), and kenaf (0.04 W/m·K) (Alaneme *et al.*, 2023). Other studies (Dias, Jayasinghe, and Waldmann, 2021) report 0.088–0.104 W/m·K, comparable to straw, hemp concrete, softwoods, and gypsum. Rock wool has a thermal conductivity of ~0.035 W/m·K for comparison.

Overall, these results confirm that mycelium composites have low thermal conductivity, low density, and a biogenic origin, making them strong candidates for sustainable insulation and energy-efficient construction.

3.3 Compressive strength

Specimens withstood forces from 0.47 to 4.19 kN, corresponding to strengths of 0.13–0.47 MPa, with a standard deviation of 0.16 MPa. Samples with dense, uniformly colonized fungal biomass showed the highest strength. The generally low values reflect the material's lightweight, highly porous nature, typical of insulating or fibrous composites. Variations between samples likely stem from differences in fiber distribution, porosity, or binder content. Despite this, the composites provide adequate stability for non-structural applications, such as thermal or acoustic insulation, rather than load-bearing use, consistent with previous reports highlighting the trade-off between low density and mechanical strength.

While compressive strength is not the main factor for insulation performance, it remains a key material property. Mycelium-based composites typically range from 0.36 to 0.52 MPa, with larger blocks in this study reaching 0.47 MPa, higher than smaller specimens (0.13–0.3 MPa).

Previous research shows mechanical performance depends strongly on substrate type, fiber condition, and processing. For example, 3D-printed mycelial blocks can reach 0.06–0.5 MPa (Soh et al., 2023; Soh and Le Ferrand, 2023), and adding fillers such as sand or chitin nanofibers can significantly increase strength and stiffness (Jones, Bhat, Huynh, et al., 2018; Jin et al., 2013). Post-processing techniques, especially hot pressing, can dramatically boost the elastic modulus—from ~9 MPa cold-pressed to ~97 MPa hot-pressed (Appels *et al.*, 2019).

Overall, the mechanical properties of mycelium composites are largely dictated by substrate composition, additive inclusion, and fabrication method rather than chemical makeup, highlighting the potential to tailor compressive strength and stiffness for specific non-structural applications.

3.4 Fire Resistance

The fire behaviour of the mycelium composites was assessed under controlled conditions using direct flame exposure at approximately 660 °C, with surface temperatures monitored through infrared thermography. The objective of the test was to compare how different formulations responded to the same heat conditions; the procedure was not intended to assign formal fire classifications.

Across all samples, the primary response involved surface charring followed by gradual thermal degradation, with no sustained flaming. The test concluded when one of three conditions occurred: ignition of the cotton indicator layer, visible structural perforation, or sustained combustion of the composite material. Wool-reinforced composites (MBCW) showed the longest resistance to flame exposure, maintaining structural integrity for more than 2100 seconds. Block-grown (MBCI) and mold-grown (MBCII) control specimens resisted between 1020 and 1200 seconds, while silica-modified composites (MBCS) reached only about 720 seconds. The improved behaviour of the wool-based samples is consistent with their more continuous hyphal networks, which support the formation of a cohesive char layer that slows heat penetration.

All formulations were combustible but did not sustain flames once the heat source was removed and produced little smoke. Cotton ignition occurred only in some of the thicker specimens, likely due to slower heat dissipation. These trends are consistent with results reported in earlier studies (Dias, Jayasinghe, and Waldmann, 2021; Liu et al., 2019; Sharma and Sumbria, 2022), which also noted that mycelium tends to char rather than burn, leading to reduced flame spread and lower heat release than is typical for synthetic foams. When compared with the flame spread index referenced in EN 13501-1:2018, the composites fall within Class B (0–25), indicating comparatively good resistance to flame propagation under the test conditions used. Wool-reinforced specimens again performed the best, followed by the control samples, while silica-containing composites consistently showed weaker performance. Taken together, the results indicate that combining mycelium with natural fibres such as wool can improve fire resistance relative to untreated mycelium and silica-modified variants.

These observations are in line with previous research by Jones et al. (2018), which reported that mycelium composites exhibit inherent resistance to ignition due to their charring behaviour. Future studies should include standardized fire testing protocols, explore additional additive combinations, and examine how these materials could be integrated into insulation or panel systems to improve overall fire performance. Table 1 summarises the comparative results obtained under the direct-flame conditions used in this study.

Table 1 –Comparative flame exposure performance of mycelium-based composites under direct flame conditions

Specimen Group	Fabrication Method	Scale	Observations regarding fire exposure	Time to endpoint (seconds)
MBC^{S}	Method II (mold-grown)	Small-scale	Rapid structural breakdown; reduced char cohesion	720
MBC^{W}	Method II (mold-grown)	Small-scale	Maintained integrity; stable char formation	>2100
MBC^{I}	Method I (block-grown)	Large-scale	Developed external char; delayed failure	1020

MBC^{II} (control group)	Method II (mold-grown)	Small-scale	Progressive charring; no sustained flaming	1200

3.5 Microstructural Observation.

SEM analysis showed mycelium uniformly coating all composites (Figure 2). Silica-containing samples had a sparser mycelial network (a), while wool-enhanced and block-grown specimens displayed dense, well-developed mycelial filaments (b, c). Sparse networks in silica samples likely contributed to their lower fire resistance, suggesting that silica should be added after filament establishment.

Block-grown specimens promoted better mycelial skin development (d), though thicker samples may reduce fire performance. Core regions generally had lower hyphal density, limiting mechanical strength, which could be improved via extended colonization or forced airflow. Fiber orientation was irregular, with average hyphae ~1.3 µm in diameter, consistent with previous studies (Appels et al., 2019; Gou et al., 2021; Aiduang et al., 2022; Islam et al., 2017).

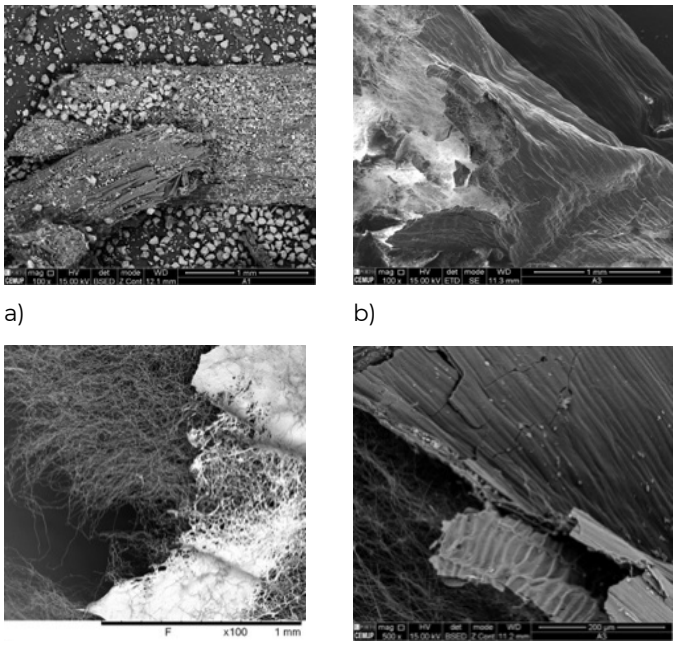

Figure 2 –SEM analyses of mycelium utilizing silica (a), wool (b) as additives, and default mycelium.

4. Conclusions

This study examined how sheep wool, silica, and fabrication method influence the performance of mycelium-based composites produced from Ganoderma lucidum grown on birch woodchips. The results show that variations in additives and growth conditions lead to clear differences in density, microstructure, thermal behaviour, mechanical strength, and fire resistance. Block-grown samples (Method I) reached higher densities (around 200 kg/m^3) and developed a continuous external mycelial layer, while mold-grown

samples (Method II) were lighter (around 140 kg/m³) and showed less developed surfaces, indicating that growth scale and confinement affect hyphal network formation.

Thermal conductivity values between 0.059 and 0.066 W/m·K confirm suitability for non-structural insulation applications. As expected for low-density porous composites, compressive strengths remained modest (0.13–0.47 MPa), appropriate for lightweight interior panels or insulation boards rather than load-bearing uses. Fire behaviour showed the most pronounced differences: wool-reinforced specimens resisted direct flame exposure for more than 2100 seconds, while silica-modified composites lasted about 720 seconds. These results suggest that natural fibres support more cohesive char formation and more stable thermal degradation. SEM images confirmed this difference, showing continuous hyphal networks in wool-based composites and disrupted filaments in silica variants.

To sum up, the findings demonstrate that both additive type and fabrication method play a significant role in determining the structural development and performance of mycelium-based composites. Wool proved to be the most effective additive for improving fire resistance, and block-grown samples offered advantages in surface consolidation and mechanical uniformity. Future studies should include standardized fire classification tests, more extensive thermal characterization—particularly specific heat capacity—and refinements to the growth process to improve internal colonization and reduce sample-to-sample variability.

Abstract: *Sargassum* is a marine macroalgae that, despite its photosynthetic capacity, has exhibited excessive proliferation and recurrent strandings along the Brazilian coastline, leading to significant environmental, social, and economic impacts. This scenario has intensified the search for sustainable strategies to valorise this biomass. In this context, Compressed Earth Blocks (CEB) stand out as a low-impact construction material, closely associated with circular economy principles and the reduction of CO_2 emissions. The incorporation of Sargassum into CEB emerges as a promising pathway for biomass reuse, with potential for carbon sequestration and waste reduction. This study aims to analyse the impact of adding *Sargassum* on the durability of CEB stabilised with different Portland cement contents (5%, 7%, and 10%, by mass), and to assess the technical feasibility of incorporating 2.5%, 5%, 7.5%, and 10% *Sargassum* by volume. The experimental programme involved moulding CEB with various formulations and assessing durability using the wire brush test, a method widely employed to simulate surface degradation by abrasion. Throughout the test cycles, moisture variation and cumulative mass loss were monitored. The results demonstrated that cement stabilisation is essential for incorporating *Sargassum*. In mixtures containing 5% cement, the maximum viable *Sargassum* content was 2.5%, whereas mixtures with 10% cement allowed incorporation of up to 7.5% biomass while maintaining satisfactory durability. Increasing cement content significantly reduced mass loss and volumetric instability, thereby enabling *Sargassum* valorisation without compromising CEB performance. Future work will include mechanical testing, microstructural analyses, and life cycle assessment to support ecodesign decisions and evaluate the environmental impact of each formulation.

Keywords: *Sargassum* biomass, Algae, CEB, Wire brush test.

1. Introduction

In 2015, the United Nations established the Sustainable Development Goals (SDGs), including a target to significantly reduce greenhouse gas emissions by 2030 (United Nations, 2015). In this context, the Intergovernmental Panel on Climate Change (IPCC) highlights urban systems as key actors in achieving this objective. The construction sector, responsible for approximately 37% of global operational energy consumption and CO_2 emissions, plays a particularly critical role. Significant reductions can be achieved throughout the building life cycle, including the design, construction, retrofit, use, and end-of-life stages (IPCC, 2023).

Within the design and construction phases, a promising strategy is the incorporation of locally available residues, by-products, and biomass into construction materials, taking advantage of the sector's high capacity to absorb large volumes of raw materials (Fagundo-Mollineda et al., 2026).

In the Brazilian Amazon coastal region, for instance, *Sargassum* represents an abundant seasonal biomass. *Sargassum* (C. Agardh) is a pelagic macroalga belonging to the class of brown algae (Rosado-Espinosa et

al., 2020). While it contributes to marine biodiversity and carbon dioxide (CO_2) sequestration during its growth (Gouvêa et al., 2020), its biomass has increased significantly in recent decades (Xiao et al., 2020).

The causes of this proliferation remain debated in the scientific literature. Nutrient enrichment is among the most frequently cited hypotheses; however, no definitive consensus has been reached regarding the factors driving this phenomenon (Wang et al., 2019). The decomposition of *Sargassum* in coastal zones increases the concentration of organic matter in the water, reducing light penetration and oxygen levels, and potentially releasing toxic gases such as hydrogen sulphide and ammonia (López-Contreras et al., 2022), as well as heavy metals such as arsenic (Fagundo-Mollineda et al., 2026). In addition, the accumulation of biomass on beaches negatively affects tourism and fisheries, generating socio-economic impacts and substantial public costs for its removal. For these reasons, *Sargassum* proliferation and beach stranding have been considered a new type of natural disaster (Robledo et al., 2021).

Despite these challenges, *Sargassum* remains a largely underutilised biomass with potential for value-added applications, circular economy strategies, and long-term CO_2 sequestration. Investigating valorisation pathways for this biomass is therefore essential to support effective management strategies and public policies and to strengthen the resilience of coastal communities affected by this phenomenon.

The incorporation of *Sargassum* into low-impact construction materials, particularly earthen construction systems, represents a promising approach to both reducing the environmental impacts of the construction sector and promoting sustainable biomass utilisation. Earthen construction techniques have gained renewed scientific interest in recent decades (Beckett et al., 2020) and are increasingly being adopted in contemporary building projects (Gharbage et al., 2025). Among these techniques, compressed earth block (CEB) represents a technological advancement over traditional adobe, as it is produced by compacting a mixture of soil, stabilisers, and water under pressure.

Despite their environmental advantages and favourable thermal and acoustic performance, the wider adoption of earthen construction remains limited due to susceptibility to water absorption and reduced long-term durability, particularly under aggressive environmental conditions (Turco et al., 2025). Failures in earthen architecture are therefore often associated with durability issues when materials are exposed to water (Morel et al., 2012).

Although the exposure of masonry to water can be mitigated through design strategies (such as wide eaves, raised foundations, protective coatings, waterproofing, and physical barriers) the durability of the material must still be ensured (ABNT, 2022; NZS, 2020). In this context, the assessment of the durability of CEB is essential, particularly in regions with high rainfall (Elahi et al., 2020).

Beckett, Jaquin and Morel (2020), in a literature review, present various tests used to assess the durability of earthen materials based on their interaction with water. Complementarily, Panagiotou et al. (2022) analyse water–material interaction mechanisms throughout the service life and the associated quantification methods.

Both studies highlight that climate-induced phenomena play a decisive role in the degradation of earthen masonry. The main durability assessment methods identified include accelerated erosion test, the wire brush test, and the ratio between dry and wet strength. Among these, the wire brush test stands out as a widely adopted method, standardised by several norms, including ASTM D559 (ASTM, 2012), IS 4332-4(IS, 1968), and NBR 13554 (ABNT, 2012).

In this context, incorporating biomass such as *Sargassum* into CEB requires technical validation to ensure that composite performance is not compromised. Improving the engineering properties of CEBs is thus essential to guarantee adequate structural performance, enhanced durability, and practical applicability. Accordingly, this study aims to evaluate the effect of *Sargassum* incorporation on the abrasion resistance of cement-stabilised CEBs using the wire brush test as an indicator of material durability. In addition, the study seeks to contribute to the optimisation of the product's ecodesign and to anticipate potential implications for its application in masonry systems.

2. Materials

2.1 Soils

For this study, a mixture of two soils was used, as neither soil alone exhibited a suitable particle-size distribution to produce CEB. The soils were collected from a site in a tropical region of Brazil, characterised by the presence of both the Atlantic Forest and *Cerrado* biomes (Figure 1). The soils mixtures were characterised in accordance with applicable Brazilian standards. As shown in Table 1, the particle size distribution exhibited a sand content slightly above the range recommended by CRATerre (2000), while the liquid limit was slightly lower. Nevertheless, both parameters remain within the limits established by national standards. X-ray diffraction analysis indicated that quartz is the predominant mineral in the soil mixture, with kaolinite identified as the main clay mineral.

Table 1 - Summary of soil mixture characterisation.

Sample	Granulometry		Specific Gravity (g/cm^3)	Atterberg Limits			Proctor Test		CS (MPa)
	Clay+Silt (%)	Sand (%)		LL (%)	PL (%)	PI (%)	MDD (kg/m^3)	OMC (%)	
Soil mixture	25.3	74.7	2,678	20	15	5	1979	12.46	1.58
Methodology	NBR 7181		Helium gas intrusion	NBR 6459 and 7180			NBR 12023		Axial compression
NBR 8492 and 10833 Limits	10-50	-	-	≤45	-	≤18	-	-	≥2
CRATerre Limits	10-30	≤70	-	25-50	-	03-10	1700-2200	≤15	≥2

Legend: LL = Liquid Limit, PL = Plastic Limit and PI = Plasticity Index, MDD = Maximum dry density, OMC = Optimum moisture content, CS = compressive strength

2.2 Cement

The Brazilian CPII-F 32 Portland cement (equivalent to ASTM Type I/II) was used as a stabiliser for CEB. Composed of Portland clinker, gypsum, and 6–10% limestone filler, it enhances workability and dimensional stability while reducing clinker content and CO_2 emissions. With a 28-day strength class of 32 MPa and a specific gravity of 3050 kg/m^3, it was selected due to its availability in the Amazon coastal region.

2.3 Sargassum

The Sargassum used in this study was collected in March 2025 from the Brazilian Amazon coastal region. The collected biomass was composed of about 10% *S. fluitans*, 15% *S. natans I*, and 80% *S. natans VIII*. Following collection, the biomass samples were washed with seawater to remove sand and subsequently

air-dried under tarpaulins with sun exposure. After drying, the material was shredded and stored under moisture-controlled conditions.

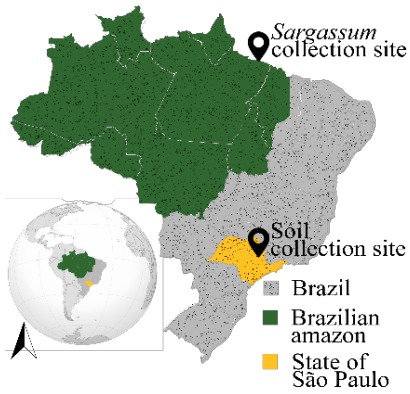

Figure 1 - Brazil and collection site.

It is important to note that fresh *Sargassum* found on beaches typically contains approximately 85% water by mass, owing to its high-water absorption capacity. For this reason, the drying stage was essential to prevent biomass degradation, preserve its integrity, and enable its use in construction applications.

To assess the toxicity of *Sargassum*, a sample was subjected to leaching and solubilisation tests in accordance with NBR 10005 and NBR 10006 (ABNT, 2004c, 2004b), and classified according to NBR 10004 (ABNT, 2004a). The results indicate that the biomass acts as a bioaccumulator of metals and organic compounds, reflecting marine environmental conditions and potential anthropogenic influences. No parameters exceeding regulatory limits were detected in the leachate extract.

In contrast, the solubilised extract exhibited a predominance of inorganic ions, including fluoride (11.3 mg/L), chloride (730 mg/L), sulphate (207 mg/L), and sodium (221 mg/L), characterising a highly saline solution. Notably, dissolved arsenic was detected at 0.453 mg/L, exceeding the drinking water limit (0.01 mg/L), indicating a potential toxicological risk, acording to NBR 10004 (ABNT, 2004a). The elevated concentrations of arsenic and sodium resulted in the classification of the material as Class II-A – Non-inert, corroborating studies reporting high arsenic contents in *Sargassum* (Fagundo-Mollineda et al., 2026).

The fact that only the solubilised extract exceeded regulatory limits suggests that these compounds may be released under prolonged contact with water, without exhibiting the typical behaviour of hazardous waste under more aggressive leaching conditions.

3. Experimental program

3.1 Mix composition and moulding process

In this study, to assess the impact of *Sargassum* incorporation on the durability of stabilised CEB, three control formulations without biomass addition were analysed, containing different cement contents (5%, 7%, and 10% by mass). The addition of cement aimed to enhance the material's durability and enable higher levels of *Sargassum* incorporation. For standardisation purposes, these formulations were designated as C5, C7, and C10.

In addition, four *Sargassum* contents (2.5%, 5%, 7.5%, and 10% by volume) were evaluated. The biomass was incorporated on a volumetric basis due to its significantly lower density compared to the soils. The nomenclature of the formulations was defined based on the cement content, followed by the letter "S" and the corresponding volumetric percentage of *Sargassum*.

For clarity, Table 2 - Formulation compositions and material contents.Table 2, summarises the compositions and materials considered in this study.

Table 2 - Formulation compositions and material contents.

	Materials		
Formulations	**Soil mixture (%)**	**Cement (%)**	***Sargassum* (%)**
C5	100	5	0
C5S2.5	100	5	2.5
C5S5	100	5	5
C5S7.5	100	5	7.5
C5S10	100	5	10
C7	100	7	0
C7S2.5	100	7	2.5
C7S5	100	7	5
C7S7.5	100	7	7.5
C7S10	100	7	10
C10	100	10	0
C10S2.5	100	10	2.5
C10S5	100	10	5
C10S7.5	100	10	7.5
C10S10	100	10	10

To mould the specimens, the oven-dried and disaggregated soils were mixed with cement. The *Sargassum* was pre-wetted to prevent water absorption from the mixture during moulding, owing to its high-water absorption capacity, and was subsequently incorporated into the blend. The mixture was mixed for 3 minutes with the gradual addition of water. The water content was adjusted to 2.5% below the optimum moisture content (OMC).

The specimens were moulded by mechanical compaction in three layers in a cylindrical mould (⌀ 5 cm × 10 cm), with scarification between layers to ensure proper bonding (Figure 2). The mass of each layer, as well as of each specimen, was measured to maintain the maximum dry density (MDD) obtained from the Proctor test.

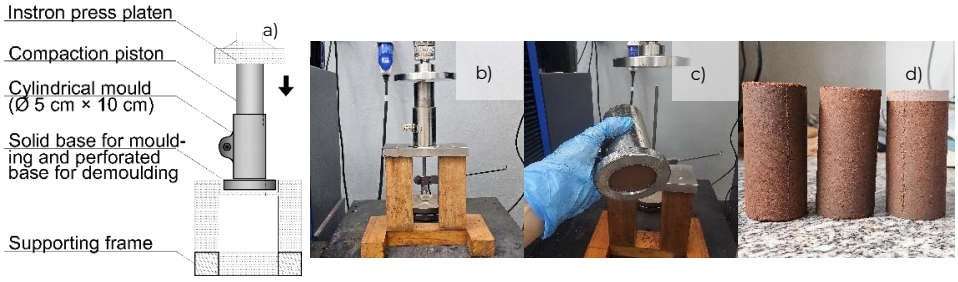

Figure 2 - Moulding process: (a) schematic of the system; (b) compaction; (c) perforated base for demoulding; (d) specimens.

After moulding, the specimens were cured for 28 days in sealed plastic bags to preserve moisture and promote cement hydration. Subsequently, they were oven-dried at 35 °C for 48 hours to reduce residual moisture.

3.2 Wire brush test

The wetting and drying test was conducted in accordance with NBR 13554 (ABNT, 2012), which is similar to ASTM D559 (ASTM, 2012), differing only in the number of wetting–drying cycles. While ASTM D559 specifies 12 cycles, NBR 13554 requires six. Minor adjustments to specimen dimensions were made due to laboratory constraints.

Cylindrical specimens measuring 5 cm in diameter and 10 cm in height were used, instead of the standard dimensions of 10 cm in diameter and 12.7 cm in height. The specimens were immersed in water for 5 hours and subsequently oven-dried at 71 °C for 42 hours. The lateral surfaces were brushed using a steel wire brush, ensuring that the entire surface was covered once (approximately 1.5 kg of applied force, 15 strokes), while the top and bottom faces received four additional strokes (Figure 3).

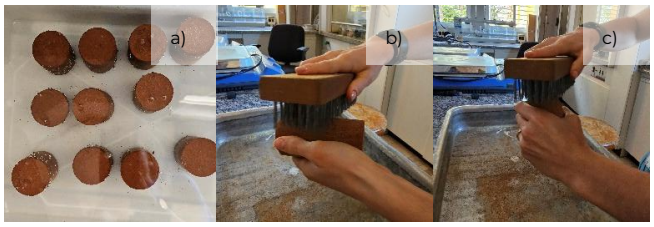

Figure 3 - Wire brush test procedure: (a) immersion in water; (b) lateral surface brushing; (c) top surface brushing.

The cycle was repeated six times. Moisture variation was calculated according to Equation 1.

$$Mv = \frac{(im - ms)}{im} x100 \quad (1)$$

Where: *Mv* is the moisture variation, expressed as a percentage (%);

im is the initial moisture content of the specimen, expressed in grams (g);

ms is the moisture content of the specimen at each stage, expressed in grams (g).

Mass loss was calculated according to Equation 2.

$$Ml = \frac{(idm - \mathrm{fdm})}{idm} x100 \quad (2)$$

Where: *Ml* is the mass loss, expressed as a percentage (%);

idm is the initial dry mass, expressed in grams (g);

fdm is the final dry mass, expressed in grams (g).

4. Results

The moisture variation of formulations containing 5% cement over six wetting–drying cycles is shown in Figure 4. Overall, there was a notable reduction in moisture variation after the first cycle. However, only formulations C5 and C5S2.5 remained stable in subsequent cycles, indicating a strong ability to release the moisture absorbed during the immersion stage.

In contrast, formulation C5S5 showed inconsistent adsorption and desorption values throughout the cycles, although similar values were observed between both stages in the final cycle. Formulations C5S7.5 and C5S10 did not complete the test, failing during the third and second cycles, respectively.

The inability of these formulations to complete all cycles is due to material degradation during the adsorption, desorption, and brushing stages, reflecting their lower resistance to moisture fluctuations and abrasion. This behaviour is a key finding in the assessment of the hygroscopic durability of the studied formulations.

In fact, the high-water retention capacity of earthen materials depends on the porous and microporous structure of the soils, as well as on the physic-chemical affinity between clays and water (Champiré et al., 2016; Giuffrida et al., 2019). In this case, kaolinite, which exhibits lower affinity compared to other clay minerals, is predominant. However, the results suggest that *Sargassum* also plays a role in this water retention capacity.

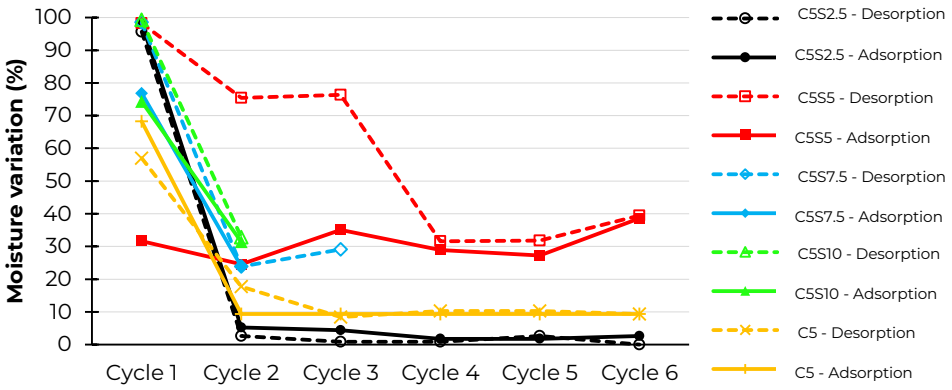

Figure 4 - Moisture variation: formulations with 5% cement.

For formulations containing 7% cement (Figure 5), all formulations exhibited relatively similar behaviour throughout the cycles, with an initial reduction in moisture variation followed by stabilisation in subsequent cycles. Notably, the formulation incorporating 2.5% *Sargassum* (C7S2.5) showed a lower final moisture variation than the reference mixture without biomass addition (C7), suggesting that a low *Sargassum* content may help reduce the hygroscopic variation of the composite.

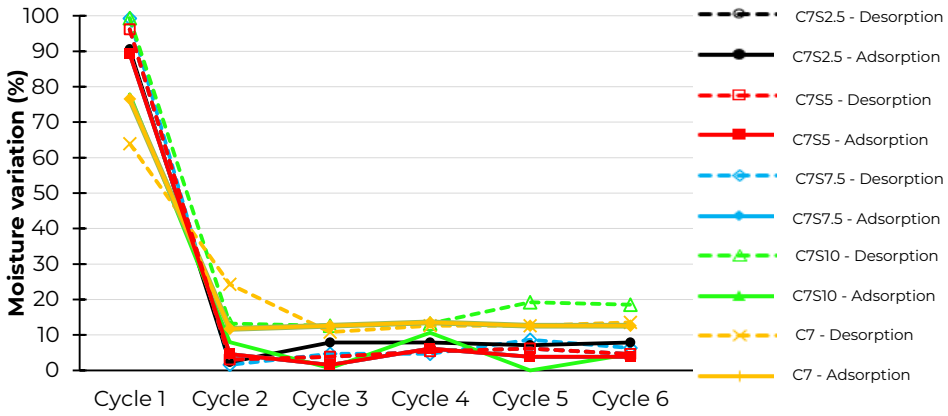

Figure 5 - Moisture variation: formulations with 7% cement.

For 10% cement (Figure 6), the formulations incorporating *Sargassum* did not exhibit significantly greater instability than the reference mixture (C10). Even at higher biomass contents (7.5% and 10%), the high content of cement proved to be effective in controlling water absorption and maintaining material integrity throughout the cycles.

These results indicate that stabilisation with 10% cement can effectively mitigate the impact of *Sargassum* incorporation on the hygroscopic durability of CEB, enabling biomass addition without compromising performance under repeated wetting–drying cycles. However, it should be noted that further durability tests should be conducted to deepen the understanding of the long-term behaviour of these materials.

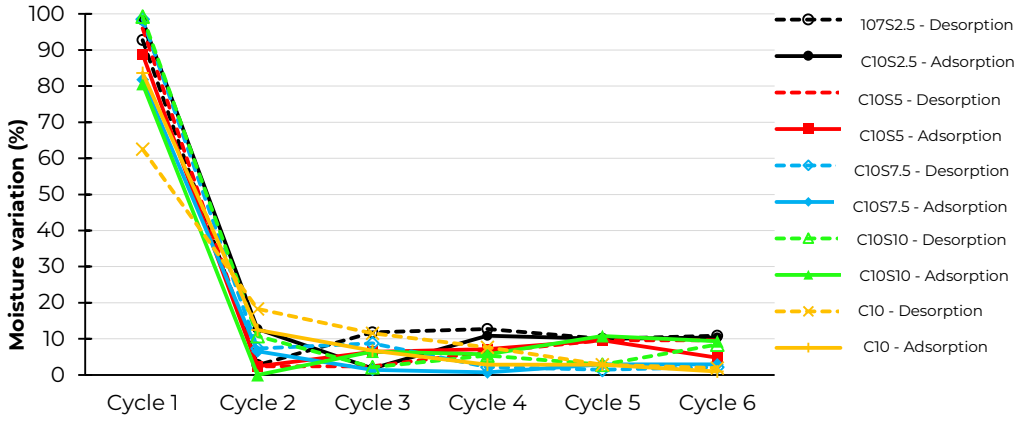

Figure 6 - Moisture variation: formulations with 10% cement.

During the immersion stage (5 hours), bubble formation was observed in the water (Figure 7). This behaviour, associated with the release of air entrapped within the pore structure, was more pronounced in formulations with higher *Sargassum* incorporation.

A possible explanation is the increase in material porosity due to the volumetric shrinkage of *Sargassum* during drying. This shrinkage may generate additional voids within the matrix, facilitating water ingress and the subsequent expulsion of air during immersion. This phenomenon may also help to explain the higher water absorption observed in mixtures containing *Sargassum*, in addition to the inherent hydrophilicity of the biomass, as previously discussed.

Figure 7 - Bubble formation during specimen immersion.

With regard to mass loss after six wetting–drying cycles, according to NBR 13553 (ABNT, 20012) and as also reported in the literature (Beckett et al., 2020), formulations are considered acceptable when mass loss remains below 14%. As shown in Table 3, formulations C5S5, C5S7.5, C5S10, C7S7.5, and C7S10 exceeded this threshold and are therefore not considered suitable. In contrast, all formulations containing 10% cement exhibited mass loss values below the specified limit.

Table 3 - Formulations and mass loss results.

Mass loss (%)					
C5	1.83 ± 0.5	**C7**	0.97 ± 0.2	**C10**	0.97 ± 0.4
C5S2.5	6.56 ± 0.7	**C7S2.5**	4.35 ± 1.0	**C10S2.5**	1.00 ± 0.3
C5S5	-	**C7S5**	13.41 ± 3.1	**C10S5**	6.02 ± 1.4
C5S7.5	-	**C7S7.5**	23.40 ± 3.1	**C10S7.5**	7.05 ± 2.3
C5S10	-	**C7S10**	31.24 ± 2.8	**C10S10**	10.38 ± 2.1

However, it is important to note that NBR 13554 (ABNT, 2012) specifies only half the number of cycles established in international standards, as previously discussed. In this context, there is evidence that some formulations with higher *Sargassum* contents, although exhibiting satisfactory performance after six cycles, may not maintain this behaviour over twelve cycles. These findings are consistent with previous studies that have also adopted six-cycle testing protocols (Bessa et al., 2018; Oliveira et al., 2025).

5. Conclusions

This study investigated the influence of incorporating *Sargassum* on the hygroscopic durability of cement-stabilised CEB using wetting-drying-brush cycles and mass-loss analysis. The results demonstrate that *Sargassum* significantly affects the moisture behaviour and durability of the material, primarily due to its hygroscopic nature and its contribution to increased porosity within the matrix.

Formulations with low cement content (5%) exhibited poor durability performance, particularly at higher *Sargassum* contents, with some formulations failing to complete the test cycles. Intermediate cement content (7%) led to more stable behaviour, although durability remained sensitive to increasing biomass content. In contrast, formulations containing 10% cement showed consistent performance across all *Sargassum* contents, with mass loss values remaining below the normative threshold and no significant instability observed during cyclic exposure.

These findings highlight a clear trade-off between environmental benefits and technical performance. While *Sargassum* represents a promising bio-based resource for sustainable construction, its incorporation must be carefully optimised to avoid compromising durability. The results indicate that adequate cement stabilisation plays a critical role in mitigating the adverse effects of biomass addition, particularly regarding moisture resistance and structural integrity.

Furthermore, the observation that some formulations performed satisfactorily under six wetting–drying cycles but may not withstand more severe conditions suggests that current testing standards may not fully capture long-term durability behaviour. Therefore, further investigations, including extended durability testing and life cycle assessment, are essential to support the development of robust and environmentally optimised CEB formulations.

In real construction scenarios, formulations with low cement content and high biomass incorporation are likely to exhibit poor resistance to moisture exposure, making them unsuitable for external applications or humid climates. Conversely, higher cement contents (e.g., 10%) enable the incorporation of *Sargassum* without compromising durability, allowing for its application in load-bearing or non-load-bearing masonry under typical environmental conditions, particularly when combined with basic protective design measures such as adequate roof overhangs and surface treatments.

The adoption of optimised Sargassum-based CEB may contribute to reducing environmental impacts, promoting circular economy practices, and supporting the valorisation of coastal biomass, especially in regions affected by large-scale Sargassum accumulation.

Abstract: Concrete is widely used in the construction industry due to its advantages in terms of workability, strength, and durability. However, its brittle nature favors the formation of cracks, compromising performance and reducing the service life of structures. As an alternative to conventional repair methods, often associated with high environmental impact, microbially induced calcium carbonate ($CaCO_3$) precipitation has emerged as a sustainable strategy. In this context, the present study aimed to evaluate the influence of the oomycete *Pythium aphanidermatum* on the surface treatment of cracks in previously carbonated concrete matrices. Specimens with a characteristic compressive strength of 25 MPa were cast, including natural samples and others artificially carbonated through 30 wetting–drying cycles. Subsequently, pre-cracks corresponding to 85% of the maximum strength were induced in the carbonated specimens. The specimens were subjected to three treatments: T1 (reference), T2 (surface application of water), and T3 (biological surface application), with a dosage of 2.50 mL/cm of crack. Mechanical strength was evaluated 28 days after treatment. The results did not indicate statistically significant differences among the treatments, suggesting that a single application is not sufficient to promote relevant mechanical recovery. However, microstructural analyses by SEM-EDS evidenced microbial development and the formation of hyphal structures in specimens treated with T3, indicating potential activity as nucleation sites for $CaCO_3$. Although no significant recovery in strength was observed, the study demonstrates advances in the use of biological approaches for crack treatment, highlighting the need to optimize the number of applications to enhance the sealing effect and mechanical recovery.

Keywords: Biological repair, concrete, accelerated carbonation, *Pythium aphanidermatum*.

1. Introduction

In recent years, advances achieved through biotechnology have enabled innovation across different fields, including the construction industry (Meyer et al. 2020). Studies have shown that the use of microorganisms presents potential in sustainable construction, being applicable in soil stabilization, wastewater treatment, and the development of new materials (Majib et al. 2025). These advances have also demonstrated the possibility of applying biotechnology in repair processes and/or crack sealing in cementitious matrices (Van Wylick et al. 2021).

Currently, a variety of products are available for the surface repair of concrete structures, commonly petroleum-derived epoxies and chemical compounds, whose application entails a certain negative impact on the environment and human health (Jonkers et al. 2010; Vijay et al. 2017; Tyagi et al. 2024). This effect can be reduced through the application of microorganisms, since the natural metabolic processes of certain species lead to the precipitation of specific crystals that can act as crack sealants in cementitious matrices. For crack closure, the basic principle consists of incorporating microorganisms capable of promoting the formation of calcium carbonate ($CaCO_3$). The technique commonly applied for this process is known as Microbial Induced Carbonate Precipitation (MICP) (Zhang et al. 2024; Sun et al. 2021), which typically achieves this precipitation of $CaCO_3$ crystals through a ureolytic mechanism. This mechanism involves the use of urea, which is decomposed by the microorganism, producing ammonia and carbonate; the latter is capable of reacting with free calcium ions in an alkaline medium, resulting in the formation of $CaCO_3$. Finally, the formed crystals are deposited on the walls of microbial cells or hyphae due to the nucleation effect (Ojha et al. 2025).

The literature reports various microorganisms, such as bacteria, fungi, microalgae, and some oomycetes, that exhibit potential for application in cementitious matrices, promoting crack closure through $CaCO_3$ precipitation (Khushnood et al. 2022; Van Wylick et al. 2024; Cayo Chileno et al. 2025). Despite the advances achieved, there are still challenges that limit their application. Among the main ones are the conditions of cementitious matrices, which represent a hostile environment for microbial development, as nutrients are not available, moisture is low, and the medium is generally highly alkaline (Jonkers et al. 2010; Ivaškė et al. 2023). However, many structures exposed to the natural environment undergo carbonation processes, in which the penetration of carbon dioxide (CO_2) through the water present in the pores reduces the alkalinity levels of the cementitious matrix (Talukdar et al. 2012; Cui et al. 2015). This effect allows the evaluation of microorganisms capable of developing in media with alkalinity levels below pH 10.

The company Basilisk is one of the leading promoters of the application of microorganisms for surface crack treatment. Through its commercial products, such as Basilisk Self-Healing Repair Mortar MR3 and Basilisk Liquid Repair System ER7, the repair of cracks of approximately 2 mm has been demonstrated (Wiktor and Jonkers 2016). Other studies also report results related to crack closure (~1.5 mm) through surface treatments based on microorganisms, especially when evaluated under controlled laboratory conditions (Li et al. 2024; Sun et al. 2020). However, despite the advances and positive results reported in the scientific literature, further investigation is still required. In this regard, the present study aims to evaluate the mechanical recovery behavior of previously cracked concrete specimens treated with surface repair. The selected microorganism corresponds to an oomycete of the genus *Pythium* and species *aphanidermatum*, which has demonstrated potential for $CaCO_3$ precipitation (calcite and vaterite) through the ureolytic mechanism (Adl et al. 2012; Mesquita Júnior 2022; Cayo Chileno et al. 2025; Chileno et al. 2026). Concrete specimens were used as test samples, which were carbonated in order to simulate aged concrete and reduce the alkalinity level, thereby enabling microbial development as a surface treatment.

2. Methodology

2.1 Material characterization

2.1.1 Concrete components

A pozzolanic cement of type CP V-AR was used, whose properties comply with the requirements established in ASTM C595 (ASTM 2025). In order to determine its chemical composition, an X-ray fluorescence (XRF) analysis was performed. The main oxides identified are presented in Table 1.

Table 1 – Chemical properties of the cement

Parameter	CaO	SiO_2	Al_2O_3	Fe_2O_3	SO_3	MgO	K_2O	TiO_2	SrO	MnO	P_2O_5	ZnO
Cement	43.62	30.32	8.48	4.61	5.71	2.95	1.99	0.78	0.73	0.56	0.20	0.05

The particle size distribution of both aggregates was obtained through sieve analysis, following the procedure described in ASTM C136 (ASTM 2006). The results corresponding to the gradation curves of the fine and coarse aggregates are presented in Figure 1.

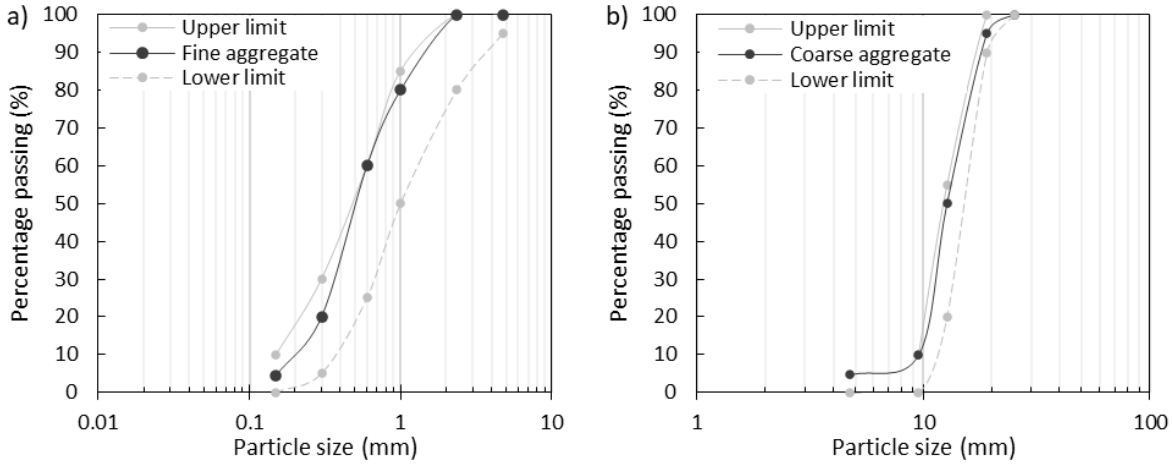

Figure 1 – Particle size distribution: (a) fine aggregate and (b) coarse aggregate

2.1.2 Microbial solution for surface treatment

The biological solution used to evaluate the self-healing process was prepared following the methodology reported in a previous study (Cayo Chileno et al. 2025; Chileno et al. 2026). The species *Pythium aphanidermatum* was employed, which was previously isolated to obtain spores with an approximate concentration of 10^{-5} cells/mL, suspended in a sterile saline solution.

Calcium acetate was used as the calcium source at a final concentration of 100 mM, while urea at 2% was used as the nitrogen source. Both compounds were dissolved in Potato Dextrose Broth (PDB), which acted as a nutrient medium for microbial development.

The spore concentration was determined by counting in a Neubauer chamber. Subsequently, microbial viability was verified through optical microscopy, evaluating active hyphal growth and the cytoplasmic integrity of the cells (Figure 2).

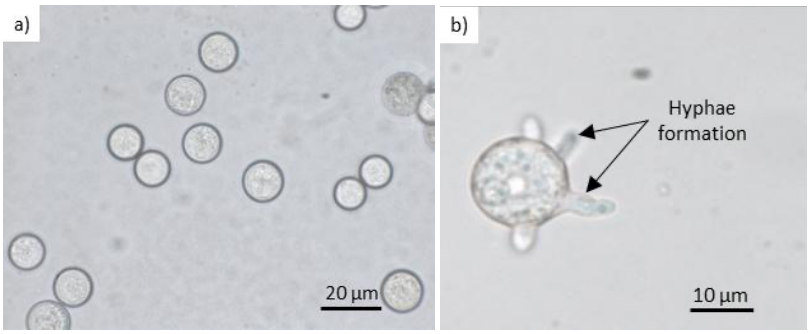

Figure 2 – Optical micrographs of *Pythium aphanidermatum*: (a) spores and (b) germination and hyphal formation

2.2 Composition of the concrete matrix

The concrete mix design was established with the aim of achieving a characteristic compressive strength of 25 MPa at 28 days. The preparation of the mixtures was carried out following the recommendations established by the Brazilian Association of Technical Standards (ABNT), particularly NBR 6118:2003 (ABNT 2023a) and NBR 14931:2004 (ABNT 2023b). The material proportions used for the concrete are presented in Table 2.

Table 2 – Concrete mix proportions with CP V-AR cement

Cement (kg)	Fine aggregate (kg)	Coarse aggregate (kg)	Water (L)	w/c
306	895	912	199	0.65

With this mix design, 16 cubic specimens with dimensions of 100 × 100 × 100 mm were cast. After completing the curing process for 28 days, the samples were classified into three experimental groups: non-carbonated (NC), carbonated (C), and carbonated for phenolphthalein control (F).

2.3 Experimental method

2.3.1 Compressive strength test

The mechanical properties of the specimens were evaluated through compressive strength tests conducted at 28 days of curing, following the procedure established in ASTM C39 (ASTM 2023).

The NC group was used to determine the maximum strength of the produced concrete and to verify whether the average strength obtained corresponded to the design value of approximately 25 MPa.

2.3.2 Carbonation process

After determining the initial strength, the remaining specimens were subjected to an accelerated aging process in order to induce carbonation of the cementitious matrix. The applied methodology was an adaptation of the procedure proposed in the literature (Toledo Filho et al. 2009). For this purpose, 12 specimens from group F were exposed to repeated cycles of water immersion for 24 hours followed by oven drying at 28 °C for 48 hours. A total of 30 cycles were performed to promote a significant level of carbonation in the specimens.

To determine the degree of carbonation of the specimens, a phenolphthalein test using a 2% solution was carried out. This procedure consists of cutting the specimen transversely and applying the reagent to the exposed surface.

2.3.3 Crack induction and repair treatments

Once the carbonation level was determined, three specimens from the NC group were again subjected to compressive testing to evaluate the residual strength of the carbonated concrete.

The remaining specimens were loaded up to approximately 85% of the recorded ultimate load in order to induce controlled crack formation. Subsequently, the pre-cracked specimens were divided into three experimental groups (n = 3): T1 (reference group, maintained under ambient conditions without treatment); T2 (samples subjected to surface application of water); and T3 (samples treated with the microbial solution). The T2 and T3 solutions were applied at a dosage of 2.50 mL per linear centimeter of crack.

2.3.4 Evaluation of mechanical recovery capacity

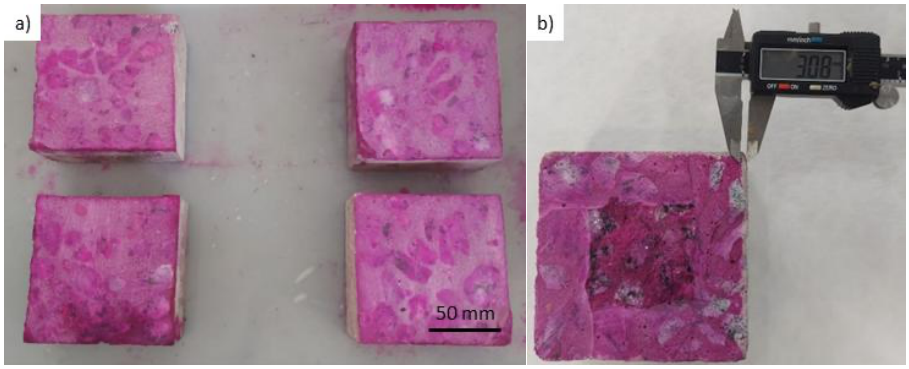
The efficiency of the repair process was evaluated through the percent regain in compression (PRC), calculated according to the methodology proposed in the literature (Khan et al. 2023), using Equation (1).

$$PRC = 1 - \left(\frac{S_u - S_{28}}{S_u}\right) x\ 100 \quad (1)$$

Where S_u corresponds to the compressive strength, and S_{28} corresponds to the compressive strength after the repair process.

3. Results

After 28 days of curing, the average compressive strength of the reference specimens (NC) was 24.12 ± 0.67 MPa, which is close to the design strength. Subsequently, the carbonation process was initiated. Figure 3a presents the degree of carbonation evaluated through the application of a phenolphthalein solution. Although the samples were subjected to a prolonged treatment of approximately 90 days (30 cycles), the designed concrete exhibited low permeability, which limited the diffusion of CO_2 into the matrix. As a consequence, a carbonation depth not exceeding 3.08 mm from the external surface toward the interior of the specimen was observed (Figure 3b).



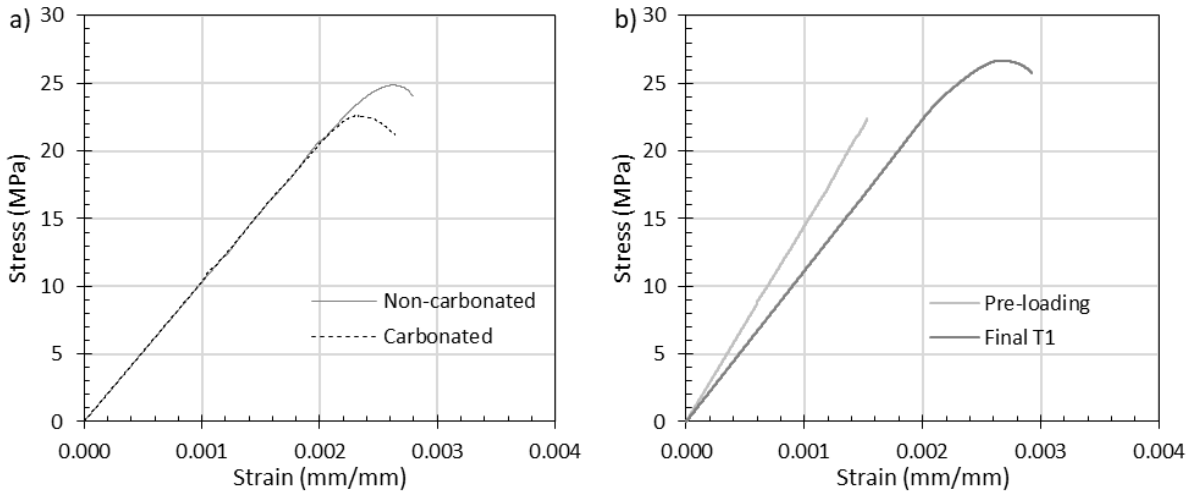


Figure 3 – Carbonation process: (a) control samples and (b) carbonation after 30 cycles

In the literature, this type of test is widely used to evaluate the durability performance of cementitious matrices. The application of a phenolphthalein solution allows the alkalinity level of the material to be visually identified: pigmented regions indicate pH values above 9–10, whereas non-pigmented zones reveal the penetration of external agents that have reacted with the cement hydration products. This phenomenon is mainly associated with the carbonation process, in which atmospheric CO_2 is transported through the water present in the pore structure, reacting with calcium-rich compounds and resulting in the formation of calcium carbonate ($CaCO_3$) (Rocha et al. 2025). These results indicate that matrices with higher porosity facilitate the ingress of aggressive agents, which may compromise the durability of cementitious systems. In particular, in the case of reinforced concrete, the reduction in pH associated with carbonation

may compromise the service life of the reinforcing steel; in the presence of hydrogen ions and oxygen, this condition promotes the initiation of corrosion processes, progressively affecting the structural integrity of the material (Chen et al. 2015).

Studies have reported that the carbonation process may induce an increase in the compressive strength of cementitious matrices (Rocha et al. 2025). This behavior was also observed in the present investigation (Figure 4), where the carbonated specimens (C) exhibited an increase in average strength from 24.12 to 25.06 MPa, corresponding to an approximate increase of 3.87%. However, this increase was not statistically significant (p-value = 0.7188). Despite this, the specimens were subsequently subjected to a pre-load corresponding to 85% of the average strength of group C (approximately 21.30 MPa). The incorporation of the carbonation process at this stage not only allows the simulation of aging conditions of the cementitious matrix but also enables the study of surface treatments based on microorganisms, which exhibit tolerance to pH ranges below 10. In particular, *Pythium aphanidermatum* has been reported to grow under alkaline conditions (pH between 9 and 11), in addition to showing potential to induce calcium carbonate ($CaCO_3$) precipitation (Cayo Chileno et al. 2025).

Figure 4a presents the stress–strain curves. It can be observed that, since the effect of carbonation was not significantly pronounced, the mechanical responses are concentrated within a narrow range of values, without showing relevant increases in either deformation capacity or strength. For the treated specimens, pre-load values close to 22 MPa were recorded, consistent with the mechanical behavior observed in the final curves. In the case of sample T1 (Figure 4b), a slightly more elastic behavior is identified compared to the pre-load condition, whereas in samples T2 and T3 (Figures 4c and 4d), the deformation capacity is similar to that initially induced. This behavior suggests that the combined effect of hydration, promoted by the different solutions used in T2 and T3, together with the exposure time, favored the rehydration of previously unreacted cement particles or those exposed during pre-loading. As a result, a deformational response comparable to the initial loading condition is obtained. Although no significant increase in load-bearing capacity relative to the reference state was observed, the results indicate the possible activation of hydration processes within the concrete matrix. This effect is reported in the literature as the autogenous self-healing process of cementitious matrices, in which cement particles may react upon contact with water (De Rooij et al. 2013; Mohamed et al. 2023).

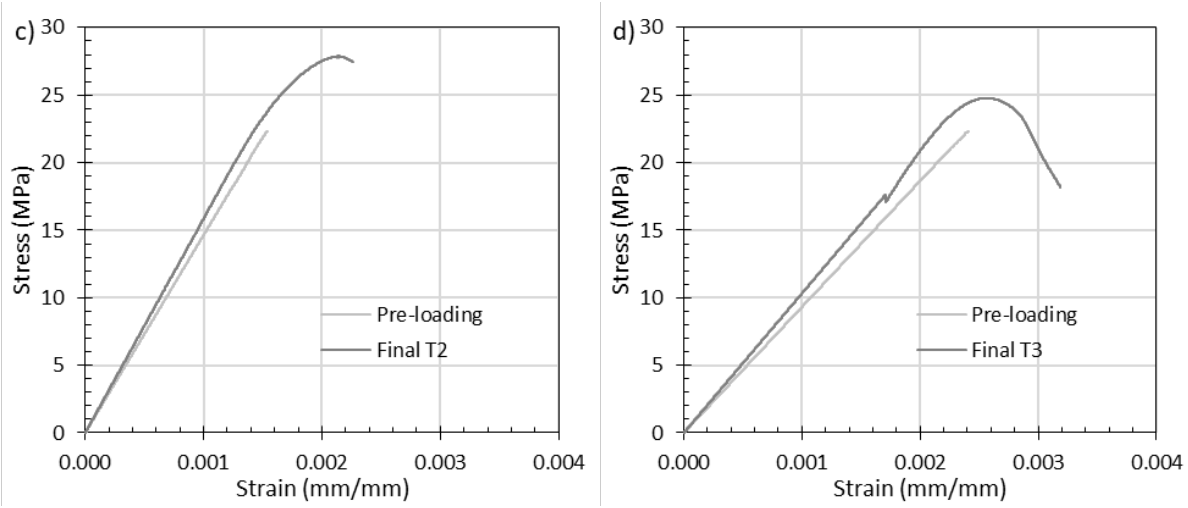

Figure 4 – Stress–strain curves obtained from compression tests: (a) reference matrix before and after carbonation; (b), (c), and (d) matrices treated with T1, T2, and T3, respectively

Figure 5 presents the percent regain in compression, considering as reference the average load of the carbonated specimens. The values corresponding to the pre-load (PT1, PT2, and PT3) are slightly above the projected level, indicating adequate consistency in the application of the loading protocol. Regarding the post-treatment recovery results (PRC), specimens T1 and T3 show values below 100%, evidencing the absence of effective mechanical recovery. On the other hand, treatment T2 reaches values slightly above 100%, suggesting the possible occurrence of a recovery effect in load-bearing capacity. However, the dispersion observed in the data indicates that this behavior was not uniform across all specimens and may have occurred in a localized manner. Finally, the ANOVA statistical analysis did not reveal a statistically significant difference (p-value = 0.3186 > 0.05).

In this context, the results suggest that a single application of 2.50 mL/cm of solution, used in treatments T2 and T3, is not sufficient to ensure consistent recovery of mechanical capacity. Therefore, there is still a need to optimize the application frequency of the treatment in order to achieve surface sealing effects and, consequently, significant load recovery.

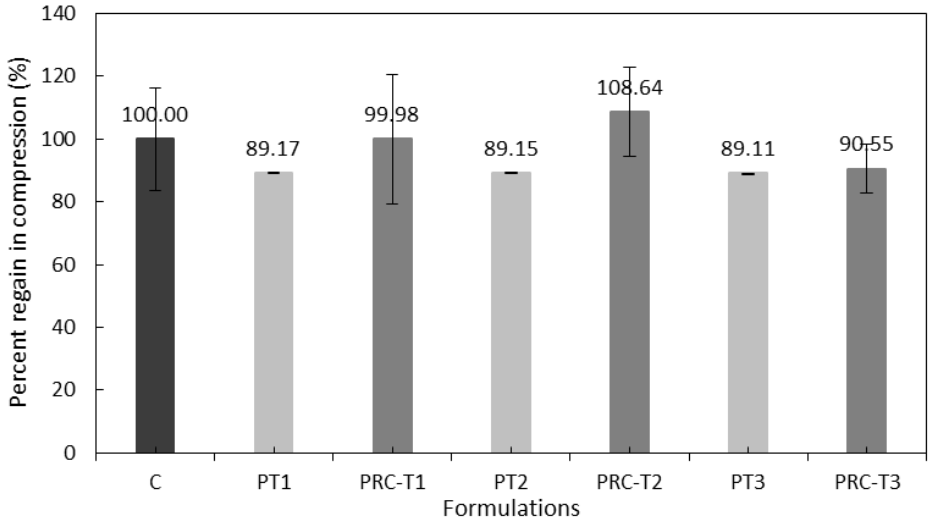

Figure 5 – Percent regain in compressive strength for the different formulations

At the microstructural level, *Pythium aphanidermatum* demonstrated not only its ability to induce $CaCO_3$ precipitation in the forms of calcite and vaterite, but also its capacity to develop within cracks in previously carbonated mortar matrices (Cayo Chileno et al. 2025). However, when evaluated in cement paste matrices, its development was null. Despite these pastes having been subjected to carbonation processes, no perceptible microbial growth was observed. This behavior may be attributed, on the one hand, to the greater difficulty of carbonation in cement pastes, which implies the maintenance of high alkalinity levels, and, on the other hand, to their lower porosity and higher impermeability, conditions that limit spore retention and, consequently, subsequent germination (Chileno et al. 2026).

In the case of the concrete analyzed in the present study, it is observed that the microstructure of the non-carbonated matrix (Figure 6a) is similar to that of treatments T1 and T2 (Figures 6b and 6c), being characterized by a typical cementitious matrix with the presence of hydration products, voids, and aggregates. In contrast, treatment T3 showed a microstructural modification associated with the formation of hyphae (Figure 6d), confirming the ability of the microorganism to develop in treated regions of previously carbonated specimens.

Although high degrees of carbonation, with extensive zones of pH below 9–10, were not achieved, *Pythium aphanidermatum* was able to develop from its spores, suggesting significant tolerance to moderately alkaline conditions and reinforcing its potential application in biomineralization strategies in cementitious matrices.

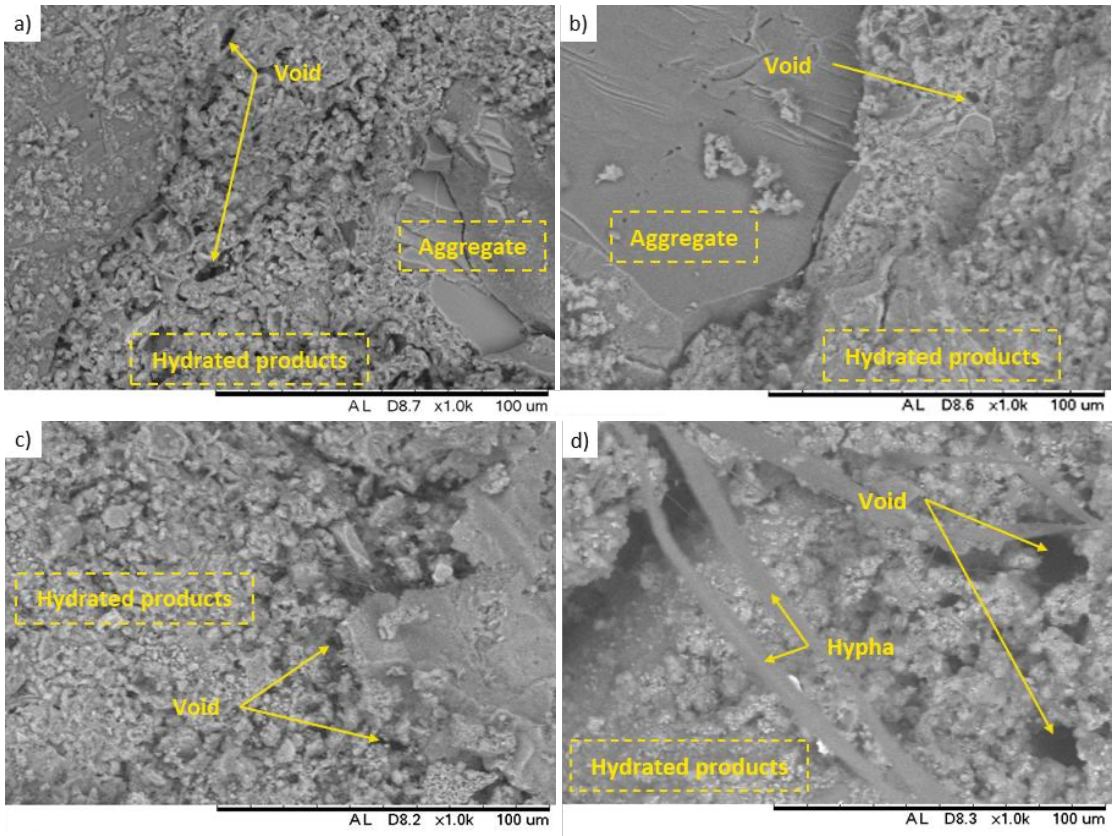

Figure 6 – SEM micrographs at 1,000× magnification: (a) carbonated matrix and (b), (c), and (d) matrix treated with T1, T2, and T3

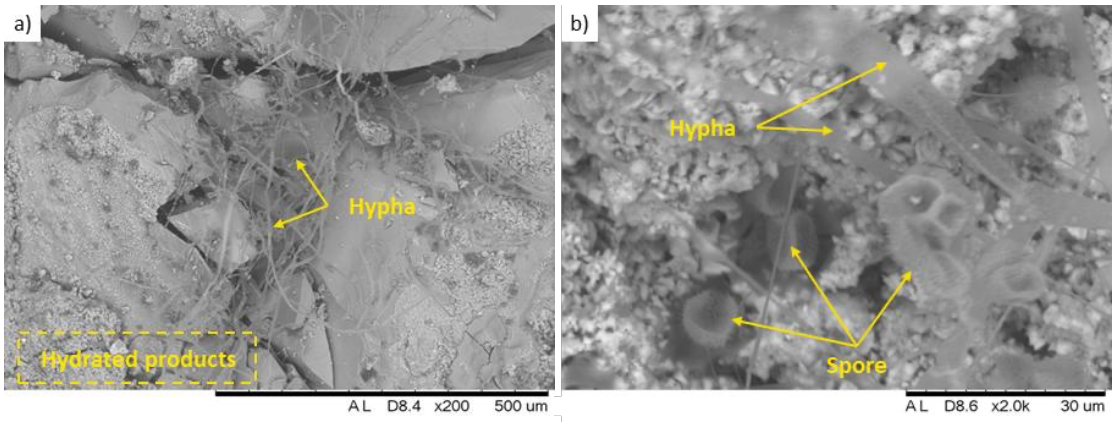
In other regions of the specimens, the presence of a well-defined mycelial network was identified (Figure 7a), a growth pattern not observed in the matrices corresponding to treatments T1 and T2, which allows this behavior to be attributed to the activity of *Pythium aphanidermatum*. Similarly, in Figure 7b, spores located in porous zones of the matrix are observed, suggesting that these regions favor spore retention and

subsequent microbial development. This effect has also been reported in recycled aggregates, which, due to their high porosity and absorption capacity, enabled the immobilization of fungal spores (Khan et al. 2023).

These findings support the proposal, indicating that the microorganism is capable of developing in cementitious matrices that exhibit a certain degree of porosity and carbonation. However, it is still not possible to precisely establish the number of applications required to achieve effective sealing based on $CaCO_3$ precipitation, highlighting the need for further studies focused on optimizing application conditions and maximizing treatment efficiency.



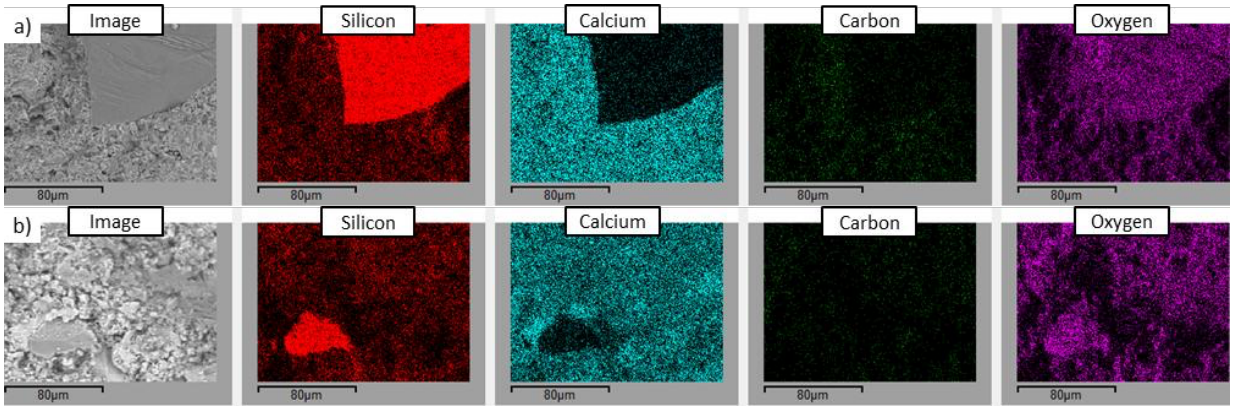


Figure 7 – SEM micrographs of matrix treated with T3: (a) 200× magnification and (b) 2,000× magnification

Additionally, an energy-dispersive spectroscopy (EDS) analysis was performed in order to identify the chemical elements present in the different samples. The carbonated reference matrix, as well as those corresponding to treatments T1 and T2 (Figures 8a, 8b, and 8c), show predominant signals of silicon, associated with aggregates, and calcium, corresponding to cement-derived compounds.

In contrast, in the matrix treated with T3 (Figure 8d), where the presence of hyphae was evidenced, a localized concentration of calcium is observed on their surface, with a slightly defined distribution. This behavior suggests that the composition of the microbial cell wall, rich in cellulose, acts as a nucleation site for calcium carbonate ($CaCO_3$) precipitation, favored by the availability of free calcium in the medium (Cayo Chileno et al. 2025; Ojha et al. 2025).

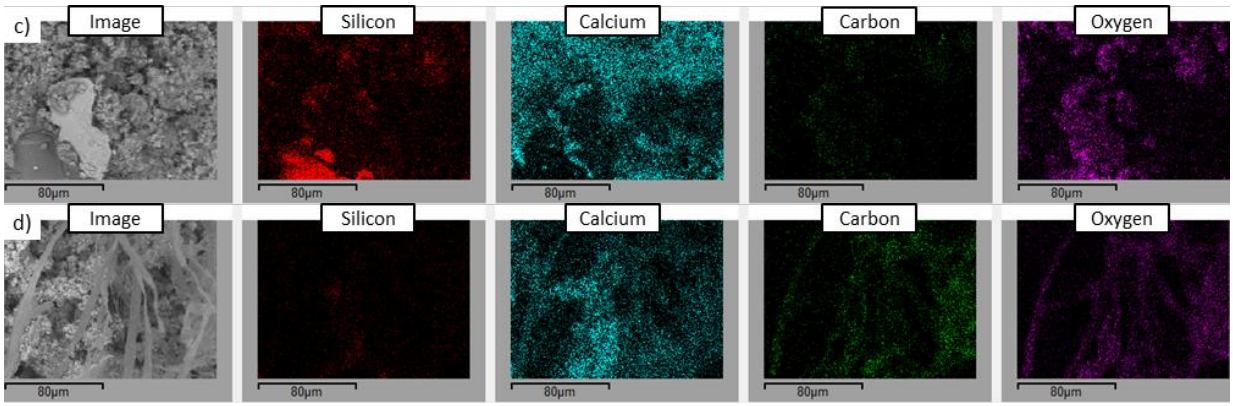

Figure 8 – SEM-EDS elemental mapping of the carbonated matrix (a) and matrices treated with T1 (b), T2 (c), and T3 (d), highlighting the spatial distribution of Si, Ca, C, and O across the microstructure

4. Conclusions

The present study evaluated the surface application of *Pythium aphanidermatum* as a $CaCO_3$ precipitation agent in previously carbonated and pre-cracked concrete matrices. The results of the carbonation process, verified through the application of phenolphthalein, demonstrated that the adopted method, based on 30 cycles, was not sufficient to generate a matrix with extensive carbonated zones. In this regard, to ensure greater depth and uniformity in surface carbonation, future studies should consider the use of controlled-scale accelerated carbonation chambers.

In terms of compressive mechanical response, the stress–strain curves showed that treatments T2 and T3 exhibited behavior similar to the pre-cracking condition, suggesting the possible occurrence of rehydration processes of residual cement particles within the matrix, a phenomenon previously reported in the literature. In turn, the results of the percent regain in compression (PRC) did not show statistically significant improvements, indicating that a single application of the treatment, under the evaluated conditions, is not sufficient to induce relevant changes in the mechanical capacity of the material. However, the microstructural analysis by SEM-EDS confirmed the deposition of spores and the development of hyphal networks, which act as potential nucleation sites for $CaCO_3$ precipitation.

Consequently, although a significant sealing effect was not achieved, the obtained results suggest that optimizing the number of applications and treatment conditions may promote the formation of biomineral products capable of improving matrix performance. Furthermore, *Pythium aphanidermatum* demonstrated its ability to develop in cementitious matrices that still exhibit relatively high alkalinity levels, highlighting its potential as an innovative and environmentally sustainable alternative for self-healing applications, despite its pathogenic nature in certain plant systems.

Abstract: The upgrading of the building stock is one of the main objectives of the European Commission's strategy to achieve climate neutrality. Around 85% of buildings in Europe were constructed before 2001, with approximately 50% of them built before 1970. These structures often fall outside the scope of modern seismic and energy regulations, creating a complex challenge in balancing between preservation and modernisation, particularly as they may require significant retrofitting to meet current standards while also maintaining their historical value.

The use of inorganic matrix composite materials has gained increasing attention in recent decades for construction sector applications. A promising solution for concurrent seismic and energy retrofitting is the Textile-Reinforced Mortar (TRM) system, which has demonstrated promising performance in seismic strengthening. However, a key challenge of conventional TRM systems is their reliance on unsustainable insulation materials for energy upgrades in masonry buildings. While these products are affordable, they often entail a high environmental impact. Therefore, to align with European and international objectives for decarbonisation and climate change mitigation, it is relevant to consider eco-friendly, bio-based composite systems, which can significantly reduce carbon emissions and promote sustainability in product development.

In this study, inorganic matrix composites enabling the integrated seismic strengthening and energy upgrading of masonry buildings are reviewed, with particular attention paid to sustainable alternatives to conventional TRM-based insulation systems.

Keywords: Masonry, Seismic and Energy Retrofitting, Textile-Reinforced Mortar (TRM), Inorganic Matrix Composites (IMCs), Sustainable Construction, Bio-based Materials

1. Introduction

The existing building stock in Europe is currently facing a challenge derived from the urgency of climate change and the persistent threat of seismic hazard. A large proportion of residential and public buildings were built without modern seismic and energy provisions, resulting in high structural vulnerability and operational energy demand (Ademovic et al. 2022; Pohoryles and Bournas 2021). This stock is dominated by unreinforced masonry (URM) buildings, which are characterised by a low tensile strength, brittle failure mechanisms, and poor energy efficiency caused by uninsulated envelopes and air leakage. Typically, seismic retrofitting and energy efficiency improvements were applied as independent and uncoordinated interventions. These interventions were frequently governed by disparate regulatory frameworks. However, investigations of damages from recent earthquake events indicated that pure energy retrofits are substantially vulnerable to seismic actions and may completely lose their functions following structural damages (Belleri and Marini 2016).

Applying energy-only retrofits to seismically vulnerable masonry structures can impede energy retrofit investment when the structure experiences earthquake damage (Bournas 2018). On the other hand, purely seismic interventions may limit improvement of long-term building performance by neglecting thermal transmittance, airtightness, and hygrothermal comfort. These investigations lead to a transformation from independent retrofits to integrated retrofit strategies that simultaneously fulfil the requirements of structural safety and thermal performance. However, implementing integrated retrofit approaches requires the development and validation of multifunctional materials presenting enhancement of mechanical and thermal performance and environmental sustainability, which can include materials that are both energy-efficient and capable of reducing carbon emissions throughout their lifecycle. In response to these needs, inorganic matrix composites (IMCs) have emerged as a key solution to enable such integration. These innovative composites enable discreet, externally applied interventions, which reduce the impact on existing structures and their inhabitants and keep their heritage value, such as minimising structural alterations and maintaining historical aesthetics.

IMCs, which are also known in the literature as Textile Reinforced Mortar (TRM), Fabric Reinforced Cementitious Matrix (FRCM), or Composite Reinforced Mortar (CRM), have become a preferred solution for the URM intervention (Papanicolaou et al. 2011). The conventional IMCs consist of high-strength fibre textiles, which are typically made of carbon, glass, basalt, or steel, embedded within a cementitious or lime-based mortar matrix, as seen in Figure 1a. The latter is often convenient for application to existing masonry and historical structures because it provides superior mechanical and hygrothermal compatibility. The transition from organic-based composites, such as Fibre Reinforced Polymers (FRP), to IMCs is motivated by several technical advancements for masonry applications. Epoxy resins, used in the application of FRPs, suffer from low fire resistance and poor vapour permeability, while the inorganic matrices used in TRM are non-combustible and allow the masonry substrate to "breathe", thus preventing the moisture trap that can lead to material degradation (Parisi et al. 2013).

This paper reviews the transition from traditional IMCs to improved solutions with enhanced structural performance, thermal efficiency, durability, constructability, and environmental properties for integrated seismic and energy retrofitting of masonry buildings. In addition, the study highlights advantages, limitations, and research gaps relevant to materials and structural engineering practice.

2. The Combination of Inorganic Matrix Composites with Thermal Insulation Systems

The mechanical properties of IMCs are highly influenced by matrix composition; therefore, the choice of matrix binder is counted as an important parameter governing both mechanical and durability performance. Cement-based matrices provide high compressive strength, but they do not always work well with traditional masonry due to stiffness incompatibility resulting in stress concentrations and cracking at the interface (Angiolilli et al. 2020). Alternatively, lime-based matrices, particularly those made with natural hydraulic lime (NHL), have lower stiffness but are more compatible, ductile, and vapour permeable. This makes them more suitable for weak or historic substrates (Pugliese et al. 2023). Other rapidly developing alternatives are alkali-activated and geopolymer matrices, which offer reduced embodied carbon and, in some cases, significantly lower thermal conductivity than traditional binders (Longo et al. 2020). However, their performance remains sensitive to precursor chemistry, activator composition, and curing conditions, which poses challenges for reproducibility and standardisation.

Experimental studies indicated the synergy between the textile reinforcement and the mortar matrix, which enables stress redistribution through multiple cracking and progressive load transfer rather than sudden brittle failure. Investigations on URM walls strengthened with TRM systems demonstrated a significant increase in shear strength, stiffness retention, and deformation capacity under cyclic horizontal loading (Kouris et al. 2024). In-plane shear capacity is reported to be increased typically from 60% to over 130%, depending on textile type, anchorage detailing, and matrix properties (Azdejkovic et al. 2025). In addition,

TRM strengthening has been shown to substantially increase out-of-plane and deformation capacity, especially when reinforcement is placed eccentrically with respect to the wall thickness (Karlos et al. 2020). Nevertheless, IMCs exhibit improved fire resistance and better compatibility with weak or historic masonry compared to their counterpart FRP systems, hence reducing the risk of substrate damage and enabling application in conservation-sensitive contexts (Triantafillou et al. 2017; Pugliese et al. 2023).

The integration of thermal insulation into the structural TRM layer can be achieved through various configurations (Triantafillou et al. 2017). Depending on structural and construction requirements, the TRM layer may be applied directly on the masonry substrate, on the external face of the insulation, or on both sides of the insulation layer (Figure 1b). In this arrangement, the insulation layer reduces thermal transmittance while the TRM provides seismic resistance through its tensile capacity.

Experimental investigations indicated that placing IMC over the insulation layer substantially improves the out-of-plane capacity by 200–340% compared to an unreinforced wall (Karlos et al. 2020) due to the increased lever arm between the textile reinforcement and masonry compression zone (Triantafillou et al. 2017). Also, further experimental studies demonstrated that such systems maintain residual stiffness and energy dissipation capacity even after cracking, which is critical for seismic intervention. From a thermal perspective, the insulation layer provides conventional U-value reductions in line with current energy regulations; in parallel, the IMC layer improves airtightness, reducing air infiltration by up to 78%, and protects the insulation layer from mechanical damage (Kallioras et al. 2024).

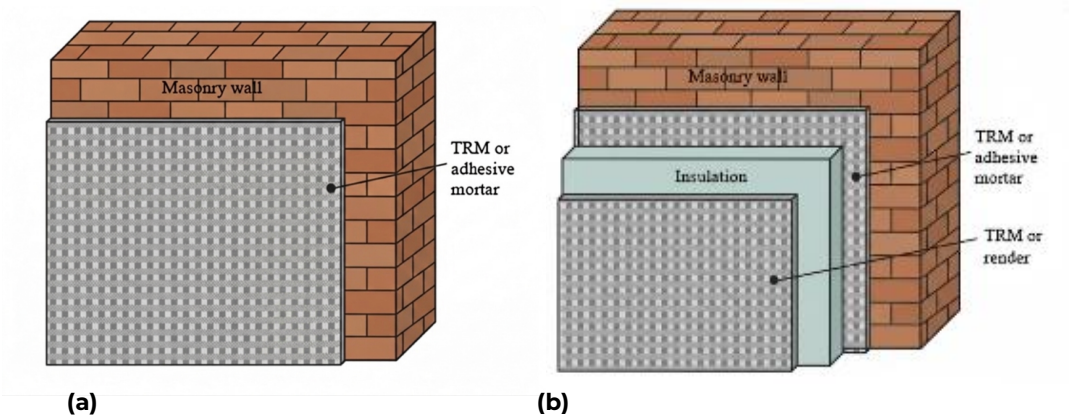

Figure 1 – Schematic view of (a) IMCs and (b) a combination of IMCs with thermal insulation systems on one side of the masonry wall (adapted from (Triantafillou et al. 2017))

Despite the abovementioned advantages, layered systems have several technical challenges. Potential weak planes resulting from multiple interfaces, such as substrate, insulation, and IMC, are vulnerable to debonding under cyclic loading (Figure 2). The associated failure modes were frequently reported from experimental studies when no mechanical anchorage is provided (Triantafillou et al. 2017; Kallioras et al. 2024). On the other hand, the connectors or anchors may present localised thermal bridges and complicate the hygrothermal behaviour, especially if metallic anchors are used without thermal breaks (Valluzzi et al. 2021).

Increased overall thickness of envelopes is another limitation of layered systems, which can be problematic in urban environments with strict façade alignment constraints or in heritage buildings where visual impact must be kept to a minimum. In addition to the above-mentioned mechanical weaknesses, the insulation layer, especially petrochemical-based products such as EPS and XPS, has high embodied carbon and exhibits poor fire performance, thus raising concerns regarding overall sustainability (Pohoryles et al. 2022). Alternatively, to these insulation layers, mineral wool and bio-based insulation materials offer improved fire and environmental performance, but mineral wool production remains highly energy-intensive. Also,

incorporating bio-based materials may need more complicated detailing to guarantee durability and moisture control. Furthermore, Life Cycle Assessment (LCA) indicates that the "carbon payback period", the duration needed for operational energy savings to offset the carbon emitted during the production and installation of these synthetic insulation systems, is much longer than for bio-based alternatives (Kallioras et al. 2024).

Another drawback of layered systems is the limited contribution of material recovery or recycling to the circular economy. In this system, monolithic integration between the layers is required, which often involves strong mechanical or chemical bonding; as a result, separating the synthetic insulation from the IMC layer becomes extremely difficult at the end of the building's service life.

In response to the abovementioned limitations, a limited number of studies have explored the development of multi-purpose composite mortars, in which IMCs are mechanically, thermally, and environmentally enhanced to provide both seismic and energy retrofitting. This methodology seeks to eliminate discrete insulation layers by reducing system thickness, minimising interfaces, and simplifying construction.

Figure 2 – Debonding failure of the composite system on (a), (b) a building prototype scale (Kallioras et al. 2024), and (c) a wallet-scale (Triantafillou et al. 2017) in the laboratory

3. Enhanced Inorganic Matrix Composites

In response to the limitations of layered systems, recent research has focused on developing multi-purpose IMCs in which the matrix itself contributes to thermal insulation. This approach aims to reduce system thickness, eliminate weak interfaces, and enhance sustainability by integrating structural and thermal functions within a single material layer. Several strategies have been proposed to enhance inorganic matrices thermally by replacing standard cement with geopolymer binders and incorporating mineral and lightweight aggregates (e.g., perlite, expanded glass), bio-based aggregates (e.g., rice husk, coffee biochar), phase change materials, and natural fibres (Longo et al. 2020).

Geopolymer binders, derived from precursors such as fly ash or metakaolin, are part of the broader family of alkali-activated materials (AAM) and are particularly suitable for multipurpose composites because of their ability to incorporate a large volume of lightweight or recycled aggregates and their lower embodied carbon compared with ordinary Portland cement (Coppola et al. 2019). Recent experimental investigations indicated that geopolymer-based IMC systems can significantly reduce thermal conductivity by up to 50%

compared to NHL-based IMC while simultaneously keeping sufficient mechanical strength for seismic retrofit (Longo et al. 2020).

The interaction between the matrix and fibre reinforcement for NHL-based and geopolymer-based IMCs was investigated from micrographs, as shown in Figure 3a and Figure 3b, respectively. It is found that in the NHL-based composite, the fabric and the matrix appeared as two distinct phases with minimal contact area, which was restricted primarily to the outer surface of the yarns (Figure 3a). In contrast, the matrix in the geopolymer-based composite effectively penetrates the yarns (Figure 3b). This leads to a significantly larger contact area, with the matrix enveloping the entire lateral surface of the external filaments, a feature likely driven by the fine particle size of the fly ash (Longo et al. 2021). Because of this penetration, the stress distribution and filament tensioning behaved differently between the two composites. The geopolymer-based IMC facilitated a more uniform distribution of stress across the filaments (Figure 3b), meaning that even after matrix cracking occurred, the geopolymer retrofitting often presents higher ductility and energy dissipation, which can partially compensate for lower peak strength.

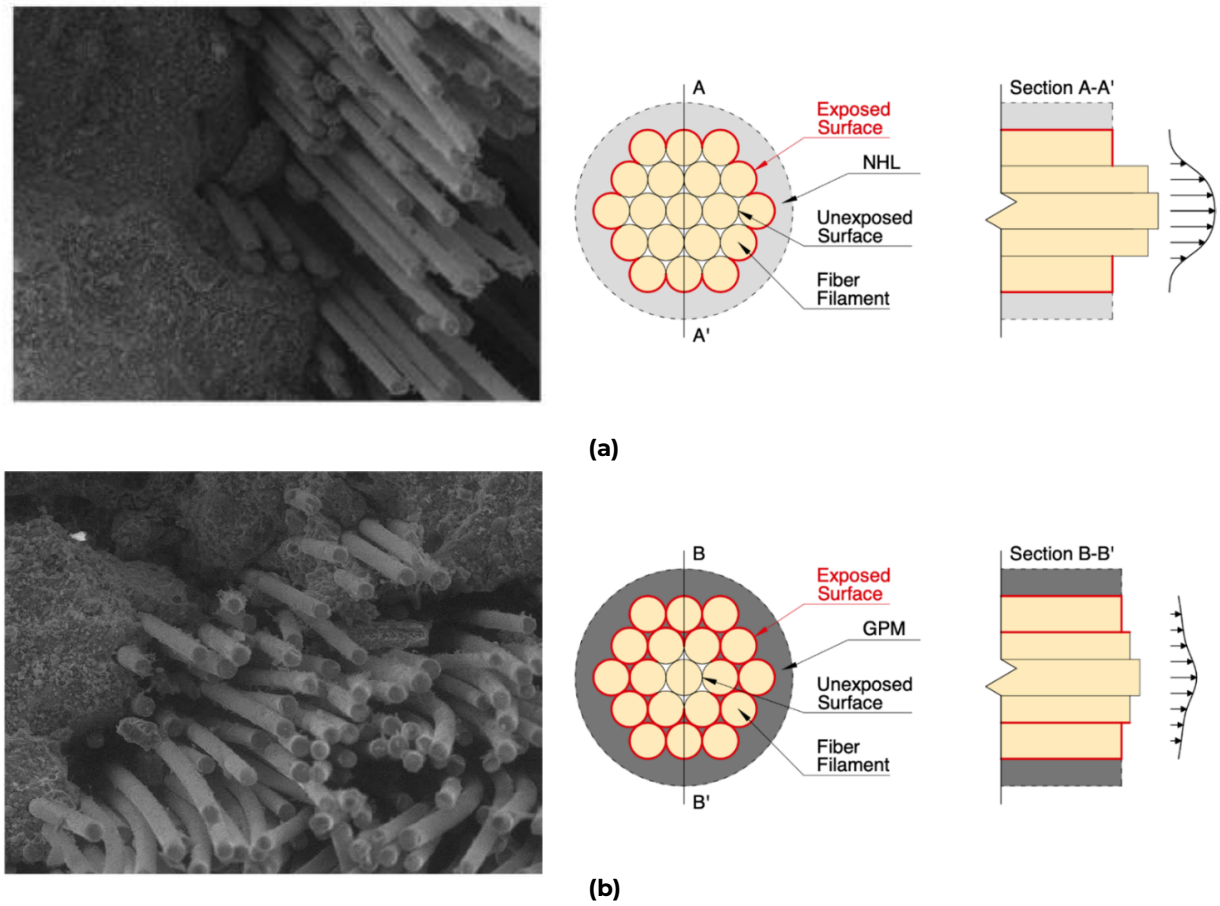

Figure 3 – Micrographs illustrating matrix/fibre interactions in (a) an NHL-based IMC and (b) a geopolymer-based IMC (Longo et al. 2021)

The incorporation of natural fibres into IMC, either as textiles (NTRM) or as dispersed reinforcement, further improves the environmental and thermal profile of multi-purpose composites. Natural fibres such as jute, hemp, and flax have low embodied energy and are renewable materials. They contribute to both crack control and thermal resistance. Recent studies showed that masonry wallets reinforced with NTRM systems achieved substantial increases in lateral load capacity alongside meaningful reductions in thermal transmittance, thus demonstrating their high potential as an integrated retrofit approach (Majumder et al. 2025).

Nevertheless, multi-purpose composites are still constrained by a pronounced thermo-mechanical trade-off. Enhancing thermal insulation of IMCs typically requires increased porosity or incorporation of low-density aggregates. These modifications reduce compressive strength, elastic modulus, and in some cases, bond strength (Ferrández et al. 2024). According to the Scanning Electron Microscope (SEM) images of rice husk ash (RHA)-based mortar, the number and size of pores increased with the RHA-based mortar. Incorporating 30% RHA by weight into the mortar shows a higher number and larger voids, which generates lower conductivity in the mortar and improves its thermal performance by reducing thermal conductivity by up to 62% while maintaining the acceptable compressive strength (Selvaranjan et al. 2021).

While many thermally enhanced mortars still meet minimum strength requirements for masonry strengthening, their reduced stiffness may change load-sharing mechanisms between the fibres and the matrix and cracking behaviour under seismic loading.

3.1 Aggregate Modification for Thermo-Mechanical Enhancement of IMC Systems

The mortar matrix has a major influence on the thermal performance of inorganic matrix composites (IMCs) used in masonry retrofitting. According to European standards (CEN 2020), conventional cement- and lime-based mortars exhibit thermal conductivity values typically in the range of approximately 0.6–1.2 W/m·K, depending on their dry density. These values are considerably higher than those of typical thermal insulation materials. Therefore, aggregate modification has been taken into consideration from recent research as an innovative approach to reduce thermal conductivity while preserving sufficient mechanical performance for seismic retrofit.

Thermal insulation can be incorporated directly into the strengthening layer by replacing natural sand with lightweight or porous aggregates. This reduces density, decreases system thickness and eliminates the need for extra interfaces. This method is especially useful for integrated seismic and energy retrofitting. However, as lightweight aggregates improve thermal properties of the matrix through reducing density and heat transfer, they may also decrease compressive strength, stiffness, and bond capacity. For example, among mineral lightweight aggregates, expanded perlite has been widely investigated due to its highly porous microstructure. The study from Fenoglio et al. (2018) indicates a reduction of thermal conductivity by 50–55% when natural sand was partially substituted by expanded perlite depending on the substitution ratio (Fenoglio et al. 2018).

Significant modifications were also offered by expanded glass aggregates, which usually achieve greater than 50% reductions in thermal conductivity and compressive strengths greater than 8 MPa (Longo et al. 2020). Because of improving matrix–aggregate bonding, natural volcanic aggregates like pumice preserve relatively strong mechanical performance while providing moderate insulating benefits.

In addition to mineral aggregates, recycled and industrial waste materials have been explored as sustainable alternatives. Crushed ceramic waste aggregates provide smaller reductions in thermal conductivity but preserve mechanical properties comparable to conventional mortars.

Recently, bio-based aggregates such as rice husk, cork granules, wood particles, and coffee biochar have been explored due to their low embodied carbon and very low thermal conductivity, frequently below 0.31 W/m·K (Roychand et al. 2023; Selvaranjan et al. 2021). It was observed that rice husk-based mortars can reduce thermal conductivity by up to 59–68%, although high water absorption may affect workability and durability. Furthermore, the mechanical strength was found to be highly dependent on the dosage ratio (Penazzato, Sakhizada, et al. 2024). Similarly, coffee biochar enhances insulation performance and reduces embodied carbon, but a high substitution rate may weaken the matrix (La Scalia et al. 2021; Penazzato, Illampas, et al. 2024). Table 1 presents a comparative overview of various IMC systems in terms of thermal conductivity, compressive strength, and test scale.

The mechanical compatibility of modified mortars is still a challenge for IMC systems. The mortar matrix must guarantee adequate compressive strength and bond capacity to allow efficient stress transfer

between the textile and the masonry substrate, even if textile reinforcement mostly transfers tensile stresses. However, excessive stiffness reductions may limit out-of-plane capacity, highlighting the need for a balanced mix design when integrating thermal and structural retrofit objectives (Majumder et al. 2025; Longo et al. 2021).

Table 1 – Comparative overview of selected IMC systems: thermal conductivity, compressive strength, and test scale

IMC System	Thermal conductivity λ (W/m·K)	Compressive strength fc (MPa)	Test scale	Key reference
Lime-/cement-based mortar	0.6–1.2 W/m·K	N/A	Material	CEN 2020
NHL + expanded perlite	~0.059–0.118 (↓50–55%)	N/A	Material	Fenoglio et al. 2018
Geopolymer + expanded glass	~0.16–0.25 (↓> 50)	>8	Material	Longo et al. 2020
Ordinary Portland Cement (OPC) + burnt rice husk ash	~0.31(↓62%)	>7	Material	Selvaranjan et al. 2021
NHL + rice husk (untreated RH-U or grounded RH-G)	0.28-0.37 (↓59–68%)	~1 (highly rate-dependent)	Material	Penazzato, Sakhizada, et al. 2024
NHL + coffee biochar (bio-aggregate)	<0.3 (↓66–77%)	~5–10 (rate-dependent)	Material	Penazzato, Illampas, et al. 2024)

Note: λ values are approximate ranges from reported mix designs; N/A = data not quantified in reviewed sources. Embodied carbon data was not consistently reported across the reviewed sources and is therefore excluded from this comparison.

3.2 Environmental Impact and Long-Term Performance

From an environmental perspective, integrated seismic-energy retrofit strategies offer clear advantages over separated interventions when assessed on a life-cycle basis. Reducing binder-related embodied carbon is a crucial goal in sustainable construction since cement production contributes significantly to global CO_2 emissions. Compared to traditional cement-based mortars, alkali-activated and geopolymer mortars can contribute to a reduction in embodied carbon, particularly when industrial by-products such as fly ash or slag are used as precursors (Coppola et al. 2019).

Aggregate substitution further influences the environmental performance of thermally enhanced matrix composites. Lightweight, recycled, and bio-based aggregates can reduce material density, embodied energy, and the need for virgin resources. Life-cycle assessment (LCA) studies indicate that aggregate substitution with lightweight or bio-based materials can contribute to reductions in embodied carbon compared to conventional cement-based mortars. For instance, perlite-based plasters have demonstrated significant reductions in embodied carbon when assessed on a cradle-to-site basis, and bio-based aggregates such as spent coffee grounds offer additional sustainability benefits through waste valorisation and reduced reliance on virgin materials (Fenoglio et al. 2018; La Scalia et al. 2021).

Despite their environmental benefits, long-term performance is still a major issue for integrated retrofit systems. The service life of retrofitted systems can be greatly impacted by the degradation of the embedded reinforcement and mortar matrix. For instance, uncoated natural fibres used in NTRM systems are vulnerable to biological deterioration, moisture absorption, and alkaline attack from the surrounding matrix. If the fibres are not appropriately treated, this could eventually result in a significant loss of strength. Surface treatments, mineral coatings, and hybrid reinforcement strategies have been proposed to mitigate these effects, although long-term experimental evidence remains limited. Similarly, compared to conventional binders, alkali-activated matrices may show more shrinkage and efflorescence, which may impact bond performance and durability (Coppola et al. 2019).

In general, performance evaluation and design implementation are becoming more difficult due to the lack of standardised durability testing procedures for integrated seismic-energy retrofit systems. The majority of existing research concentrates on short-term mechanical behaviour, underscoring the necessity of long-term studies that address the interrelated effects of environmental degradation, thermal exposure, and mechanical stress.

4. Discussion and Research Gaps

Comparing layered systems and thermally enhanced composites reveals that neither strategy is superior. Layered systems benefit from technical maturity, predictable structural performance, and compatibility with established insulation technologies, but they suffer from interface-related vulnerabilities and increased thickness. On the other hand, multipurpose composites present strong benefits in terms of material efficiency, decreased thickness, and decreased embodied carbon, but they encounter difficulties with durability, thermo-mechanical trade-offs, and a lack of standardisation.

Critical gaps remain for thermally enhanced IMCs, including the need for standardised mix designs that address thermal, mechanical, and durability aspects. Most studies focus on short-term material performance, neglecting real-world long-term effects. Additionally, while small-scale successes are documented, full-scale system behaviours under various conditions are still missing, particularly in terms of how these systems perform over extended periods and in diverse environmental scenarios. There is also a lack of a numerical approach to evaluate the efficiency of the enhanced system for different climate and seismic regions. Furthermore, sustainability assessments often only cover early lifecycle stages, with methodological inconsistencies impacting robust evaluations of lifecycle implications, which can lead to an incomplete understanding of the long-term environmental impacts of the system across various climate and seismic regions.

5. Conclusions

This study has examined advances in thermally enhanced Inorganic Matrix Composites (IMCs) for the integrated seismic and energy retrofitting of masonry buildings, with particular emphasis on the role of alternative aggregates in replacing natural sand, as well as on sustainability and durability. The investigation demonstrates that lightweight mineral, waste-derived, and agricultural bio-based aggregates offer advantages in reducing thermal conductivity and environmental impact, although they have varying performance in terms of mechanical strength and long-term stability.

While mineral lightweight aggregates currently provide the most balanced combination of thermal and mechanical performance, bio-aggregates present substantial opportunities for reducing embodied carbon and promoting circular economy principles. However, their widespread adoption is constrained by durability concerns and performance variability. Overcoming these limitations through performance-based mix design, interface engineering, long-term and numerical validation is essential.

Thermally enhanced IMC systems offer a promising approach toward multipurpose retrofit solutions that can concurrently enhance environmental sustainability, energy efficiency, and structural safety. To enable the utilisation of this solution in the rehabilitation of the stock of masonry buildings, more research on durability, standardisation, and full-scale system validation are essential.

Abstract: Historic buildings are subject to natural deterioration processes over time, compromising their construction systems. In this context, the use of compatible repair mortars is essential for the preservation of built heritage. Therefore, this study aimed to develop low environmental impact mortars for repair interventions in historic buildings. The mixtures were produced with a 1:5 ratio (binder:aggregate), respecting the typical composition of historic mortars from the state of Ceará, Brazil. Cement and lime were used as binders, with steelmaking slag employed as a full replacement for natural sand. The mortars were characterized in both fresh and hardened states, evaluating their physical and mechanical performance. The results indicated higher apparent density, lower void index and water absorption, as well as superior mechanical performance for the slag-containing mortars compared to historic mortars. Although the use of residues from the steelmaking industry is applicable in mortars, the results demonstrate that their application in interventions on historic buildings should be carried out with caution, particularly due to the increase in mechanical performance, which may compromise material compatibility and the long-term behavior of the construction system.

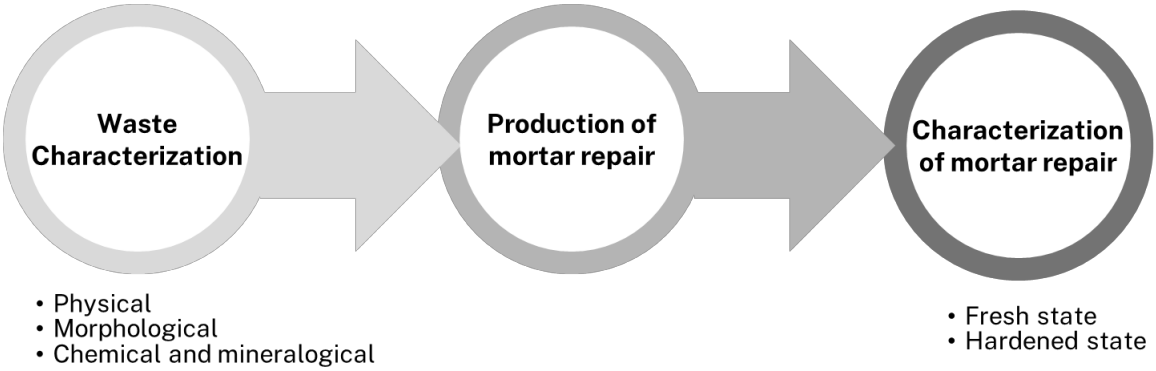
Keywords: Repair mortars. Historic buildings. Steelmaking slag. Sustainability.

1. Introduction

Historic buildings hold significant cultural and scientific value, serving as testimonies to past construction technologies and architectural expressions (Longobardi and Formisano, 2022). Their preservation safeguards heritage and contributes to the advancement of technical knowledge, as established in the Venice Charter (1964), which guides interventions toward maintaining the historical and aesthetic values of such constructions.

Restoration consists of reintegrating damaged parts of a cultural asset using original or equivalent materials, while preserving its heritage value (Lin et al., 2024). This procedure is essential due to the ageing of historic buildings and their consequent deterioration (Pescari, Budau and Vilceanu, 2023). To achieve this, interventions must reconcile authenticity and functionality, minimal intervention and safety, material compatibility and durability, as well as legibility and aesthetic integration (Vysvaril et al., 2020; Papayianni, Pachta and Stefanidou, 2013).

Despite these well-established conservation principles, the selection of repair materials remains a challenge. The application of mortars incompatible with historic substrates may lead to mechanical decoupling, moisture accumulation, cracking, and long-term accelerated deterioration (Nogueira, Pinto and Gomes, 2020; Loureiro, 2019; Aggelakopoulou et al., 2011). In this context, the characterization of composition, mechanical and hygroscopic parameters is essential to ensure compatibility and the long-term performance of repair interventions in historic buildings (Pavlik et al., 2023).



In parallel, the incorporation of industrial by-products into construction materials has been widely explored as a sustainable strategy for construction sector (Salles, 2017; Magalhães, 2018; Loureiro, 2019). However, in heritage applications, such materials must exhibit adequate mechanical performance and ensure physicomechanical compatibility with the original substrate (Groot & Gunneweg, 2019; Veiga, 2017; Posani, Veiga and Freitas, 2022), since not all by-products are compatible with historic constructions. Thus, their use requires careful evaluation prior to application in repair mortars (Gonzalez-Sanchez et al., 2021).

In this context, steelmaking slag emerges as an industrial by-product with potential application in repair mortars, due to its physical and chemical characteristics that may contribute to both mechanical performance and material sustainability. However, its feasibility in heritage interventions still requires investigation regarding its compatibility with historic substrates. Therefore, this study evaluated the performance of repair mortars incorporating steelmaking slag, with emphasis on mechanical and physical parameters relevant to applications in historic buildings.

2. Methodology

Figure 1 presents the experimental flowchart of the research procedure. Initially, the residue used in the production of the repair mortars was characterized. Simultaneously, a sample of the original mortar from the historic building under study was analyzed. Based on these results, the proposed mortar mixtures were produced and subsequently evaluated in fresh and hardened states.

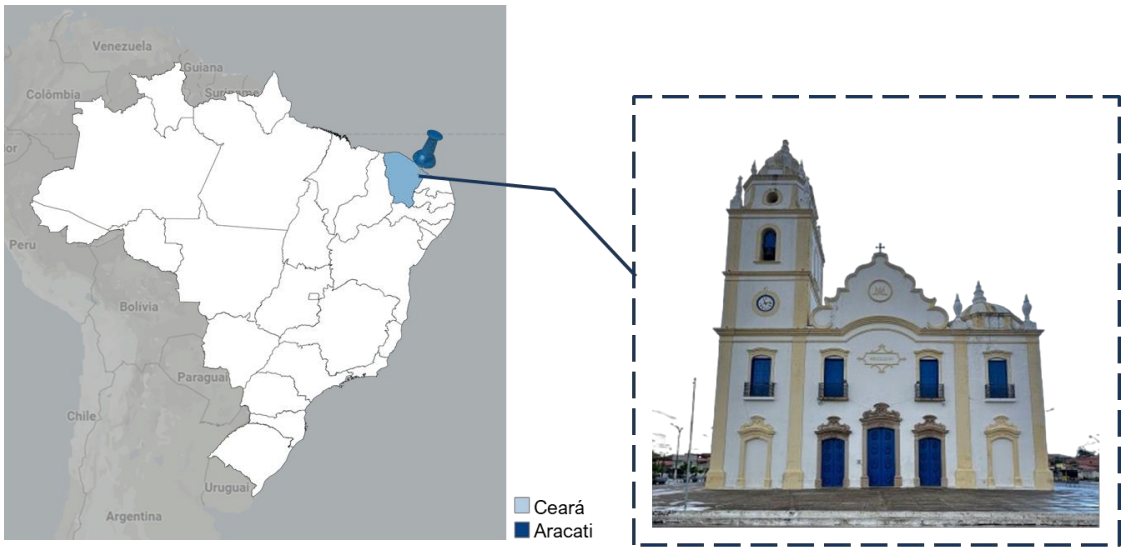


Figure 1 - Flowchart of the research stages.

2.1 Reference historical mortar

The reference historic mortar considered in this study was previously characterized by Souza et al. (2026), based on samples collected from the Church of Nossa Senhora do Rosário (Figure 2). This mortar served as the basis for the development of a repair mortar compatible with the original construction system of the building. The church is located in the municipality of Aracati, in eastern Ceará, Brazil.

Figure 2 – The Church Matriz of Nossa Senhora of Rosário and location in Aracati, Ceará.

The Church of Nossa Senhora do Rosário represents a significant example of Ceará's regional religious architecture constructed using traditional materials and techniques. Originally built in the early 18th century as a small chapel, it underwent successive expansions and was completed in the second half of the 19th century. It is currently designated as the main parish church (Matriz de Nossa Senhora do Rosário).

In the study by Souza et al (2026), a representative mortar sample was extracted from the left lateral façade of the building. The sample was taken from an area that already exhibited signs of deterioration, thereby minimizing intervention in well-preserved regions. The collected material was subjected to physical, chemical, and morphological characterization. The historic mortar exhibited a maximum aggregate size of 2.4 mm and a binder-to-aggregate ratio of approximately 1:5, indicating a composition consistent with traditional construction practices. These characteristics were used as the basis for the formulation and compatibility assessment of the proposed repair mixtures.

2.2 Waste Characterization

The residue selected for this research was a steelmaking slag (SS), generated from the refining process (Figure 3). The material was supplied by an integrated steelmaking facility in Ceará. Its selection was motivated by the economic relevance of the steelmaking sector in the state.

Figure 3 – Steelmaking slag used in this study.

SS was investigated as a full replacement for natural fine aggregate in the proposed repair mortars. The material was reduced by quartering to obtain a representative sample and oven-dried at 105 °C for 24 h prior to use. Particles larger than 4.75 mm were crushed in a jaw crusher (I-4198, Contenco) and sieved to meet the particle size limits for fine aggregates established by NBR 7211 (ABNT, 2019) and to ensure compatibility with

the particle size distribution of the historic mortar (Souza et al, 2026). The materials were then physically characterized, as summarized in Table 1.

Table 1 - List of physical characterization tests performed on the waste.

Property	Principle	Standard
Particle size distribution	Sieving	NBR 17054 (2022)
Specific gravity	Chapman flask	NBR 16916 (2021)
Bulk density	Weighing in a graduated container	NBR 16972 (2021)
Fines contente (material under 75µm)	Washing through sieves	NBR 16973 (2021)

The elemental composition of the SS was determined by X-ray fluorescence (XRF) analysis using a PANalytical Epsilon 3X spectrometer. For this purpose, the sample was previously milled to pass the 75 µm sieve. Mineralogical aspects were discussed based on data available in the literature for steelmaking slags with comparable origin and production process.

2.3 Production and characterization of mortar repair

Based on the reference mix proportion determined through the reconstruction method (Souza et al 2026), repair mortars compatible with the historic build were formulated with a binder-to-aggregate ratio of 1:5. The integration of mix reconstruction and performance analysis enabled the development of mortars with improved physical behaviour, contributing to restoration strategies for historic buildings.

Two binders were used: hydrated lime (CH-I) and Portland cement (CP II-F), allowing evaluation of the influence of binder type on physical and mechanical performance. Natural quartz river sand from Russas, Ceará, Brazil, was adopted as the reference fine aggregate, and potable water supplied by the local utility company was used in all mixtures. After grinding, SS presented a suitable particle size distribution, enabling its use as a full replacement for natural sand. Mixtures were identified using the format XX–YYY, where XX denotes the binder (CP for cement and CH for lime) and YYY indicates the fine aggregate: (REF: conventional aggregate; SSA: steelmaking slag aggregate).

The water-to-binder ratio (w/b) was adjusted to achieve a consistency index of 260 ± 5 mm, in accordance with NBR 16541 (ABNT, 2016). The mortars were evaluated in both fresh and hardened states, and their physical and chemical properties were determined according to the procedures summarized in Table 2.

Table 2 - Experimental program for fresh and hardened mortars.

Test	State	Age (days)	n.	Standard
Consistency index	Fresh	–	–	NBR 13276
Bulk density	Fresh	–	–	NBR 13278
Compressive & flexural strength	Hardened	7 and 28	3	NBR 13279
Void index and specific gravity	Hardened	28	3	NBR 9778

The adopted methodology enabled a systematic assessment of the proposed repair mortars, encompassing material characterization and performance evaluation in both fresh and hardened states. The experimental program provided a consistent basis for comparing conventional and SSA-based mixtures, supporting the development of compatible repair solutions for heritage conservation.

3. Results and Discussion

3.1 Waste Characterization

Table 3 presents the chemical composition of the SS. The slag is characterized by a high content of iron (III) oxide (Fe_2O_3), as expected for a steelmaking by-product. This feature is directly related to the steelmaking refining process, resulting in a material rich in metallic oxides and high-density phases (Baeza et al., 2018). Additionally, considerable amounts of SiO_2 were identified, a compound commonly found in natural sands, along with CaO, a major constituent typically observed in steel slags (Dias et al., 2020; Wang and Chen, 2015).

Table 3 - Chemical composition of the SS.

Component	CaO	Fe_2O_3	SiO_2	MgO	Al_2O_3	MnO	P_2O_5	NaO_2	SO_3	Cr2O3	CO_2
Content (%)	38.45	30.66	12.27	4.96	3.36	3.44	1.88	0.44	0.19	0.48	2.91

Regarding the mineralogical characteristics, Amancio et al. (2020) identified the presence of crystalline phases such as wustite (FeO) and magnetite (Fe_3O_4) in SS. The occurrence of these iron-rich phases confirms that the material was subjected to intense thermal processes typical of steelmaking furnaces. These mineralogical features are consistent with the steelmaking origin of the residue and reflect the high-temperature conditions involved in its production.

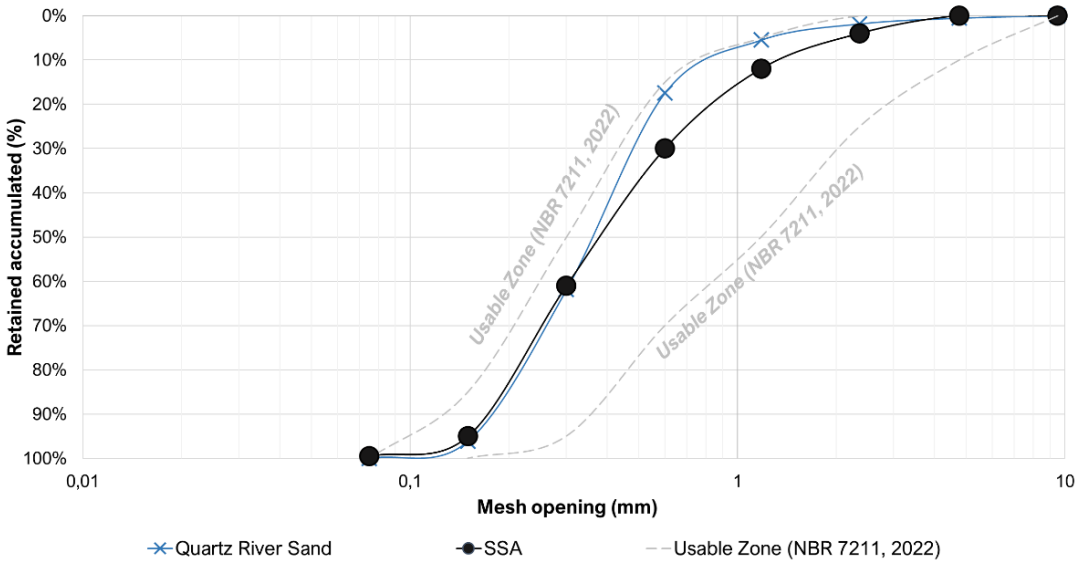
The physical properties of the studied materials are presented in Table 4. The SS exhibited the highest specific gravity, approximately 40.15% greater than natural quartz river sand (REF). This result is consistent with chemical composition of SS and its high iron oxide content.

Table 4 - Physical properties of the materials used.

Propriety	**SSA**	**REF**	**Lime**	**Cement**
Specific mass (g/cm³)	3.63	2.61	2.24	3.10
Unit mass (g/cm³)	1.78	1.42	0.43	1.20
Fineness modulus	2.02	1.83	-	-

The fineness modulus of SS indicates a relatively coarse particle size distribution compared to conventional fine aggregates (REF). Figure 4 provides an overview of the granulometric distribution of the studied materials. Both aggregates exhibit a particle size distribution curve within the usable range established by ABNT NBR 7211 (2022), indicating the effectiveness of SS processing to achieve a distribution closer to that of natural sand.

Figure 4 - Particle size distribution curves of the materials used in the research.



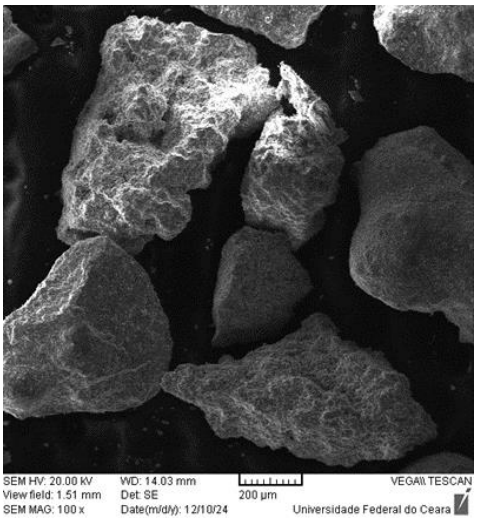


Figure 5 presents the morphological characterization of the SSA, revealing that its particles exhibit an angular morphology. This characteristic is commonly observed in materials subjected to rapid cooling and subsequent mechanical fragmentation processes.

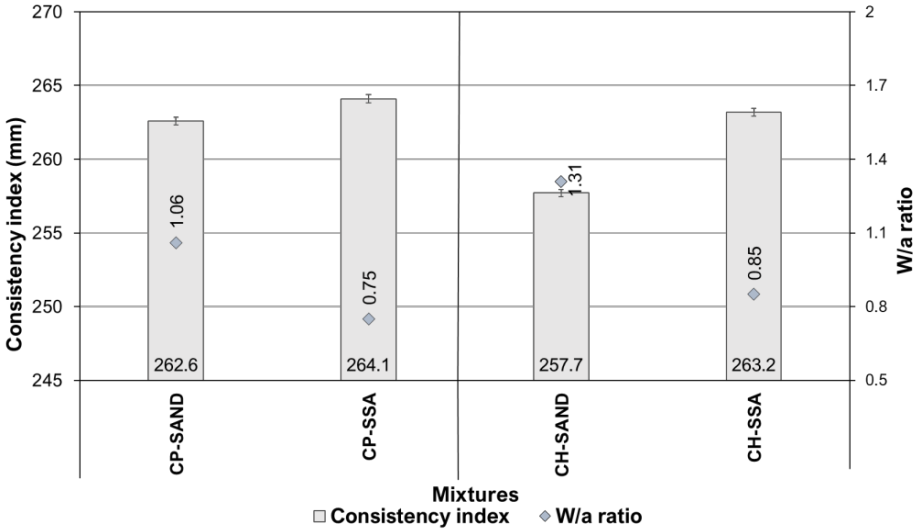

Figure 5 - Morphology of SSA particles obtained with SEM at 100x magnification.

3.3 Characterization of repair mortars in the fresh state

Figure 6 presents the consistency index and corresponding water-to-binder (w/b) ratios of the proposed mortars. Binder type and SSA incorporation significantly affected water demand. Cement-based mortar required a w/b ratio of 1.06, reduced to 0.75 with SSA. Lime-based mortar showed higher water demand, with w/b ratios of 1.31 and 0.85 for the conventional and SSA-modified mixtures, respectively.

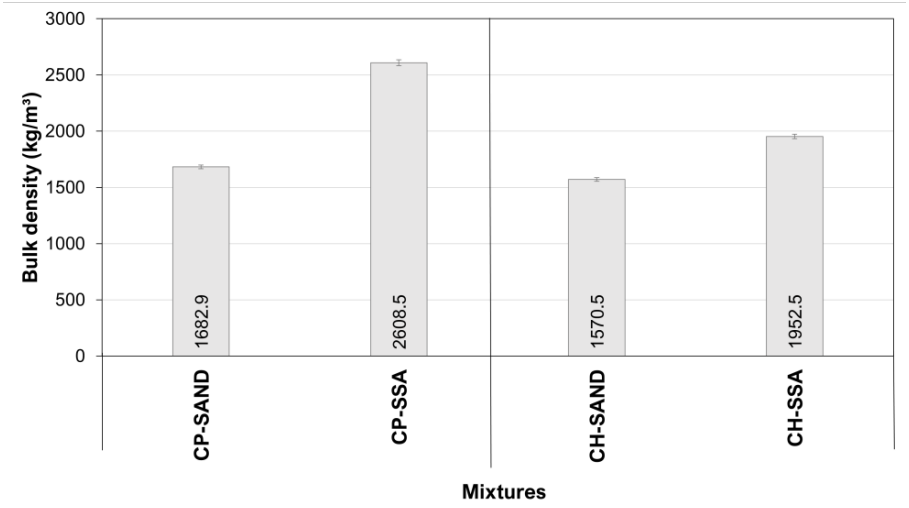

Figure 6 - Consistency index and water/binder ratio of the proposed mortars.

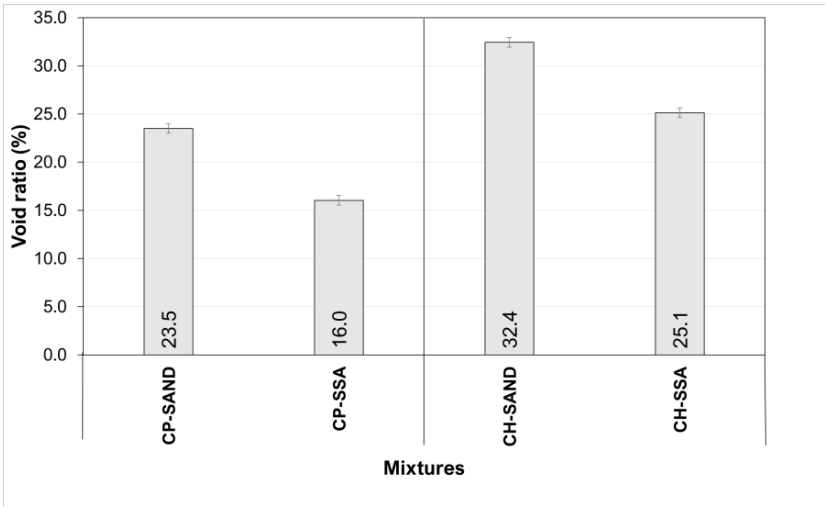
The incorporation of SSA promoted increased flowability despite the lower water content. This behavior is related to its higher specific gravity, which reduces the volumetric proportion occupied by the solid particles and, consequently, the amount of water required in the mixture (Ripardo et al., 2025). Furthermore, because the consistency test is based on impact spreading, denser mixtures tend to disperse more easily under repeated drops, resulting in greater apparent fluidity.

Figure 7 shows the bulk density values of the mortars in the fresh state. This property is directly influenced by the specific gravity of the constituent materials and the volumetric proportions within the mixture.

Figure 7 - Bulk density of the mortars in the fresh state.

The incorporation of SSA led to a substantial increase in fresh bulk density. In cement-based mortars, the replacement of natural sand with SSA resulted in an increase of approximately 55%, which is consistent with the fact that the slag presents a specific gravity about 41% higher than that of the conventional aggregate.

For lime-based mixtures, the lower specific gravity of hydrated lime compared to Portland cement, combined with the higher water demand previously observed, contributed to reduced density values, a behavior also reported by Malathy et al. (2022). Nevertheless, when SSA was incorporated into lime mortars, an increase of approximately 24% in bulk density was observed, highlighting the significant influence of the residue's higher specific gravity when used as a full replacement for natural aggregate. Regarding the fresh-state properties,



the incorporation of SSA affects the bulk density, primarily due to the intrinsic characteristics of the material; however, it does not significantly impair the workability when compared to the reference historical mortar.

3.4 Characterization of repair mortars in the hardened state

3.4.1 Void ratio and specify mass

Figure 8 presents the void index of the mortars. Lime-based mixtures exhibited higher void index values compared to cement-based mortars, a result consistent with the inherently more porous microstructure of lime-based systems, as widely reported in the literature (Silva, Guerreiro and Duarte, 2025; Gonzalez-Sanchez et al., 2021).

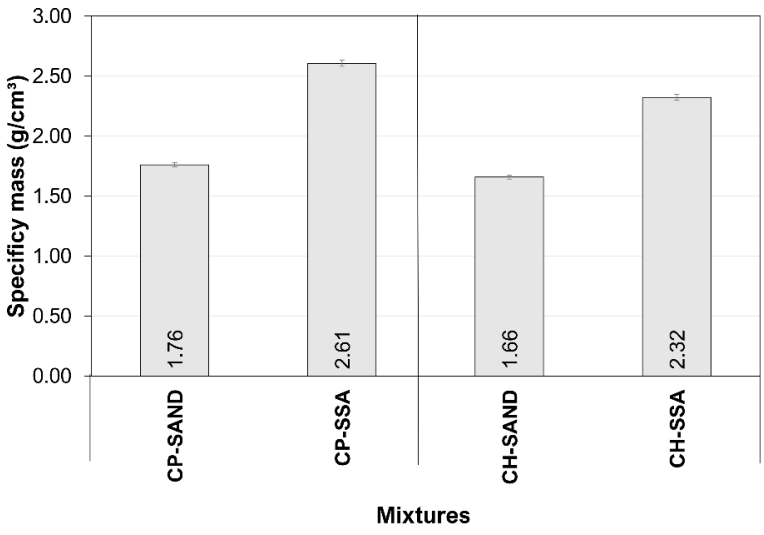


Figure 8 - Void index of the mortars in the hardened state.

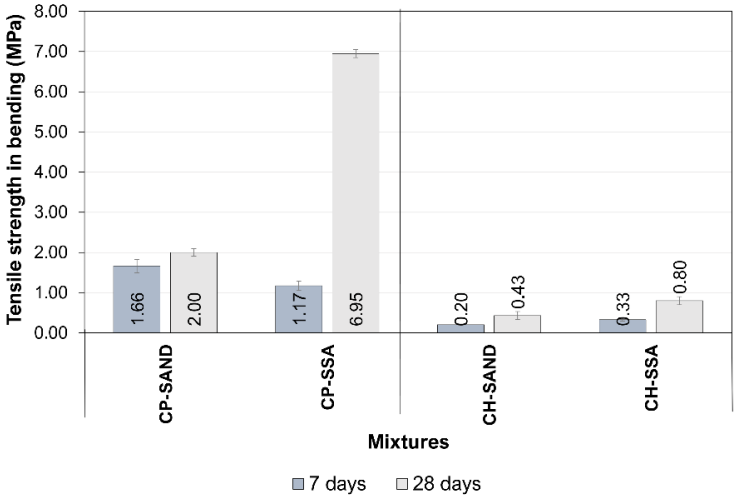
Among the mixtures incorporating SSA, the lowest void index values were observed across all studied formulations. The slag presents angular particles and a relatively coarse particle size distribution, characteristics that enhance particle interlocking and packing efficiency, leading to a denser and more compact matrix. This densification effect has also been reported in the literature (Miah et al., 2020).

Figure 9 presents the specific gravity results of the mortars in the hardened state. In general, this property is strongly influenced by the density of the constituent materials, particularly the aggregate, which represents the largest volumetric fraction of the mixture.

Figure 9 - Specific gravity of the mortars in the hardened state.

In cement-based composites, the incorporation of SSA resulted in the highest specific gravity values. This increase is primarily attributed to the elevated density of the steelmaking residue, which is approximately 39% greater than that of the conventional fine aggregate (Table 5), a trend also observed by Amancio et al. (2020).

For lime-based mixtures, the specific gravity values were generally lower than those of cementitious systems. This behavior is associated with the lower density of hydrated lime, approximately 28% lower than that of Portland cement, as well as the higher void index previously observed. Nevertheless, within the lime-based group, the mixture containing SSA exhibited the highest specific gravity, consistent with the greater density of the incorporated residue.



As observed in the fresh state, the incorporation of SSA leads to an increase in the bulk density of the mortar. Nevertheless, this is accompanied by matrix densification and a reduction in pore volume, which may adversely affect the historical substrate.

3.3.2 Mechanical performance of repair mortar

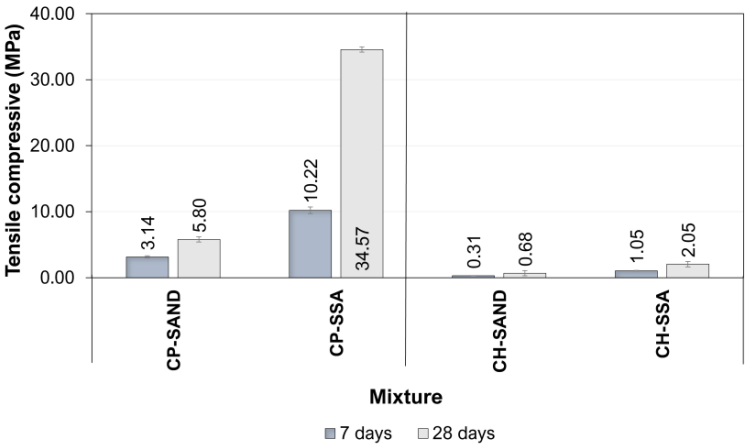


Figure 10 presents the mechanical performance of the mortars at 7 and 28 days, including flexural tensile strength (a) and compressive strength (b). These properties are essential for evaluating the structural behavior of the material, as they reflect its capacity to withstand stresses, control crack propagation, and ensure durability under service conditions.

Figure 10 – (a) Flexural tensile strength and (b) Compressive strength of mortars.

a)

b)

The incorporation of SSA produced mortars with a more resistant and denser matrix, increasing their capacity to withstand internal stresses generated by structural movements. This behavior is associated with the high

density of the residue, the angular morphology of its particles, and its greater hardness compared to conventional aggregates such as quartz and granite (Motz and Geiseler, 2001; Amancio et al., 2020), contributing to better compaction efficiency, lower porosity, and improved mechanical performance.

As a result, the incorporation of SSA led to an increase in both compressive and tensile strength, reflecting the densification of the matrix and the improvement in particle interlocking. These mechanisms also contribute to better stress distribution and resistance to cracking under tensile stresses. As reported in the literature (Liang et al., 2025; Yu et al., 2026), mechanical strength is closely associated with the void ratio, with denser and more compact matrices exhibiting superior performance, while higher porosity levels promote microcracking and reduce structural efficiency.

In lime-based mortars, the incorporation of SSA contributed, albeit slightly, to mechanical performance. However, this improvement was not sufficient to compensate for the lower reactivity of the lime binder, and the mechanical strength values remained significantly lower than those observed in cement-based mixtures.

From a restoration perspective, however, the increased strength associated with the incorporation of SSA can promote mechanical incompatibility with the historical substrate, concentrating stresses at the interface and increasing the risk of localized cracking (Silva, Pinto and Gomes, 2015). Therefore, although SSA contributes to matrix densification and increased strength, ensuring mechanical compatibility remains essential for long-lasting and adequate conservation performance.

Overall, the results show that SSA markedly improves the mechanical performance of cement-based mortars, although this may compromise compatibility with historic substrates. For lime-based mortars, all mixtures, including those with SSA, remain within a low and comparable range, preserving a similar mechanical behavior to the reference mortar. These findings indicate that SSA may have potential for use in lime-based mortars for historic rendering and repair applications, provided that mix proportions are appropriately adjusted to ensure compatibility with the substrate.

4. Conclusions

The use of SSA as a total replacement for natural fine aggregate significantly influenced the behavior of repair mortars in both fresh and hardened states, mainly due to its high specific gravity, angular morphology, and mechanical hardness. Therefore, it can be concluded that:

- The residue reduces water demand while increasing bulk density and apparent fluidity, as a result of its high specific gravity and particle hardness.
- The angular morphology of SSA particles promotes matrix densification, leading to a lower void index and reduced capillary absorption, as well as improved mechanical strength, particularly in cement-based mixtures.
- In lime-based mortars, although strength gains were observed due to enhanced particle interlocking, the intrinsic characteristics of the aerial binder continued to control porosity and overall mechanical performance.

From a conservation perspective, the design of sustainable repair mortars for historic buildings requires careful assessment. Although the incorporation of industrial residues such as SSA is technically viable and may enhance certain properties, not all by-products will be compatible with historic substrates. Ensuring mechanical and physical compatibility remains essential to guarantee durable and appropriate heritage interventions.

Abstract: The current climate crisis, driven by high carbon dioxide (CO_2) emissions, has intensified the occurrence of extreme events on the planet. In this context, the construction industry stands out both for its high environmental impact and for its potential to contribute to mitigation solutions, especially through the development of more sustainable materials. Among these solutions, those incorporating waste materials, such as those from the steel industry, stand out. Thus, this research aims to use steelmaking waste as a component in the production of cementitious composites. The composites were developed with total replacement of conventional aggregates by steelmaking waste, Basic Oxygen Furnace (BOF) steel slag, and Kambara Reactor (KR) slag. For comparative purposes, a reference mix was also produced with conventional materials. The composites were characterized in terms of water absorption by capillarity, compressive strength, and their interaction with atmospheric CO_2 using TGA and SEM/EDS. Composites containing steelmaking waste showed compressive strengths similar to those of the reference elements, without compromising mechanical performance. Analyses also revealed high water absorption and the presence of carbon incorporated into the matrix after environmental exposure. Mixtures containing KR and BOF, and KR alone, showed the highest water absorption rates. Regarding carbonation, the reference composites showed lower incorporated carbon content compared to composites with steelmaking waste, with differences of 2.9% and 2.4%, respectively, indicating a lower occurrence of carbonation processes. Therefore, the use of these residues proves to be a viable alternative, without compromising mechanical properties, contributing to the reduction of environmental impacts and the development of more sustainable solutions in civil construction. However, further studies are needed to evaluate in more depth the potential of these materials in CO_2 capture.

Keywords: Climate crisis. CO_2 sequestration. Steelmaking waste. Composite. Sustainable civil construction.

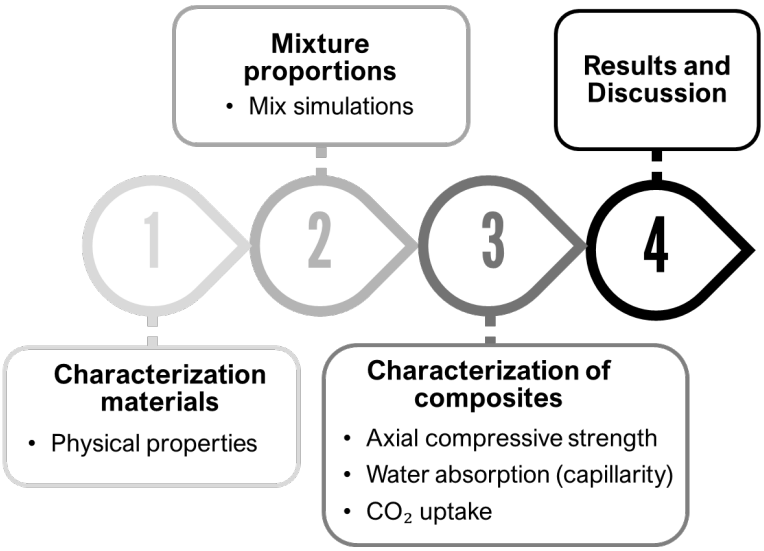
1. Introduction

The global climate crisis has been widely associated with the increase in greenhouse gas emissions, particularly carbon dioxide (CO_2). The growth of carbon emissions over recent decades has intensified extreme climatic events, making it necessary to adopt strategies to mitigate these impacts. Among the various sectors contributing to global emissions, the construction industry stands out, mainly due to concrete production. Currently, it is estimated that Portland cement manufacturing is responsible for approximately 7 to 8% of global CO_2 emissions (Lehne & Preston, 2018; Kajaste & Hurme, 2016).

Other inputs used in the production of cementitious matrices also contribute indirectly to this environmental impact. Mineral extraction for aggregate production affects water and energy consumption, resulting in

indirect CO_2 emissions (Alexander & Mindness, 2005; Padmalal et al., 2008). Considering that concrete is the most widely used construction material in the world, the search for alternatives that progressively reduce the environmental impact associated with its production has become a priority in sustainability-oriented research in civil engineering.

In this context, solutions based on the circular economy have gained significant attention by proposing the reintegration of industrial waste into new production cycles, thereby reducing the need for extracting new natural resources and minimizing associated impacts. A promising approach that has emerged is the use of waste materials as raw materials in construction. Among these, residues from the steel industry stand out. These include basic oxygen furnace (BOF) slag, generated during pig iron refining, and KR slag, originating from the desulfurization process of pig iron (Kambara Reactor). BOF slag is generally composed of calcium, iron and silicon oxides (He, Yang & Guo, 2024), while KR slag is characterized by high contents of calcium compounds, magnesium oxide and residual desulfurizing agents (Pires et al., 2019). The steel industry is characterized by a production route with high embedded CO_2 emissions, while also playing a significant economic role (IABR, 2018).



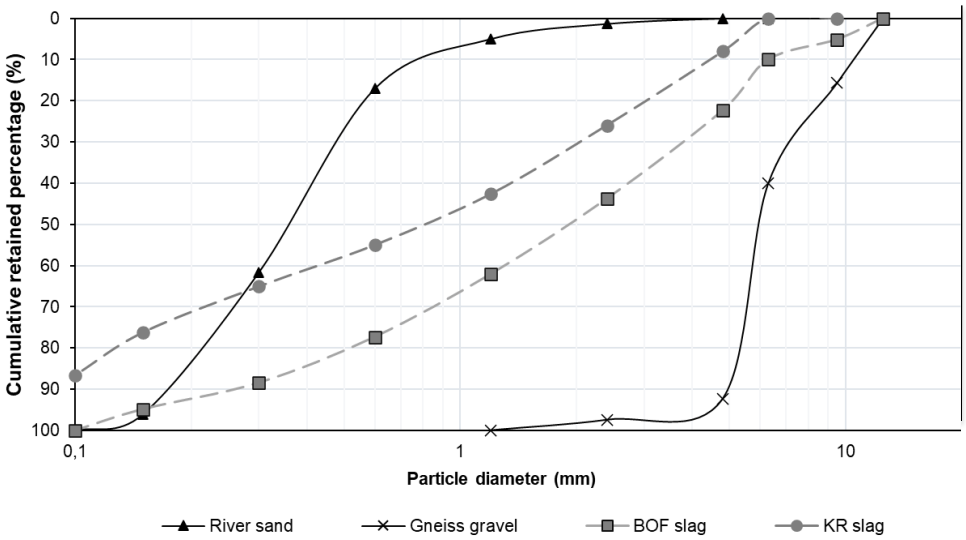
Steel industry residues present chemical and physical characteristics that allow their incorporation into cementitious matrices and have been widely investigated for applications in construction (Guo et al., 2019; Monosi et al., 2016; San-José et al., 2014; Pellegrino & Gaddo, 2009; Lai et al., 2021). In addition to their viability as substitutes for conventional aggregates, studies indicate that steelmaking residues exhibit relevant behavior with respect to carbonation, particularly regarding their durability in CO_2-exposed environments. However, most of these studies focus on specific types of residues, such as BOF slag, while materials like KR slag remain less explored, especially in combined applications. Furthermore, there is a lack of studies that investigate, in an integrated manner, the microstructural changes associated with this process, particularly under real environmental exposure conditions.

Given this scenario, this study aims to evaluate the mechanical performance and behavior under atmospheric CO_2 exposure of cementitious composites produced with the total replacement of conventional aggregates by waste from the steel industry, specifically steelmaking slag (BOF) and annealing slag (KR). To this end, compressive strength tests were performed, along with physical characterizations through capillary water absorption and microstructural characterizations using thermogravimetric analysis (TGA) and scanning electron microscopy coupled with energy dispersive spectroscopy (SEM/EDS), in order to investigate possible evidence of carbonation after environmental exposure, thus contributing to the advancement of sustainable building materials.

2. Methodology

Figure 1 presents the experimental flowchart of the research procedure. The methodology began with the characterization of the raw materials, including steel industry waste and conventional aggregates. Based on the characterization results, the mixture proportions were defined through optimization, aiming to obtain an adequate particle size distribution. Subsequently, the test specimens were molded and evaluated through mechanical, physical, and CO2 interaction tests.

Figure 1 - Flowchart of the research stages.



2.1 Materials

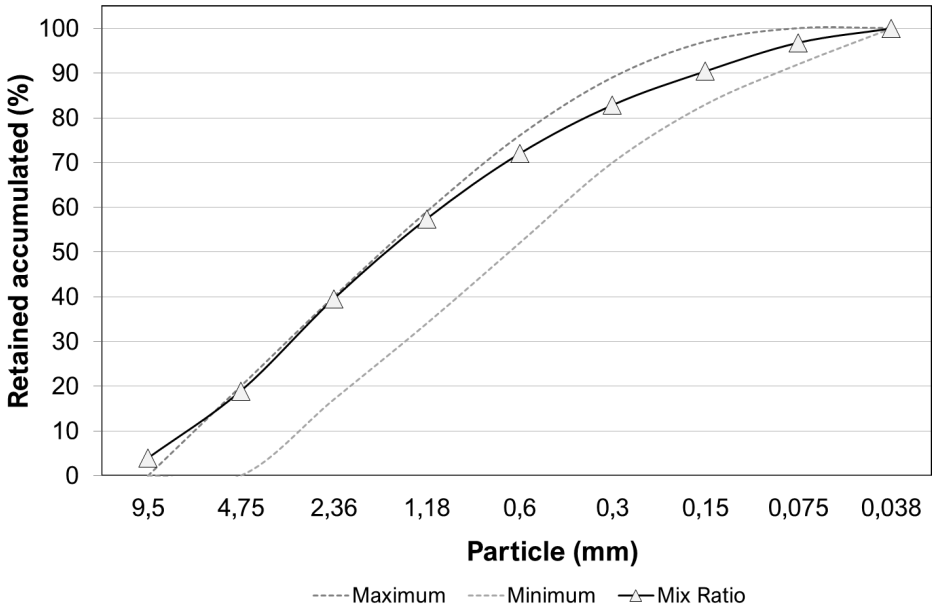
For the development of this study, steel industry residues from an integrated steel plant located in the state of Ceará, Brazil, were used, namely basic oxygen furnace (BOF) slag (maximum particle size of 9.5 mm) and KR slag (maximum particle size of 6.3 mm), originating from the pig iron desulfurization process (Kambara Reactor). These materials exhibit physical and granulometric characteristics suitable for their use as substitutes for natural aggregates in cementitious composites.

For comparison purposes, conventional aggregates widely used in the construction industry were employed, namely river sand (maximum particle size of 2.4 mm) and gneiss crushed stone (maximum particle size of 9.5 mm). The particle size distribution of all materials was determined according to ABNT NBR 17054 (2022) and is presented in Figure 2.

Figure 2 – Particle size distribution curve of the materials used in the study.

The main physical properties of the materials and the standards followed for their determination are presented in Table 1. The characterization of the materials ensures an adequate comparison between conventional aggregates and waste from the steel industry, contributing to a better understanding of their behavior in cementitious composites.

Table 1 - List of physical characterization tests performed on the waste.



Porperty	Standard	BOF slag	KR slag	River sand	Gneiss gravel
Specific gravity (g/cm^3)	NBR 16916 (2021)	2.95	3.28	2.62	2.63
Bulk density (g/cm^3)	NBR 16972 (2021)	1.80	1.16	1.56	1.37
Fines contente (%)	NBR 16973 (2021)	1.64	1.16	4.70	0.56
Fineness modulus	NBR 17054 (2022)	3.93	2.79	1.81	5.90

The binder used was Type V Portland cement, selected due to its low content of mineral additions and its high early-age compressive strength (ABNT NBR 16665, 2018). The mixing water was potable water supplied by the Water and Sewage Company of Ceará (CAGECE), responsible for the region's water supply.

2.2 Mixture proportioning

The mixture proportions were defined based on particle packing principles. The objective was to develop compositions with a significant content of steel industry waste, without the need for prior processing, adapting the particle size distributions of the materials. To this end, the dosage method proposed by Fernandes (2012) was adopted. This method consists of adjusting the proportions of aggregates so that the resulting particle size distribution approximates as closely as possible an ideal target curve. In this way, the method improves particle packing, reduces void content, and contributes to better mechanical performance of the material. The curve adopted for all mixes produced in the study is shown in Figure 2.

Figure 2 - Curve adjusted for the production of the studied traits.

Using the data obtained in the material characterization stage, mixture simulations were performed to define compositions that presented an adequate particle size distribution. These simulations resulted in different experimental mixtures, including a reference mixture composed entirely of conventional materials and others with partial or total replacement of natural aggregates by steel industry waste.

The experimental mixtures include compositions with replacement of coarse aggregate by KR slag, partial replacement of sand by BOF slag, as well as mixtures that combine different steelmaking residues, aiming at

their direct use without prior processing. These variations allowed for the evaluation of the behavior and performance of the composites under different mixture configurations. All mixture compositions are presented in Table 2.

Table 2 - Composition of the composite mixtures with replacement of natural aggregates by steel industry.

Mixture	Cement	River sand	Gneiss gravel	BOF slag (BF)	KR slag (KR)	Water
REF	1	2.5	3	0	0	0.5
T-BF	1	1.75	3	0.75	0	
T-KR	1	2.5	1.5	0	1.5	
T-BF-KR	1	1.25	1.5	0.75	0.75	

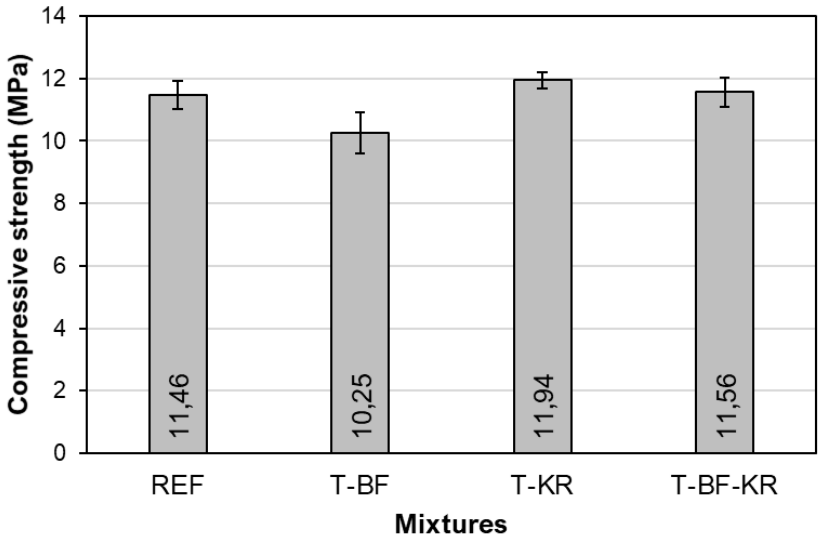
2.3 Characterization of composites

The produced mixtures were analyzed in their hardened state, with their physical and chemical properties evaluated according to the tests presented in Table 3. The composites were cast into cylindrical specimens with dimensions of ø5x10 cm. The specimens remained in the molds for 24 ± 2 hours under controlled environmental conditions (23 ± 2 °C and relative humidity above 90%), followed by demolding.

Table 3 - Experimental tests performed on the hardened composites.

Test	**Standard / Method**	**Age of testing**
Axial compressive strength	ABNT NBR 13279 (2015)	28
Water absorption by capillarity	NBR 9779 (2012)	28
CO_2 uptake	Thermogravimetric analysis (TGA)	28

Regarding the interaction of the produced composites with atmospheric CO_2, samples were collected before and after exposure to a CO_2-rich environment for 20 days.



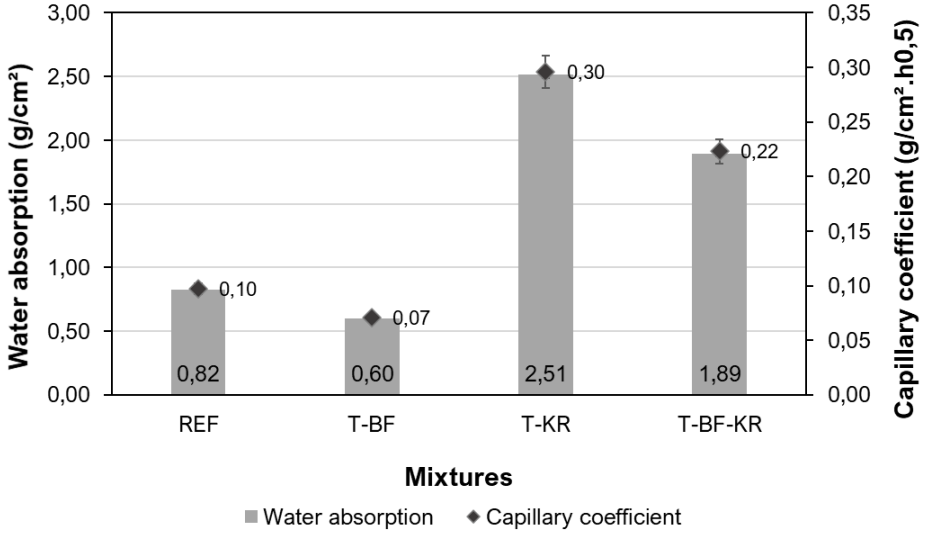
Thermogravimetric analysis (TGA) was employed to evaluate the mass variation as a function of temperature, allowing the identification of thermal decomposition stages and mass changes associated with the release or absorption of gases, such as CO_2. Samples were ground to a particle size of 75 µm before testing. This procedure allowed the comparison of samples under different exposure conditions, providing information on potential CO_2-related reactions over time. CO_2 absorption was indirectly quantified through the mass variations observed during thermal analysis.

Additionally, the point chemical composition was also investigated using energy-dispersive X-ray spectroscopy (EDS) coupled to a TESCAN Vega XMU scanning electron microscope. For this analysis, samples with an approximate diameter of 1 cm were prepared for each mixture.

3. Results and Discussion

Figure 4 presents the compressive strength results of the produced composites. The T-BF-KR mixture exhibited the highest mechanical performance, whereas the T-BF mixture showed the lowest compressive strength values. This behavior may be associated with the irregular particle size distribution of BOF slag, which could have affected particle packing and the interfacial bonding between the cement paste and the aggregates (Chang et al., 2021). However, the observed reduction was not significant, indicating comparable mechanical performance among the mixtures.

Figure 4 – Compressive strength of composites.

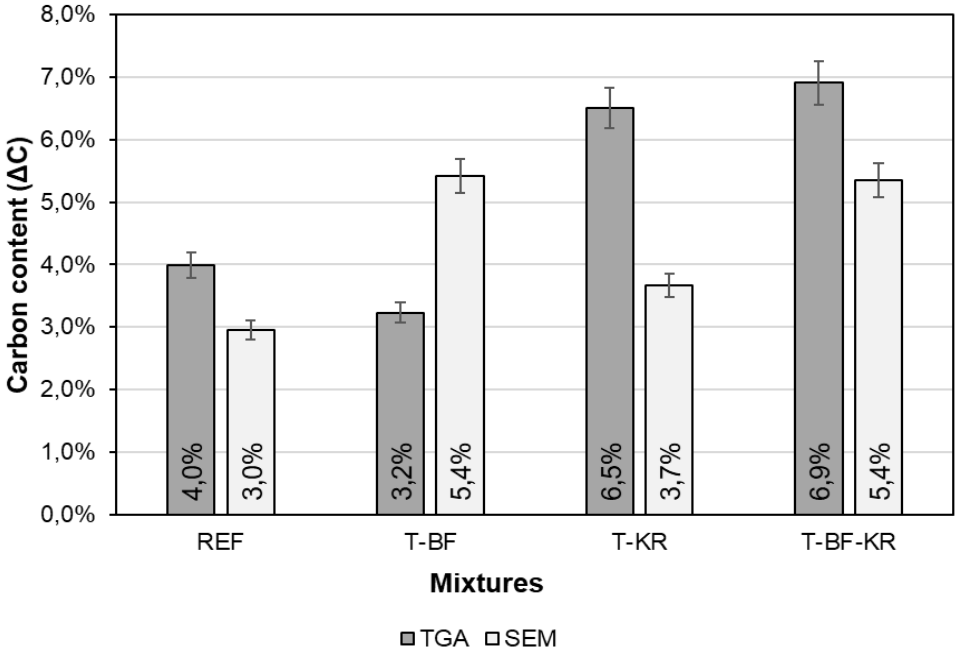


In general, the literature reports that the incorporation of steel industry residues can lead to improvements in mechanical performance on the order of 30 to 50% (Andrade et al., 2021; Costa et al., 2021). However, these results are often associated with the use of previously processed materials, involving strict control of particle size distribution and optimized particle packing.

In the present study, the direct use of these residues was adopted, without prior processing, prioritizing the compatibility of particle size distributions among the available materials. Although the strength gains were less pronounced than those reported in the literature, the results indicate that the replacement of conventional aggregates with steel slags did not impair the mechanical performance of the composites. These findings demonstrate the feasibility of using such residues under simplified application conditions, with potential benefits in terms of cost reduction and lower environmental impact associated with material processing.

Figure 5 presents the results of capillary water absorption of the evaluated mortars. In general, the incorporation of steel industry waste led to distinct behaviors, depending on the mixture.

Figure 5 – Water absorption and Capillary coefficient of mixtures.



The incorporation of BOF contributed to a reduction in water absorption, indicating a possible refinement of the pore structure and a decrease in the connectivity of capillary pores. In contrast, the presence of KR

resulted in a significant increase in capillary absorption, suggesting the development of a more open pore network. The combined mixture showed an interaction between the wastes, in which the BOF partially mitigated the effects associated with the KR. These results indicate that the nature and reactivity of the incorporated materials directly influence the microstructure of the mortars, leading to changes in their capillary absorption behavior, which is consistent with findings reported in the literature (Monosi et al., 2016; Guo et al., 2019). Despite the increase in capillary absorption associated with the KR, no reduction in mechanical strength was observed, which can be considered a positive outcome for its potential application.

Figure 6 presents the absolute variation in carbon content for the different mixtures, as obtained by TGA and SEM/EDS analyses. In general, all mixtures exhibited an increase in carbon content after exposure, indicating the occurrence of carbonation processes. The observed increase in carbon content after 20 days of environmental exposure suggests the interaction between the composites and atmospheric CO_2, evidencing the occurrence of carbonation reactions.

Figure 6 - Absolute variation in the carbon content of the composites by TGA and SEM/EDS analyses.

The composites incorporating steel industry residues exhibited greater variations in carbon content compared to the reference mixture, indicating a higher tendency for the formation of carbonated compounds. Overall, the results suggest that both BOF and KR slags influence the interaction of the composites with CO_2, although exhibiting distinct behaviors.

The differences observed between the results obtained by TGA and SEM/EDS can be attributed to the specific characteristics of each technique. Thermogravimetric analysis provides a higher level of experimental control, whereas SEM/EDS, applied in an adapted manner, may be influenced by sample heterogeneity and limited representativeness. Nevertheless, both methods indicate consistent trends regarding the increase in carbon content after environmental exposure.

Thus, TGA results suggest a stronger contribution of KR to the increase in carbon content, SEM/EDS measurements indicate a more pronounced effect associated with BOF containing mixtures. These differences suggest that carbonation is not spatially homogeneous within the matrix and is influenced by the heterogeneity of the composites. Although both techniques show an overall increase in carbon content for some mixtures compared to reference, the magnitude and significance of these changes vary depending on

the measurement approach, highlighting the importance of combining bulk and localized analyses to interpret carbonation behavior.

4. Conclusions

This study aimed to evaluate the mechanical performance and the interaction with atmospheric CO_2 of cementitious composites produced with the replacement of natural aggregates by steel industry residues. The main conclusions are as follows:

- The results demonstrated that the use of steel industry residues as a replacement for natural aggregates in cementitious composites is technically feasible, without significant impairment of mechanical performance.
- The incorporation of steelmaking waste directly influences the microstructure and capillary absorption behavior of mortars, with distinct effects observed depending on the type of waste used, without compromising mechanical performance. This highlights the potential application of these materials in sustainable cementitious composites.
- Even without prior material processing, the composites exhibited compressive strength comparable to the reference mixture, highlighting the potential application of these residues under simpler and more cost-effective conditions.
- Regarding interaction with atmospheric CO_2, an increase in carbon content was observed in all samples after the exposure period, indicating the occurrence of carbonation processes.
- The composites incorporating steel industry residues showed greater variations in carbon content, suggesting a higher tendency for the formation of carbonated compounds compared to the conventional material.

Overall, the findings indicate that the use of steel residues may contribute to the reduction of natural resource consumption and support the development of materials with potential interaction with CO_2. Further studies are recommended to investigate the CO_2 uptake potential of these composites in greater depth, including evaluations under controlled conditions and different exposure scenarios.

Abstract:

The evaluation of shear performance of masonry strengthened with Natural Fiber Reinforced Cementitious Matrix (NFRCM), adopting "modified" triplet specimens, derived from the Representative Elementary Volume (REV) of the running bond masonry texture, is presented in this research. Diagonal Compression Tests (DCT) were conducted, and an adapted Digital Image Correlation (DIC) technique was adopted to capture the deformation at the microstructural level.

Two specimen configurations were studied: an unreinforced triplet and a triplet strengthened with bi-directional jute mesh-reinforced NFRCM. The results demonstrate an improvement in the shear resistance and deformation capacity in the strengthened specimens. Further, a Finite Element (FE) model based on a multi-leaf homogenization technique was also adopted and was validated based on the experimental outcomes.

With this, the research presented, aims at combining novel small-scale specimen derived from a REV where the microstructure is significant, with the well-established shear identification with DCT, to demonstrate an accessible and sustainable testing methodology for masonry, advancing the understanding of micro-mechanical interactions in strengthened masonry.

Keywords: Masonry, Shear characterization, Modified Triplets, Jute-NFRCM.

1. Introduction

Masonry remains one of the most widely used construction system, particularly in historic and vernacular structures. Despite being advantageous due to its ease of construction and load bearing capacity, masonry is inherently weak in resisting tensile and shear stresses. Shear failure represents one of the most critical and recurrent collapse mechanisms, especially under seismic or lateral loading conditions. Improving this shear performance of masonry, therefore, continues to be a major focus of research, both for the preservation of existing structures and the development of more resilient construction systems (Corradi and Borri, 2018).

In recent years, strengthening techniques have gained significant attention as effective strategies to improve the in-plane performance of masonry, especially to resist lateral actions (Alecci *et al.* 2019; Cheng *et al.* 2020). Among these, composite-based solutions such as Fiber Reinforced Cementitious Matrix (FRCM) systems have emerged as a compatible method for masonry strengthening. Unlike Fiber Reinforced Polymers (FRP) (Mazzotti *et al.* 2016), FRCM systems or more commonly Textile Reinforced Mortars (TRM) employ fiber matrices, which allow loads to be distributed more evenly, while also retaining compatibility with the masonry (Garcia-Ramonda *et al.* 2020; Libre *et al.* 2023), a key consideration in conservation engineering and while intervening with built heritage (Valluzzi et al. 2014).

A sustainable evolution of this approach is represented by Natural Fiber Reinforced Cementitious Matrix (NFRCM) systems, which replace synthetic fibers with organic alternatives such as jute, flax, hemp, or sisal (Li *et al.* 2020). Natural fibers have long been a key aspect in improving the flexural and ductile strength of mortars and plasters in traditional constructions, with several examples of short or shredded fibres introduced to the admixtures. While offering several advantages, including low environmental impact, cost-effectiveness, and wide availability, the fiber mesh matrix allows for a high degree of adaptability in tailoring the reinforcement system to specific applications (Codispoti *et al.* 2015; Li *et al.* 2020). As a result, NFRCM systems are increasingly the focus of investigations into sustainable strengthening solutions for masonry structures. Despite their potential, several challenges remain in fully understanding and optimizing the performance of NFRCM-strengthened masonry.

The current research focuses on jute fibers, a widely available and cost-effective natural fiber exhibiting good tensile strength, ductility, and adequate moisture resilience (Majumder *et al.* 2022). These properties make jute particularly suitable for enhancing the mechanical performance of masonry when embedded in a lime-based inorganic matrix. Consequently, experimental investigations evaluating the performance of NFRCM systems applied to masonry, particularly under stresses that are representative of real structural behaviour, are essential (Trochoutsou *et al.* 2021).

With this context established, the research revisits the experimental characterization of masonry shear behaviour which is essential for a reliable and scalable application of such systems. Tests on masonry, both un-strengthened and strengthened, are typically conducted by adopting scaled masonry specimens tested in diagonal compression or shear compression, as outlined in the ASTM standards and RILEM recommendations (ASTM E519/E519M-22; RILEM T. C. LUM B6: 1994). While such tests provide valuable insights into the global response of masonry system, the testing scales with large 1m X 1m masonry wallets present practical challenges, primarily due to the quasi-brittle nature of masonry, making the setups often impractical. These constraints become particularly significant when investigating the performance, with respect to a diverse set of parameters, such as masonry textures and material properties, textile configuration and matrix composition or even durability and resistance (Boem 2022).

With an aim to address these limitations, the current research, proposes a redefinition of the specimen scale. Derived from the Representative Elementary Volume (REV) of the running bond masonry, a 'modified' masonry triplet specimen is adopted. This small-scale configuration improves the ease of experimentation drastically, while retaining prominent microstructural definition of the overall masonry typology adopted (Thatikonda *et al.* 2024). In Section 2.1, the two modified triplet specimen configurations are presented: an unreinforced triplet and a symmetrically strengthened triplet with jute-NFRCM. The diagonal compression test conducted, and the deformations captured with the aid of an adapted Digital Image Correlation (DIC) technique are then presented in Section 2.2. Section 3 presents the proposed multi-leaf homogenization based Finite Element (FE) model, validated with the experimental data, following a discussion of the outcomes and conclusions.

2. Experimental Campaign Modified Masonry Triplet Specimens

2.1 Specimen choice and configurations

Considering the primary aim to revisit the experiment scale, particularly in the context of strengthened specimens, it is essential to rationalize the choice of specimen. The ASTM standards and RILEM recommendations (ASTM E519/E519M-22; RILEM T. C. LUM B6: 1994) outline the Diagonal Compression Test (DCT) to evaluate the shear strength of masonry, with axial force applied along one diagonal to introduce orthogonal tensile stresses. As noted, the proposed specimen is a scaled masonry wall, with dimensions about 1m x 1m, rotated at an angle of 45°, while the load is introduced along one diagonal of the specimen. This specimen scale and test setup are both accompanied with their own set of challenges. Researchers have attempted to address this through redefinition of the test setup, where specimens remain in horizontal

configuration and the force along one diagonal (de Carvalho Bello *et al.* 2021). The quasi-brittle nature of masonry further complicates the interpretation of results, as the measured shear response or crack initiation and propagation are highly sensitive to boundary conditions, loading configuration, and specimen size. This often raises questions regarding the representativeness and scalability of the test outcomes, particularly when extended to strengthened configurations. Further, within these strengthened configurations, recent studies have attempted reducing the specimen scale (Libre *et al.* 2023; Thatikonda *et al.* 2025b).

To redefine the specimen scale, the current research considers the Representative Elementary Volume (REV), fundamental for the micro-mechanical analysis of periodic media such as masonry. A REV together with its neighbouring elements, incorporates the heterogeneity associated with the masonry texture, capturing the overall mechanical response while also accounting for the material micro-structure and stress–strain distributions (Cecchi and Sab, 2002). To practically realize the REV, the masonry triplet defined in the standard EN 1052-3 (2002) is taken as the reference configuration and subsequently modified, by introducing a head joint to better represent the running bond masonry texture, as shown in Figure 1a,b. The specimens are constructed with brick units of length b= 250 mm and height a= 55 mm and depth t= 120 mm, and with mortar joints both bed and head joints with a thickness of e_h = e_v = 10 mm. This specimen configuration can be considered the smallest representative masonry assemblage capable of capturing the governing microstructural characteristics and interactions of the material. In fact, the proposed tests try to avoid capturing the simple mortar joint sliding that can typically be obtained with standard triplet tests (EN 1052-3 (2002)) and aims to activate a more complex shear behaviour involving both the blocks and the mortar joints.

Further, the strengthened specimen, hereby referred to as reinforced specimens, adopts a jute-fibre NFRCM embedded in an inorganic hydraulic lime composite matrix. The reinforcement is provided by a jute fibre mesh with bidirectional yarns arranged in a grid of approximately 10 × 10 mm^2. The mechanical properties of the jute and composite are presented in Table 2. An effective thickness of s=15 mm on each face was achieved, see Figure 1c,d, where the mesh was approximately placed at the mid-thickness of the matrix, as seen constructed in Figure 1e. A coordinate system is introduced, with axes x_1 and x_2 along the horizontal and vertical in-plane directions, respectively, and the x_3 axis along the thickness of the specimen, in the out of plane direction.

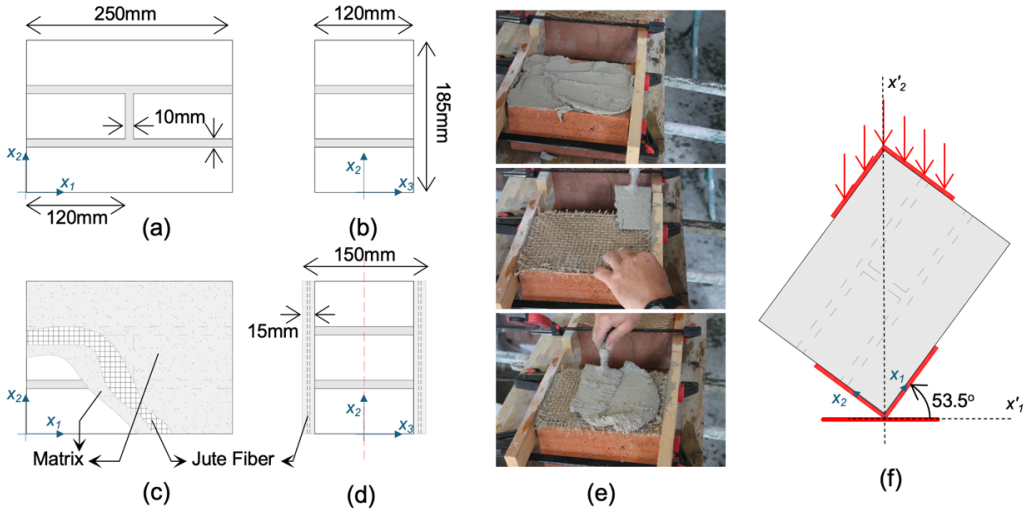

Figure 1 – (a, b) Modified masonry triplet specimen in the unreinforced configuration, (c, d) Triplet symmetrically strengthened with jute-NFRCM, (e) construction of the specimen (f) test setup for DCT

2.2 Test setup and DIC technique

To simulate the diagonal compression and the indirect tension along the orthogonal direction, the specimens were rotated about the x_3 axis at an angle of 53.5°, rotating axes x_1 and x_2 of the original reference system of the triplet to x'_1 and x'_2. The applied load is along the new vertical x'_2 and is aligned with the diagonal of the triplet, as shown in Figure 1f. Using loading and footing shoes of 100 mm each, to minimize local stress concentrations at the contact and to ensure a uniform stress distribution, the load was applied under displacement control, at a rate of 0.1mm/sec. The deformation presented was captured with the aid of an adapted Digital Image Correlation (DIC), outlined in Thatikonda *et al.* (2024). The specimens were equipped with high-contrast targets, and a sequence of high-resolution images captured their motion through the test. Processing this motion with respect to the undeformed state, the deformations and strains were computed by creating a system of virtual extensometers. In this method, the resolution of the images captured impacts the accuracy of these extensometers, allowing a displacement precision to track 10^{-2} pixels and derive a 0.02% strain accuracy.

2.3 Experimental outcomes

A total of eight specimens were tested, four in the unreinforced configuration: URM 04, 05, 06, 07 and four in the strengthened configuration: RM01, 02, 03, 04. Although the DIC technique captured a range of deformations, two of these were considered for the current research; the vertical deformation along the x'_2 axis and along the applied force (Δv), and the deformation presented orthogonally (Δh) along the x'_1 axis. The force-deformations for the unreinforced specimens and the reinforced specimens are plotted in Figures 2 and 3, respectively.

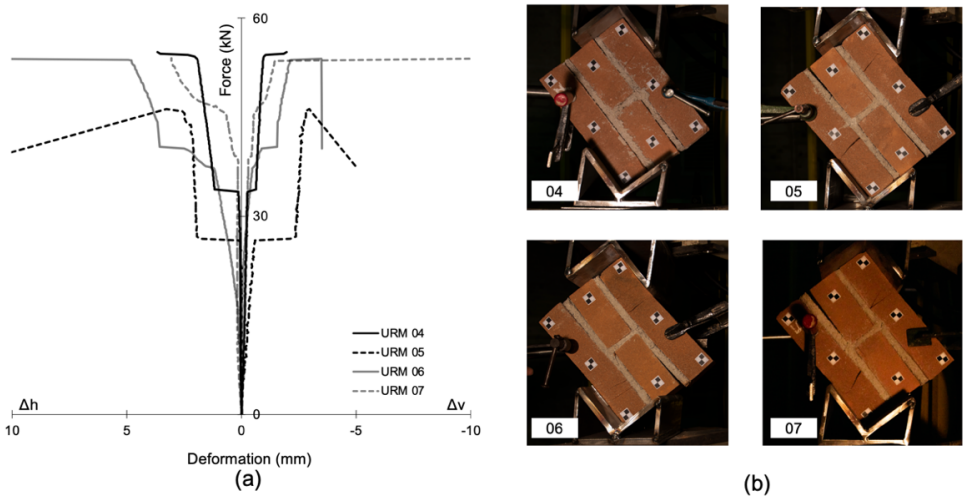

Figure 2 – Unreinforced specimens (a) Applied force and deformation Δv and Δh captured, (b) Failures presented at critical load

Despite some variation in deformation capacities of the specimens, the shear resistance and the ultimate strength of among the tested specimens remains comparable. The unreinforced specimens reached maximum loads of approximately 50–55 kN, whereas the reinforced specimens exhibited higher load capacities, reaching 60–95 kN approximately.

Following crack initiation, the specimens maintained an almost constant shear resistance over a finite displacement range, indicating stable post-cracking behaviour. The unreinforced specimens exhibited an initially brittle response, followed by progressive crack propagation and degradation of the resisting mechanism, governed by a combination of shear and bending actions. In contrast, the reinforced specimens demonstrated improved ductility, evidenced by both the more distributed crack patterns and the post-peak

defamations observed in the force–deformation curves. Further, the reinforced specimens sustained larger deformations before significant loss in the resistance, while a sharp drops in the post crack behaviour was seen is the unreinforced specimens indicate.

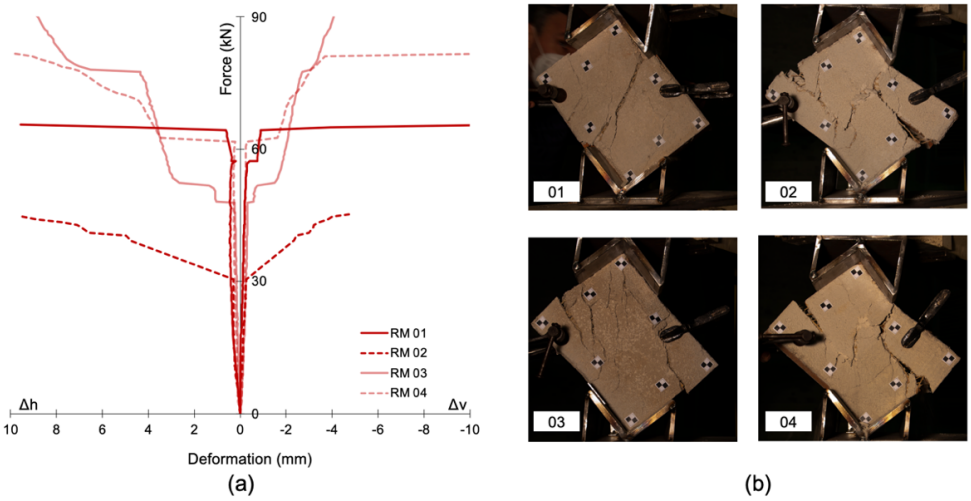

Figure 3– Jute-NFRCM strengthened reinforced specimens (a) Applied force and deformation Δv and Δh captured, (b) Failures presented at critical load

Further, to evaluate the shear stiffness (G) of the specimens, the initial slope of the force displacement curves is considered, the shear stress (τ). shear stain (γ) are calculated as presented in Equation 1, where F is the applied load and A is the normalized cross-sectional area, v_0 and h_0 are the initial lengths in the orthogonal directions.

$$G = \frac{\tau}{\gamma} \; ; \quad \tau = \frac{F}{A} \; ; \quad \gamma = \frac{\Delta v}{v_o} + \frac{\Delta h}{h_o} \tag{1}$$

The shear stiffness computed experimentally are presented in Table 1. The experimental outcome highlights a clear distinction between the unreinforced and strengthened specimens. While the unreinforced masonry exhibits a brittle response with limited deformation capacity, seen in Figure 2a, the strengthened specimens show improved load-carrying capacity, with higher deformation, of about more than 10mm in the orthogonal direction, improved ductility and delayed failure indicating the effectiveness of the reinforcement system, seen in Figure 3a. The average stiffness of the unreinforced and reinforced specimens presented in Table 1 also indicates about 50% increase in the performance of masonry in the presence of jute-NFRCM strengthening.

Table 1 – Initial stiffnesses presented in the specimens, computed according to Equation 1

Unreinforced triplets		**Reinforced triplets**	
URM 04	537.65 MPa	RM 01	655.45 MPa
URM 05	405.16 MPa	RM 02	737.50 MPa
URM 06	622.87 MPa	RM 03	703.15 MPa
URM 07	496.57 MPa	RM 04	979.11 MPa
Average	**515.56 MPa**	*Average*	**768.80 MPa**

3. Finite Element Modelling

The finite element model adopted in this study builds upon the multi-leaf homogenization framework developed by Cecchi (2006) initially introduced for the analysis of CFRP-strengthened masonry walls subjected to both in-plane and out-of-plane loading in the elastic range. The application of this model for NFRCM matrix is elaborated in Thatikonda *et al.* (2025b). Here a two-step homogenization is adopted for deriving the equivalent mechanical characteristics of the elastic continua.

First the NFRCM system and masonry are modelled separately. The NFRCM is modelled as a 3D orthotropic continuum, accounting for the bidirectional fiber mesh embedded mid-width of the composite matrix, following the nomenclature presented in Cecchi (2006) and modelling approach proposed in Thatikonda *et al.* (2025b). The 3D equivalent elastic properties of the strengthening applied is given by the tenor $\mathbf{A}^{\mathbf{NFRCM}}$ or A_{ijkl}^{NFRCM}, where *i,j,k,l* = {1,2,3}, see Table 2.

Table 2 – Mechanical properties of jute-NFRCM constituents and 3D homogenized tensor $\mathbf{A}^{\mathbf{NFRCM}}$

Jute - NFRCM	**Homogenized properties**		
Jute fiber mesh E = 524 MPa ν = 0.2	A_{1111} = 1289.52 MPa	A_{1122} = 231.88 MPa	A_{1133} = 230.45 MPa
	A_{2211} = 231.87 MPa	A_{2222} = 1289.51 MPa	A_{2233} = 230.45 MPa
Mortar matrix E = 1300 MPa ν = 0.2	A_{3311} = 232.22 MPa	A_{3322} = 232.23 MPa	A_{3333} = 1258.39 MPa
	A_{1212} = 525.35 MPa	A_{2323} = 4870.12 MPa	A_{3131} = 4870.37 MPa

For the masonry triplet, a 2D homogenization is adopted and the equivalent elastic continua is presented in the tensor $\mathbf{A}^{\mathbf{M}}$ or A_{ijkl}^{M}, in Table 3.

Table 3– Mechanical properties of masonry constituents and 2D homogenized tensor $\mathbf{A}^{\mathbf{M}}$

Masonry Constituents	**Homogenized properties**		
Brick units E = 4387 MPa ν = 0.2	A_{1111} = 3312.49 MPa	A_{1122} = 261.66 MPa	-
	A_{2211} = 271.51 MPa	A_{2222} = 1119.37 MPa	-
Mortar Joints E = 128 MPa ν = 0.2	-	-	A_{3333} = 3508.55 MPa
	A_{1212} = 398.34 MPa	-	-

In the second step of the homogenization, the previously homogenized jute NFRCM matrix (A_{ijkl}^{NFRCM}) and the masonry (A_{ijkl}^{M}) are integrated following the Equation 2, where t is the masonry thickness, and s is the thickness of each of the NFRCM strengthening layers. The equivalent elastic properties of the reinforced specimen A_{ijkl}^{H}, as presented in Table 4.

$$A_{ijkl}^{H} = \frac{1}{t+2s}\left(tA_{ijkl}^{M} + 2sA_{ijkl}^{NFRCM}\right) \tag{2}$$

Table 4 – Homogenized mechanical properties of the reinforced specimen $\mathbf{A^H}$

Reinforced specimen - Homogenized properties		
A_{1111} = 2907.89 MPa	A_{1122} = 255.7 MPa	-
A_{2211} = 263.58 MPa	A_{2222} = 1153.39 MPa	-
-	-	A_{3333} = 3058.52MPa
A_{1212} = 423.74 MPa	-	-

The triplet specimens are modelled in the commercial software Straus7, where the Finite Element (FE) model adopts anisotropic quadrilateral deformable elements under 2D plain stress hypothesis, aimed at capturing the elastic response and initial shear stiffness, providing a basis for the validation with the experimental results. To establish a comparison between the unreinforced, and the reinforced specimens and to evaluate the reliability of the homogenization method adopted at this scale and heterogeneity, three FE models are proposed.

The first two models consider the unreinforced specimen, with the first one (Model 1) modelling the masonry texture, with brick and mortar discretely defined (see Table 3 for masonry constituent properties adopted), to present a heterogenous model, and the second as a homogeneous FE model (Model 2) with the unreinforced masonry homogenized properties (A_{ijkl}^M). The third model (Model 3) adopts the homogenized properties of the reinforced masonry specimen (A_{ijkl}^H). To simulate the specimen geometry, test setup and boundary condition the FE models were also rotated, and a unit displacement was introduced along the x'_2 axis, and the vertical (Δv) and horizontal (Δh) deformations computed along the x'_2 and x'_1 axes respectively. The deformation distribution of three FE models is presented in Figure 4. For each of these models the resultant force was recorded, along with the orthogonal deformation presented and a comparison with these force-displacement outcomes with that of the experimental data is presented in Figure 5.

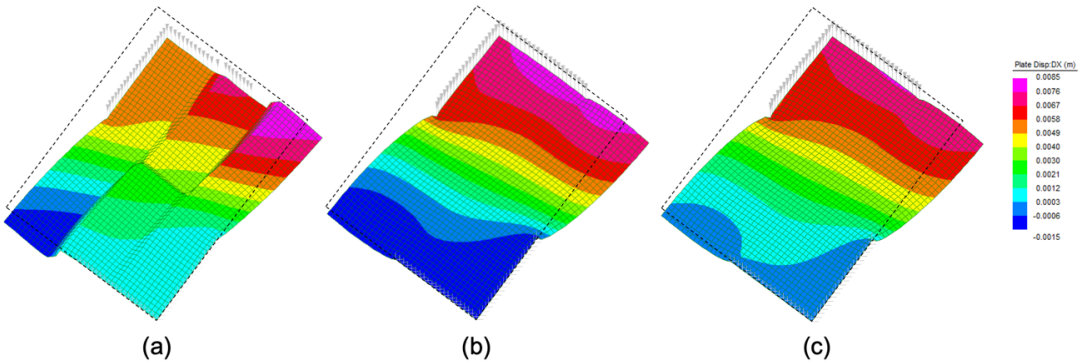

Figure 4 – FE deformations distribution (a) Model 1 - heterogeneous unreinforced triplet model (b) Model 2 - homogenised unreinforced triplet model and (c) Model 3 - reinforced homogenised model

Further adopting the formulation presented in Equation 1, the initial shear stiffness (G) is computed for each of these FE models. The unreinforced specimen models 1 and 2 present an initial stiffness of 678 MPa and 660 MPa, respectively, whereas the reinforced specimen model 3 presents an initial stiffness of 864 MPa. Although the distribution of the deformation is distinguishable in the two unreinforced models presented,

the stiffness computed is alike. The heterogeneous model, similar to the experimental outcomes, shows an improved stiffness with the presence of the jute-NFRCM reinforcement.

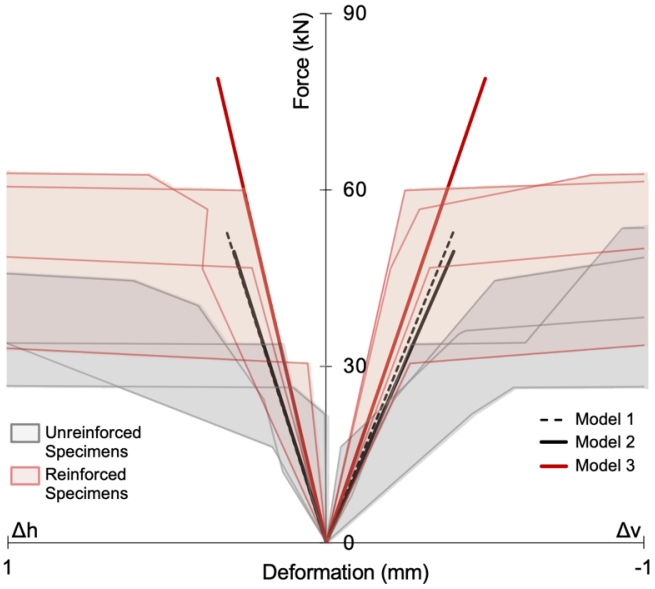

Figure 5 – Initial stiffness computed from the FE model outcomes - compared to the experimental data

4. Conclusion

The current research aims at demonstrating that the proposed modified masonry triplet provides an effective and practical alternative to conventional large-scale specimens for the shear characterization of masonry. The experimental results show that jute-NFRCM strengthening enhances both shear resistance and deformation capacity, with an average improvement of approximately 50% in shear stiffness when compared to unreinforced specimen. The finite element models, particularly based on the multi-leaf homogenization approach, are comparable with experimental results, both in terms of the deformations predicted and the initial stiffness computed, supporting the validity of the adopted modelling strategy.

Further, the manageable specimen scale provides a good foundation for the research within the framework of innovative composites, evaluating various parameters of the NFRCM strengthening, such as textile architecture, durability, and resilience under different mechanical and environmental conditions, amongst others. Furthermore, the FE models present a simple and efficient tool to estimate the performance, and this could be taken forward to introduce non-linear parameters, evaluating ductility and the post peak behaviours of reinforced specimens.

Abstract: Historic masonry structures, widely distributed in seismic-prone regions, are characterised by low tensile strength, limited deformation capacity, and brittle failure mechanisms under cyclic loading and combined axial–bending actions. Improving their structural performance while preserving material compatibility and architectural integrity remains a major challenge in the seismic rehabilitation of built heritage. In this context, Fibre-Reinforced Cementitious Matrix (FRCM) systems have emerged as effective strengthening solutions due to their compatibility with masonry substrates and reduced invasiveness. Among them, PBO-FRCM composites—consisting of polyparaphenylene benzobisoxazole (PBO) fibre meshes embedded in inorganic matrices—have shown significant potential for confinement of masonry elements. This study investigates the compressive behaviour of masonry columns confined with PBO-FRCM systems through a combined experimental and numerical approach. Square masonry columns were tested under monotonic axial compression loading, including unconfined reference specimens and confined specimens strengthened with a PBO-FRCM system, in order to assess the effectiveness of the confinement. The experimental results confirmed that FRCM confinement enhances both compressive strength and deformation capacity. These results were subsequently used to evaluate the accuracy of the numerical modelling strategy in reproducing the compressive behaviour of both confined and unconfined specimens. To this end, a three-dimensional (3D) numerical model based on the Discrete Element Method (DEM) was developed using 3DEC software, in which the masonry column was represented as an assemblage of deformable blocks interacting through contact interfaces. The model was first calibrated against the experimental response of unconfined columns and then extended to confined configurations through liner elements, adapted to simulate an external FRCM jacketing within a discontinuum framework. The proposed modelling strategy captures the interaction between the masonry substrate and the strengthening system in terms of stress transfer and confinement mechanisms. In particular, the numerical results show good agreement with the experimental response in terms of peak compressive strength, with differences of approximately 6,84 % and 1,36 % for the unconfined and confined configurations, respectively. These results provide quantitative insight into the role of interface behaviour and lateral dilation in the activation of the confinement mechanism, confirming the potential of DEM-based approaches for the simulation of FRCM-strengthened masonry elements.

Keywords: Masonry structures, Columns, FRCM confinement, Discrete Element Method.

1. Introduction

1.1 Literature review

The reuse and rehabilitation of existing buildings represent one of the most effective strategies for reducing the environmental impact associated with the construction sector (Aigwi *et al.* (2023)). Across Europe, a large

portion of the built heritage consists of existing structures, many of which are currently abandoned or affected by various levels of structural degradation. A considerable portion of this stock is composed of masonry constructions, often characterised by significant historical and cultural value.

From a mechanical standpoint, masonry is a quasi-brittle material exhibiting low tensile strength, limited deformation capacity and sudden failure mechanisms. Such behaviour is inherently incompatible with modern seismic design philosophies, which promote ductile structural responses to ensure adequate energy dissipation during earthquake events. For this reason, the development of strengthening techniques capable of enhancing deformability and damage tolerance, while preserving material compatibility and architectural integrity, has become a central topic in structural engineering research.

Among the available solutions, Fabric-Reinforced Cementitious Matrix (FRCM) systems have progressively gained attention (Kouris and Triantafillou (2018)). These systems consist of high-strength fibre meshes embedded in inorganic matrices and have proven particularly suitable for strengthening masonry substrates. Compared with Fibre-Reinforced Polymer (FRP) systems, which were developed earlier, FRCM solutions offer several advantages, including improved compatibility with masonry substrate, vapour permeability and enhanced reversibility of the intervention (Di Tommaso *et al.* (2017)). These characteristics make them particularly attractive for applications involving historical masonry structures.

Extensive experimental research demonstrated the effectiveness of FRCM systems in improving the structural performance of masonry elements (Aiello *et al.* (2021); Ponte *et al.* (2023)), showing their ability to modify typical brittle failure modes and promote a more gradual damage evolution.

Among structural elements, masonry columns have attracted particular attention due to their primary role in load transfer and their vulnerability to brittle failure under combined compression and bending, often induced by seismic actions or load eccentricities. For this reason, they represent an ideal benchmark for evaluating FRCM-strengthening techniques.

Several studies investigated the influence of fibre type in FRCM systems. In addition to steel-based systems, commonly referred to as Steel-Reinforced Grout (SRG) composites (De Santis *et al.* (2017)), other fibres such as glass, carbon, basalt and polyparaphenylene benzobisoxazole (PBO) have been widely employed (Di Ludovico *et al.* (2020); Jing *et al.* (2021)). Among these, PBO fibres have attracted increasing interest due to their high tensile strength and elastic modulus, which enhance the load-carrying capacity of strengthened elements. The increase in ductility is instead primarily related to the interaction between the fibre mesh and the inorganic matrix, as well as to the progressive activation of the reinforcement (Ombres and Verre (2020)).

The role of the inorganic matrix was also extensively investigated, as it represents a key parameter governing the overall response of the composite system (Cascardi *et al.* (2018)). Additional factors influencing performance include load eccentricity (Ombres (2015)), discontinuous reinforcement configuration (Campolongo *et al*. (2023)), and geometric features such as corner rounding (Sneed *et al.* (2017)).

Despite the considerable experimental effort, several uncertainties still affect the design and assessment of FRCM-strengthened masonry columns. Existing analytical models for FRCM-strengthened masonry are typically calibrated on experimental datasets (Ameli *et al.* (2022); Napoli and Realfonzo (2022)), and their reliability is therefore strongly dependent on the representativeness of the available data. In addition, design-oriented formulations have been proposed in international guidelines, such as those provided by the CNR (2020) recommendations, which offer practical approaches for estimating the strength of FRCM-retrofitted masonry elements.

Although the prediction of strength enhancement has been extensively addressed in the literature, greater uncertainty still exists in the quantification of the deformation capacity of strengthened masonry, particularly under complex loading conditions. In this context, axial compression tests play a fundamental role in the mechanical characterisation of the material and in the calibration of numerical models, providing a necessary basis for more advanced investigations involving cyclic or dynamic loading, where post-peak behaviour and damage evolution become critical.

The inherent variability of masonry materials further complicates this issue, as specimens with similar geometry and strengthening configurations may exhibit significantly different mechanical responses. As a result, large experimental datasets would be required to ensure robust and generalisable predictions.

1.2 Numerical approaches

Several numerical modelling approaches have been developed to investigate the mechanical behaviour of masonry structures. Owing to the composite and heterogeneous nature of masonry, governed by the interaction between units and mortar joints, two main strategies are generally adopted: equivalent continuum approaches and discontinuum approaches (Lourenço (2002); Lemos (2007)).

Within continuum frameworks, masonry is typically represented as an equivalent homogeneous material through suitable constitutive relationships capable of reproducing its global response. In this context, modelling strategies are commonly classified into macro-modelling, where masonry is treated as a homogenised continuum, and micro-modelling approaches, in which units and mortar joints are explicitly represented through interface elements. Continuum-based approaches, most commonly implemented through the Finite Element Method (FEM), are widely used due to their versatility and their ability to capture the global structural behaviour of masonry systems. In addition, simplified modelling strategies such as the Equivalent Frame Modelling (EFM) approach are also widely adopted for structural analysis, particularly when reduced computational effort is required.

However, the response of masonry is strongly governed by discontinuities associated with mortar joints, which may undergo opening, sliding and progressive detachment under increasing load levels. The accurate representation of these mechanisms, particularly in the presence of crack propagation and large displacements, may be difficult to achieve within purely continuum-based formulations.

For this reason, discontinuum-based approaches have gained increasing attention in the analysis of masonry structures (Lemos (2007)). In these approaches, masonry is modelled as an assemblage of distinct interacting bodies, where the global response emerges from the interaction between units and their contact interfaces. Among these methods, the Discrete Element Method (DEM) has proven particularly suitable for materials characterised by a block-like structure, such as masonry (Bui *et al.* (2017); Lemos and Costa (2017); Sarhosis *et al.* (2016)).

Originally introduced by Cundall (1971), DEM was developed to simulate the mechanical behaviour of systems composed of interacting discrete bodies. Within this framework, masonry is represented as an assembly of blocks connected through contact laws governing normal and tangential interactions. This approach naturally allows key mechanisms observed in masonry structures to be captured, including joint opening, sliding, block separation and large displacement effects, which play a fundamental role in the structural response and failure modes.

Despite the increasing use of DEM approaches for the analysis of unreinforced masonry structures, their application to FRCM-strengthened systems remains very limited. To the authors' knowledge, no studies are currently available in the literature addressing the modelling of FRCM reinforcement within a three-dimensional (3D) DEM framework such as 3DEC (Itasca Consulting Group (2024)). Only limited contributions can be found for simplified two-dimensional (2D) cases. For instance, Gobbin *et al.* (2020) recently studied the structural behaviour of masonry arches strengthened with externally bonded reinforcement using a 2D DEM approach, where the masonry was modelled as an assemblage of rigid blocks and the reinforcement was represented through truss elements connected to the substrate by means of non-linear springs. This highlights a clear research gap in the numerical modelling of FRCM-strengthened masonry within a discontinuum framework, particularly in 3D analyses.

In this context, the present study proposes a 3D DEM-based strategy for simulating the compressive behaviour of square masonry columns, both unconfined and confined with PBO-FRCM systems. The adopted methodology includes: (i) the experimental characterisation of the constituent materials, FRCM

coupons and masonry columns; (ii) the calibration of the DEM model through the experimental response of the unconfined specimens; (iii) the extension of the modelling framework to FRCM-confined configurations; and (iv) the validation of the proposed approach through comparison between numerical and experimental results in terms of axial stress–strain response and failure mechanisms.

2. Resume of the Experimental Campaign

This section provides an overview of the experimental campaign carried out in Mauro *et al.* (2026), from the characterisation of the constituent materials to the assessment of the FRCM-strengthening system applied to masonry columns. The mechanical properties of the mortars were determined through standard flexural and compressive tests, while the behaviour of the PBO fibre mesh was characterised by means of direct tensile (DT) tests in order to evaluate its tensile strength and stiffness. Subsequently, the mechanical response of the FRCM-strengthening system was investigated through uniaxial DT tests performed on FRCM coupons, allowing the interaction between the fibre mesh and the mortar matrix to be assessed. The strengthening system (Figure 1) was then applied to masonry columns, and its effectiveness was evaluated through axial compression tests carried out on both unconfined reference specimens and confined columns strengthened with FRCM system. All columns had a square cross-section of 250 × 250 mm² and an overall height of 485 mm. Each specimen was constructed using seven courses of two solid clay bricks (250 × 125 × 55 mm³), separated by mortar joints approximately 10 mm thick. The bedding mortar was classified as type M5 in accordance with EN 1996-1-1 (CEN 2005). To ensure uniform load transfer during testing, 20 mm-thick mortar capping layers were applied to the top and bottom surfaces of each specimen.

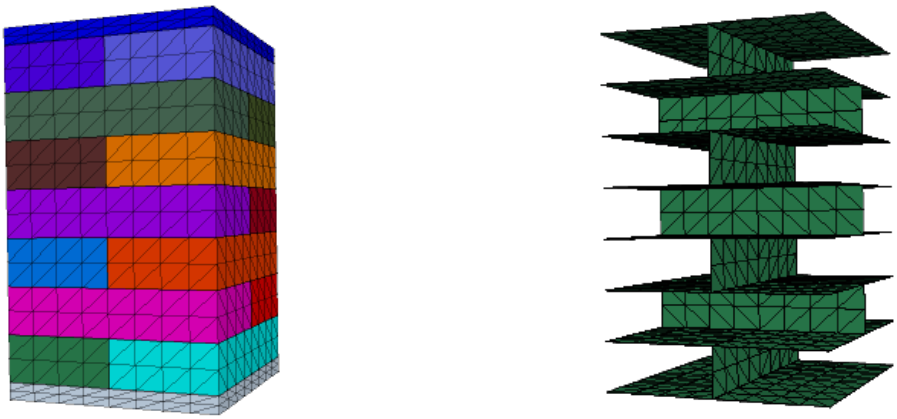
(a) (b) (c)

Figure 1 – Strengthening procedure: (a) first mortar layer, (b) PBO mesh application, and (c) final mortar layer

For the FRCM reinforcement system, a balanced bidirectional PBO fibre mesh was adopted, characterised by equal fibre densities in both warp and weft directions (22 g/m²) and an equivalent thickness of 0,014 mm in both directions. The mesh exhibited an average tensile strength of 3160 MPa and an elastic modulus of 212 GPa. The matrix consisted of a commercial inorganic lime-based mortar, which exhibited an average compressive strength of 17 MPa and a flexural strength of 5,8 MPa. The FRCM coupons exhibited an average tensile strength of 1325 MPa.

Regarding the columns response, unconfined specimens exhibited a brittle failure mode, characterised by vertical cracks propagating through mortar joints and bricks up to crushing (Figure 2.a). In contrast, confined specimens showed distributed cracking along the FRCM jacket (Figure 2.b), mainly concentrated at the

corners (Figure 2.c), followed by crushing of the masonry core. Further details on the experimental setup, testing procedures, and complete results are provided in the dedicated study (Mauro *et al.* (2026)).



(a) (b) (c)

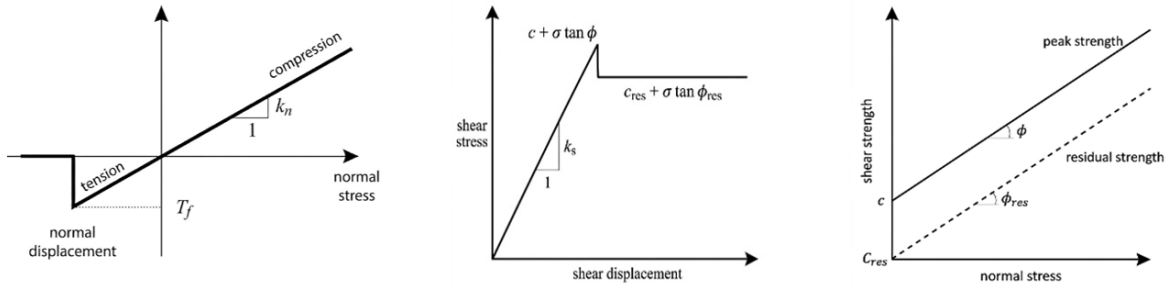
3. DEM Modelling Approach

3.1 Brick Masonry

The numerical analyses were carried out using the 3D distinct element code 3DEC (Itasca Consulting Group (2024)), based on DEM, which represents masonry as an assemblage of interacting blocks (Figure 3.a) separated by both horizontal and vertical contact-joint interfaces (Figure 3.b). Within this framework, the mechanical response of the masonry column results from the interaction between individual units and the constitutive laws governing their interfaces, making this approach suitable for materials characterised by a discontinuous internal structure (Lemos (2007)).



(a) (b)

Figure 3 – DEM model of the unconfined masonry column: (a) geometric configuration and (b) joint arrangement

The masonry units were modelled as deformable blocks discretised using hexahedral zones, with a mesh defined by 2 × 4 × 8 divisions for the masonry units and 2 × 8 × 8 divisions for two steel plates used at the top and bottom of the specimen to simulate the application of a uniform axial load. Large-strain conditions were activated in order to account for the evolution of displacements during loading.

The mechanical behaviour of the masonry units was described using a Mohr–Coulomb constitutive model. The tensile strength was assumed equal to 5 % of the compressive strength, reflecting the brittle behaviour of masonry in tension. The interaction between adjacent units was represented through zero-thickness contact interfaces governed by a Mohr-type contact model (Figure 4), capable of reproducing opening, sliding and inelastic behaviour along the mortar joints. The interface strength parameters were defined based on the mortar properties. Consistently with the assumption adopted for the masonry units, the tensile strength was assumed to be equal to 5 % of the compressive strength. In addition, residual values of cohesion and friction angle were introduced to account for the post-peak degradation of the joint behaviour, as permitted by the adopted contact model.

(a) (b) (c)

Figure 4 – Mohr-Coulomb Joint Model: (a) normal stress vs normal displacement behaviour, (b) shear stress vs shear displacement behaviour, and (c) shear failure criterion (adapted from Itasca Consulting Group (2024))

The contact stiffness parameters were defined according to classical formulations commonly adopted in discrete element modelling of masonry joints. In particular, the normal and shear stiffness, k_n and k_s respectively, were expressed as:

$$k_n = \frac{E_m}{t}, \tag{1}$$

and

$$k_s = \frac{G_m}{t}, \tag{2}$$

where E_m is the Young's modulus of the mortar, t is the average real joint thickness, and G_m is the shear modulus defined as:

$$G_m = \frac{E_m}{2(1+\nu)}. \tag{3}$$

The cohesion parameter of the interface was derived from the compressive strength of the mortar according to the Mohr–Coulomb relationship:

$$c = \frac{f_c(1-\sin\,\phi)}{2\cos\,\phi}. \tag{4}$$

These relations were adopted as a theoretical reference for defining the contact properties, which were then calibrated to reproduce the experimental response of the specimens, with particular reference to the initial stiffness and peak compressive strength. Table 1 summarises the main mechanical parameters adopted in the DEM model, whereas Table 2 presents the key interface properties of the joints.

Regarding the boundary conditions, the bottom steel plate was fully constrained, whereas the top one was restrained in the horizontal directions and allowed to move vertically.

Table 1 - Mechanical parameters adopted for the materials considered in the DEM numerical model

Part	Density (kg/m³)	Young modulus (GPa)	Poisson ratio (-)	Compressive strength (MPa)	Tensile strength (MPa)	Friction angle (°)
Plate	7850,0	210,0	0,30	-	-	-
Brick	1700,0	9,8	0,20	6,60	0,33	32
Mortar	-	4,9	0,20	5,00	0,25	30

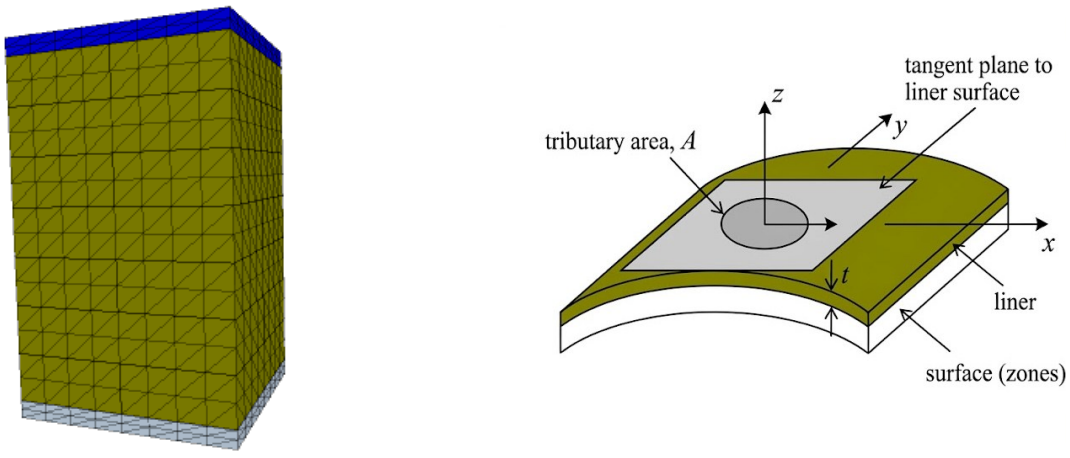


Table 2 – Joint interface properties adopted in the DEM numerical model

	t (m)	K_n (MPa/m)	K_s (MPa/m)	G_m (GPa)	c (MPa)
Joint	0,01	4900	2040	2,04	1,44

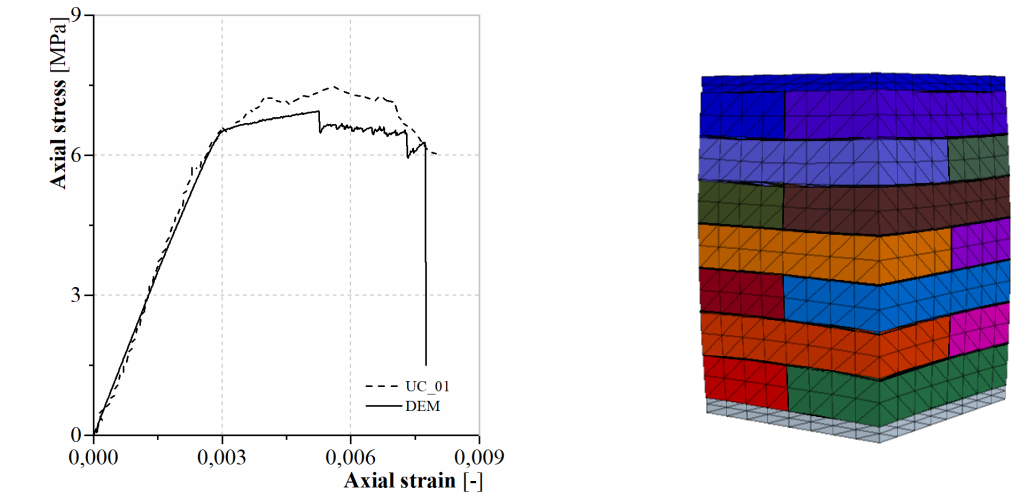
A displacement-controlled loading condition was applied by imposing a constant vertical velocity to the top plate. A global numerical damping coefficient equal to 0,3 was introduced to ensure quasi-static conditions and dissipate kinetic energy, while gravity was included to account for the self-weight of the masonry assemblage. The global compressive stress was evaluated by dividing the total reaction force at the loading plate by the cross-sectional area of the column, enabling direct comparison with the experimental stress–strain response.

3.2 FRCM retrofit

The modelling framework was extended to FRCM-confined masonry columns by introducing an external strengthening system through the use of structure liner elements available in 3DEC (Figure 5). In this study, the liner elements, formulated as shell-type structural elements capable of representing thin continuous layers, were employed to represent an equivalent continuous FRCM jacket, following approaches commonly adopted in geomechanics for modelling surface support systems (Chen and Teng (2024); Itasca Consulting Group (2024); Zhang and Nordlund (2021)).

(a) (b)

Figure 5 – DEM model of the FRCM-confined masonry column: (a) geometric configuration and (b) Idealization of interface behaviour at a liner node (adapted from Itasca Consulting Group (2024))



The liner elements were mechanically coupled to the masonry substrate through interface laws governing the transfer of normal and shear stresses, allowing the interaction between the strengthening system and the underlying masonry to be captured (Figure 5.b). The interface behaviour was defined by means of normal and shear coupling stiffness, cohesion and friction parameters, including residual values to account for progressive degradation. Within this framework, the FRCM system was modelled as an equivalent homogeneous membrane characterised by linear elastic behaviour, defined by an assigned Young's modulus, Poisson's ratio and thickness. It should be noted that this approach does not explicitly account for the internal interaction between fibre and matrix, which is inherently simplified into an equivalent constitutive response of the composite system.

The onset of damage in the strengthening system is governed by the interface behaviour between the liner and the masonry substrate, through the definition of strength and residual parameters controlling debonding and sliding mechanisms. Therefore, the adopted modelling strategy aims to capture the global confinement effect rather than the detailed meso-scale behaviour of the FRCM composite.

4. Preliminary results and discussion

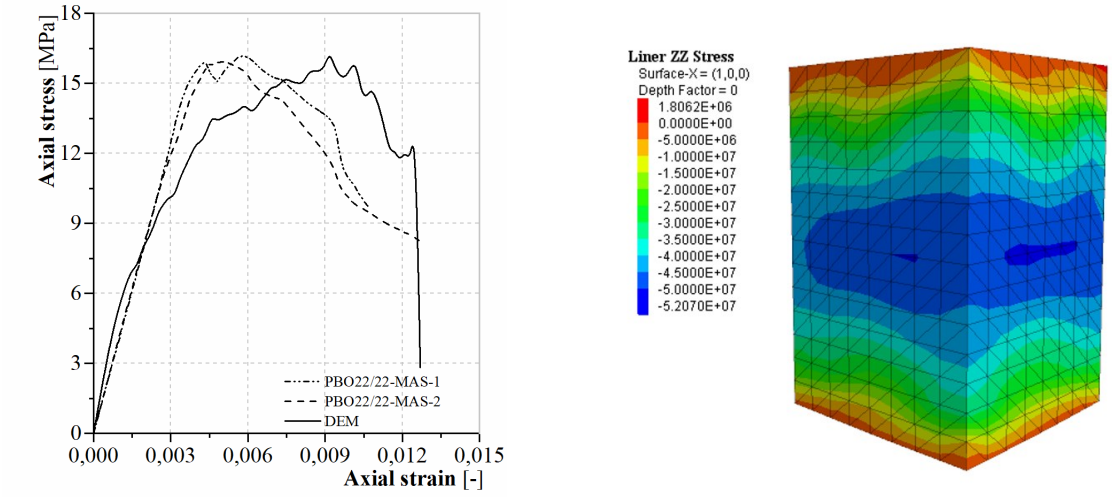
The experimental and numerical results are presented in terms of axial stress–strain response for both unconfined and FRCM-confined masonry columns. The calibrated numerical model was first validated against the experimental response of the unconfined specimen.

Although the model does not explicitly incorporate a strain-softening constitutive law, the introduction of residual parameters at the contact level allows the degradation of the masonry response to be effectively captured, resulting in an overall satisfactory agreement with the experimental behaviour. This is confirmed by the comparison between numerical and experimental stress–strain curves, which shows good agreement in terms of initial stiffness, peak compressive strength and overall deformation capacity. Figure 6 presents the experimental–numerical comparison of the axial stress–strain response for the unconfined column, as well as with the corresponding deformed configuration at failure. With reference to the peak strength, the numerical model provided a close estimation of the experimental value, with a difference of approximately 6,84 % (7,46 MPa experimentally versus 6,95 MPa numerically). In terms of axial strain, evaluated by normalising the vertical displacement with respect to the column height, the ultimate value was 0,0081 experimentally and 0,0077 numerically, corresponding to a difference of approximately 4,94 %, as summarised in Table 3.

(a) (b)

Figure 6 – Unconfined masonry column: (a) experimental vs DEM axial stress–strain response and (b) deformed configuration at failure

Table 3 – Comparison between experimental and numerical results for the unconfined masonry column



Unconfined Column	Maximum axial stress (MPa)	Ultimate axial strain (-)
Experimental	7,46	0,0081
DEM	6,95	0,0077
Error (%)	6,84	4,94

This validation step provides confidence in the adopted modelling strategy and is subsequently employed for the simulation of the confined configurations.

The comparison between experimental and numerical results (Figure 7.a) highlights the effect of external confinement on the global response of the column. An increase in peak compressive strength is observed, together with a modification of the stress–strain behaviour, characterised by a more gradual evolution of deformation prior to failure. The numerical curves show good agreement with the experimental results in terms of strength enhancement and overall response. However, some discrepancies can be observed in the initial stiffness, particularly after the activation of the reinforcement, leading to differences in the slope of the pre-peak branch. This behaviour can be attributed to the adopted modelling strategy for the external reinforcement.

With reference to the peak strength, the numerical model provided a close estimation of the experimental value, presenting a difference of approximately 1,36 % (16,16 MPa experimentally versus 16,38 MPa numerically). In terms of ultimate axial strain, the experimental value was 0,0118, while the numerical prediction was 0,0125, corresponding to a difference of approximately 5,93 %, as summarised in Table 4.

Moreover, the stress distribution within the liner elements confirms the effectiveness of the confinement provided by the strengthening system (Figure 7.b). The results show a well-distributed compressive stress field, indicating that the jacket actively contributes to the lateral confinement of the column. This indicates that the activation of the confinement mechanism is associated with the progressive dilation of the masonry assemblage, which mobilises the tensile capacity of the external FRCM reinforcement. Moreover, crushing of the masonry core is observed in the numerical model after the activation of the confinement mechanism induced by the external reinforcement, in agreement with the experimental evidence.

Figure 7 – FRCM-confined masonry column: (a) comparison between experimental and DEM axial stress–strain responses, and (b) stress distribution in the FRCM jacket at peak

Table 4 - Comparison between experimental and numerical results for the FRCM-confined masonry column

Confined Column	Maximum axial stress (MPa)	Ultimate axial strain (-)
Experimental	16,16	0,0118
DEM	16,38	0,0125
Error (%)	1,36	5,93

5. Conclusions

This study investigated the compressive behaviour of masonry columns strengthened with PBO-FRCM systems through a combined experimental and DEM-based numerical approach. From an experimental perspective, the results confirmed that FRCM confinement enhances both the compressive strength and the deformation capacity of masonry columns.

From a numerical standpoint, a DEM-based modelling framework was developed and proposed to simulate the behaviour of both unconfined and confined masonry columns. The model, based on the representation of masonry as an assemblage of deformable blocks interacting through contact interfaces, proved capable of reproducing the global compressive response of unconfined specimens with satisfactory accuracy. In particular, differences of approximately 6,84 % and 4,94 % were obtained for peak compressive strength and ultimate axial strain, respectively.

The modelling strategy was extended to FRCM-confined configurations through the introduction of structure liner elements, enabling the interaction between the masonry substrate and an external reinforcement to be represented within a discontinuum framework. The comparison with experimental results for confined columns showed a very good agreement in terms of peak compressive strength and ultimate deformation capacity, with differences of approximately 1,36 % and 5,93 %, respectively.

The numerical results highlighted that the confinement effect is governed by the dilation of the masonry core and by the interface behaviour between the FRCM reinforcement and the substrate, confirming the capability of the proposed approach to reproduce the main features of the confined response.

The proposed DEM-based modelling strategy provides a robust initial framework for the analysis of FRCM-confined masonry elements and establishes a basis for further developments aimed at improving the modelling of interface behaviour and of the strengthening system. In this perspective, the adoption of advanced constitutive laws, such as strain-softening formulations, is expected to enable a more accurate representation of damage evolution and post-peak response.

Acknowledgments

The authors gratefully acknowledge the TEACH (Technology Applied to Cultural Heritage) Doctoral School of the University of Calabria for the financial support provided through the doctoral scholarship that contributed to this research. The authors also acknowledge the NESDE unit (Seismic Engineering and Structural Dynamics) at the National Laboratory for Civil Engineering (LNEC), Lisbon, Portugal, for hosting the research stay and for the valuable scientific guidance provided during the development of this study.

Abstract: This study investigates the alkaline durability of a Fabric-Reinforced Cementitious Matrix (FRCM) system reinforced with alkali-resistant (AR) glass textiles embedded in a cement-based matrix. The experimental programme was designed to assess the influence of alkaline exposure on both bare fibres and composite coupons, considering different conditioning scenarios. Direct tensile tests were performed on dry AR-glass fibres after 1000 h, 2000 h and 3000 h of alkaline conditioning, as well as on FRCM coupons directly immersed in the same alkaline environment for the same durations. In addition, a further series of FRCM coupons was manufactured using pre-conditioned textiles, in order to evaluate the feasibility of an accelerated ageing procedure based on pre-exposed reinforcement. The results showed that alkaline exposure caused a severe deterioration of the bare fibres, with average tensile strength losses of approximately 61%, 64% and 65% after 1000 h, 2000 h and 3000 h, respectively, whereas the corresponding reduction in elastic modulus remained more limited. By contrast, the tensile performance of the FRCM coupons was less affected. Specimens directly exposed to the alkaline solution exhibited average strength reductions of about 5%, 24% and 14%, while those manufactured with pre-conditioned textiles showed more regular decreases of about 1%, 15% and 16%. Despite this degradation, the composite response was primarily governed by the poor fibre–matrix interaction. All FRCM specimens exhibited a brittle behaviour, characterised by the formation of a first and only crack followed by immediate failure, without the development of an effective multi-cracking stage.

Keywords: AR-glass; FRCM; Alkaline Conditioning; Tensile Behaviour.

1. Introduction

FRCM (Fabric-Reinforced Cementitious Matrix) systems, also referred to as TRM (Textile-Reinforced Mortar), are now widely recognised as effective solutions for the strengthening of existing masonry and reinforced concrete structures, owing to their high compatibility with mineral substrates, vapour permeability, and favourable application-related features. Over the last decade, a substantial body of experimental research has confirmed the structural effectiveness of these systems in various strengthening and rehabilitation applications, highlighting their potential in terms of increased load-carrying capacity, improved deformational response, and control of cracking phenomena (Kouris and Triantafillou (2018); D'Antino (2025); Cascardi *et al.* (2026)). Despite the well-established effectiveness of FRCM systems, their long-term reliability still represents a critical issue, which has not yet been fully clarified from a scientific standpoint nor adequately incorporated into design procedures. Among the potentially aggressive environmental conditions most widely investigated in the literature, alkaline exposure, elevated service temperatures, freeze–thaw cycles, and saline environments are particularly relevant to civil engineering applications (D'Antino (2025)). With regard to the alkaline durability of such systems, the available literature is still limited and fragmented. Basalt fibres have shown marked sensitivity to alkaline attack already at the level of dry

fibres and unembedded textiles, with strength losses increasing significantly with exposure duration and temperature (Micelli and Aiello (2017); Williams Portal *et al.* (2016); Canestri *et al.* (2023)). Subsequent evidence obtained at composite level has confirmed that this vulnerability is also reflected in the mechanical response of FRCM systems, with appreciable reductions in tensile strength, post-cracking stiffness and, in more recent studies, bond capacity to the substrate (Signorini and Nobili (2021); Canestri *et al.* (2025)). By contrast, carbon-based systems have generally shown greater chemical stability in alkaline environments. The available experimental investigations indicate that carbon fibres, considered both in the dry state and within the composite, do not undergo significant reductions in strength under the most commonly investigated exposure conditions (Nobili and Signorini (2017); Signorini *et al.* (2018)). In such systems, the most influential variables appear to be not so much the intrinsic degradation of the fibre itself, but rather the curing conditions, surface treatments, and fibre–matrix interaction mechanisms, which may modify the composite response in terms of bond and stress transfer (Bompadre and Donnini (2022)). The case of glass-based systems is more complex, and the distinction between E-glass and AR-glass plays an essential role. E-glass is known for its high susceptibility to strongly alkaline environments, and the available studies, although still limited in number, show rapid and pronounced degradation of its mechanical properties, observed mainly at yarn and textile level (De Santis and de Felice (2014); Micelli and Aiello (2017)). By contrast, AR-glass fibres exhibit significantly slower degradation kinetics and a greater ability to retain residual strength over time (Canestri *et al.* (2023); Butler *et al.* (2010)). Nevertheless, even in the case of AR-glass, its combination with highly alkaline cement-based matrices still requires further investigation, since microstructural transformations at the fibre–matrix interface may significantly affect the mechanical response of the composite (Butler *et al.* (2009); Butler *et al.* (2010); Donnini *et al.* (2020); Cascardi *et al.* (2025)).

In light of these considerations, the present study is aimed at systematically investigating the durability of FRCM systems exposed to alkaline environments. In particular, attention is focused on the assessment of the behaviour of composites reinforced with AR-glass textiles combined with cement-based matrices; on the evaluation of the influence of curing conditions in terms of duration; and, finally, on the possibility of employing specimens manufactured with pre-aged textiles as an accelerated procedure to simulate the long-term effects of alkaline attack. The results obtained are expected to contribute to a clearer understanding of the degradation mechanisms and residual mechanical response of FRCM systems, providing useful indications both for the updating of accelerated ageing protocols and qualification procedures, and for the development of more reliable design formulations and the technological improvement of inorganic-matrix composite materials intended for the strengthening of the existing built heritage.

2. Materials and methods

2.1 FRCM constituent materials

The FRCM system investigated in the present study consisted of dry alkali-resistant glass (AR-glass) fibres arranged in a uniformly distributed mesh with an areal density of 200 g/m². The bundle spacing was 12 × 12 mm², while the equivalent thickness was 0,040 mm (Figure 1). The tensile properties at ambient temperature were determined by the authors according to the methodology reported in Section 2.2. In particular, the textile exhibited a tensile strength of 1200 MPa, an elastic modulus E_f of 65 GPa, and an ultimate strain of 0,015. As regards the cement-based mortar, the average compressive strength f_{cm} and flexural strength f_{fm}, taken from Cascardi *et al.* (2025), were equal to 14,5 MPa and 3,2 MPa, respectively.

Figure 1 – AR-glass reinforcing textile used in the investigated FRCM system

2.2 Test set-up

The experimental campaign on the FRCM systems was carried out in accordance with the testing protocols defined by RILEM TC 290-IMC. In particular, the specimens were subjected to different exposure conditions in order to assess the influence of the alkaline environment and of curing duration on the tensile response of the composite. With regard to alkaline exposure, both FRCM specimens and dry fibres were immersed in an environment consisting of distilled water containing 0,16% $Ca(OH)_2$, 1% NaOH, and 1,4% KOH. The exposure durations considered were 1000 h, 2000 h, and 3000 h (Figure 2). At the end of each conditioning period, the specimens were removed from the solution, dried, prepared, and then tested in tension according to the set-up and specifications reported later in the text.

Figure 2 –FRCM specimens during curing/conditioning in an alkaline solution bath

Finally, a portion of the previously conditioned textiles was used to manufacture new FRCM coupons, in order to verify the feasibility of an accelerated ageing procedure based on the use of pre-exposed reinforcements. In these cases, the overall curing duration of the coupons was assumed to be equal to the conditioning time undergone by the aged textiles used for their manufacture, namely 1000 h, 2000 h, and 3000 h. All FRCM coupons investigated in the experimental campaign were subsequently dried for 7 days before tensile testing. For comparative purposes, an additional group of reference specimens was also

prepared, left to cure in water for 21 days, and then used as a benchmark for the direct comparison of the obtained results.

Direct tensile (DT) tests were carried out on both the textiles and the FRCM specimens. In particular, the textiles had dimensions of 50 × 500 × 0,04 mm^3 (width × length × thickness), whereas the FRCM specimens were characterised by a cross-section of 50 × 10 mm^2 and a length of 500 mm. As regards the preparation of the FRCM specimens, a single layer of textile (consisting of 5 yarns) was placed between two layers of inorganic matrix, each having a thickness of 5 mm, defined in accordance with the manufacturer's instructions. Before testing, PVC tabs were bonded to the ends of both fibres and composites by means of a conventional epoxy adhesive. This procedure was necessary to improve the gripping of the samples during testing and to ensure proper load transfer from the testing machine to the specimens.

The tests were performed by applying a monotonic load up to failure under displacement control, at a rate of 0,5 mm/min for the textile tests and 0,2 mm/min for the FRCM composites. The tensile strains of both the textiles and the FRCM specimens were measured by means of a video extensometer, which monitored the position of target points arranged along different longitudinal alignments (Figure 3).

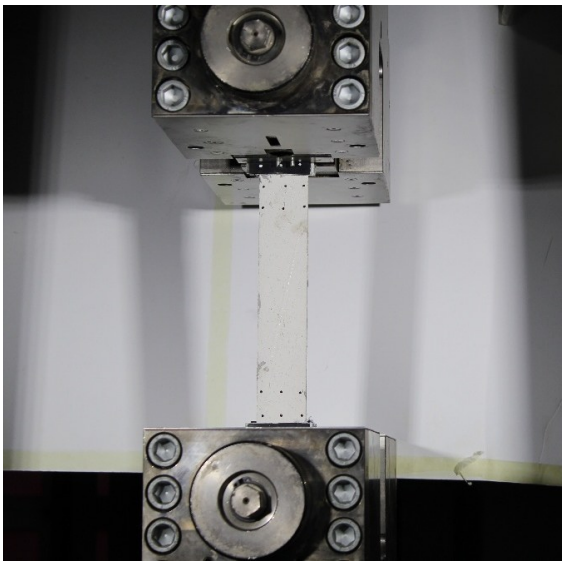

Figure 3 – Tensile test setup for FRCM specimens

3. Experimental results

3.1 Dry fibres

As shown in Figure 4, the results for the dry fibres highlight a marked reduction in tensile strength after conditioning, accompanied by a more limited decrease in elastic modulus. For the unconditioned specimens (NC), the average tensile strength was approximately 801 MPa, with an average elastic modulus of 73 GPa. After 1000 h of conditioning, the average tensile strength decreased to 310 MPa, whereas the average elastic modulus dropped to 66 GPa. For exposure durations of 2000 h and 3000 h, the average tensile strength was equal to 291 MPa and 282 MPa, respectively, while the average elastic modulus reached values of 60 GPa and 59 GPa. Overall, the results show that conditioning produced a severe reduction in tensile strength, with a very pronounced decrease already after the first 1000 h, followed by more limited reductions with increasing exposure duration. In percentage terms, the average residual tensile strength was about 39% of the initial value after 1000 h and decreased to approximately 35% after 3000 h (Figure 5). By contrast, the elastic modulus exhibited a more gradual and less severe decrease, from about 73 GPa to

59 GPa, corresponding to an overall loss of approximately 19% at the end of the maximum conditioning period.

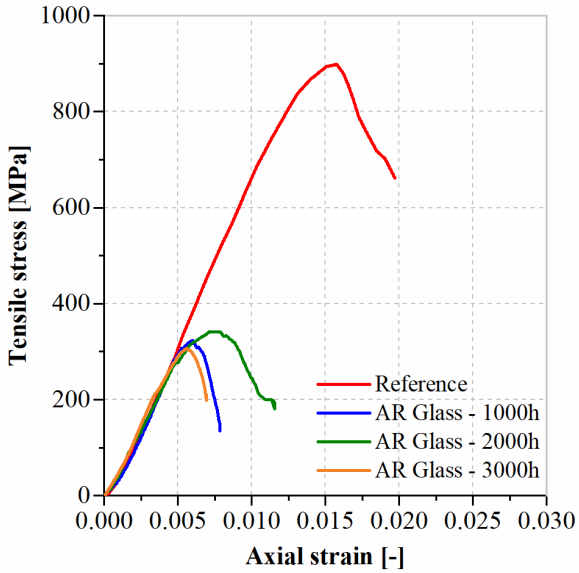

Figure 4 – Tensile stress vs axial strain curves for both unconditioned and conditioned specimens

These results indicate that the effect of conditioning was particularly severe on the load-carrying capacity of the fibres, whereas stiffness was compromised to a comparatively smaller extent.

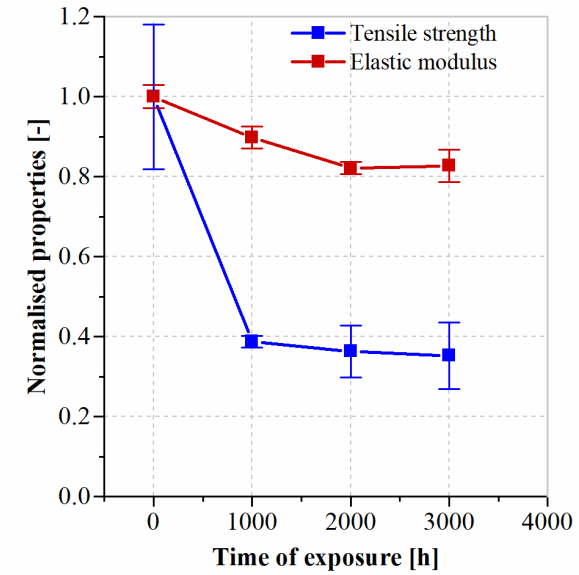

Figure 5 – Normalised properties vs time of exposure

The marked reduction in average tensile strength may be attributed to the fact that the alkaline environment acted directly on the elementary filaments, progressively altering their surface. Although AR-glass exhibits higher alkali resistance than E-glass owing to its zirconia content, this protection does not make the material completely immune to alkaline attack. The strength loss should therefore be interpreted as a consequence of the progressive surface damage of the individual filaments, with the development of local weak points, surface irregularities, and a gradual reduction in filament integrity (Figure 6). In this light, the sharp drop in average tensile strength already observed after 1000 h can plausibly be attributed to the rapid degradation of the most vulnerable filaments, namely those characterised by surface defects more

sensitive to the alkaline environment. The more limited reduction observed between 1000 h and 3000 h suggests instead that, once the weakest fraction of the material had been compromised, degradation proceeded with slower kinetics in the remaining material. The smaller decrease in average elastic modulus may be interpreted by considering that stiffness is less sensitive than strength to the presence of surface-localised defects affecting only part of the filaments. In other words, localised surface damage may severely impair the ultimate tensile capacity, while affecting the global elastic response to a relatively smaller extent, at least until degradation becomes more widespread. This interpretation is plausible, although direct confirmation would require morphological observations on the conditioned filaments.

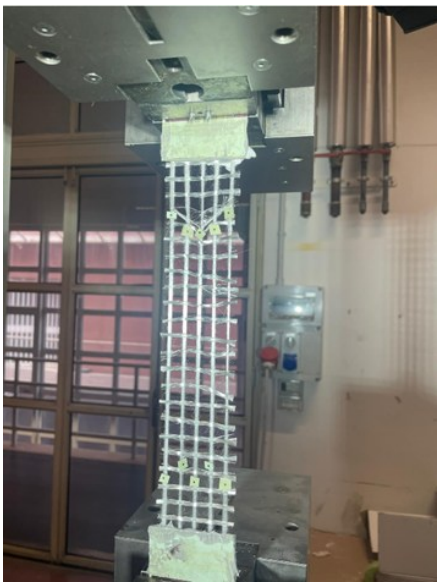

Figure 6 –Failure mode observed in the tensile tests on AR glass specimens

3.2 FRCM composites

For the FRCM specimens exposed to the alkaline environment, the obtained results showed a reduction in tensile capacity with respect to the unconditioned samples, although to an extent significantly smaller than that observed for the dry fibres. Under reference conditions (NC), the average tensile strength was approximately 406 MPa. After 1000 h of alkaline exposure, this value decreased to about 385 MPa, corresponding to a reduction of approximately 5% relative to the initial value (Figure 7). After 2000 h, a more marked decrease was observed, down to approximately 310 MPa, corresponding to a reduction of about 24%, whereas after 3000 h the average tensile strength increased again to approximately 350 MPa, remaining nevertheless lower than the reference value, with an overall loss of about 14%.

Overall, these results indicate that alkaline exposure produced a detrimental effect on the tensile response of the composite, although to a lesser extent than that observed at dry-fibre level. The non-monotonic trend, with the minimum value recorded after 2000 h and a subsequent increase after 3000 h, nevertheless suggests that the results should be interpreted with caution, since this apparent recovery may reasonably be attributed to experimental scatter, the limited number of specimens, and the possible competition between reinforcement degradation and matrix evolution.

By contrast, for the FRCM specimens manufactured with textiles previously conditioned in the alkaline environment and subsequently used for coupon fabrication, the average results showed a more regular and substantially monotonic decay in tensile response with increasing pre-conditioning time of the reinforcement. In particular, for the specimens manufactured with textiles pre-conditioned for 1000 h, the average tensile strength was approximately 402 MPa, showing a very limited reduction, below 1%, with respect to the reference specimens. As the pre-exposure duration increased, the detrimental effect became more evident: after 2000 h, the average tensile strength decreased to approximately 347 MPa,

corresponding to a reduction of about 14%, whereas after 3000 h it decreased further to approximately 340 MPa, corresponding to an overall loss of about 16%.

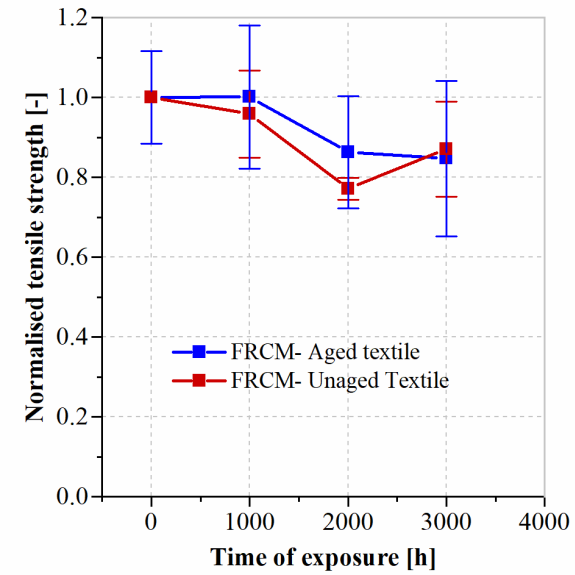

Figure 7 – Reduction of tensile strength observed in the tensile tests on AR glass specimens

The overall interpretation of these results must, however, take into account the peculiar response mechanism of the investigated system. The stress–strain curves in fact showed a substantially similar behaviour for all the examined configurations: the absence of a surface treatment on the textile led to a markedly brittle response of the composite. In particular, the response was characterised by an almost linear initial branch, followed by the formation of a first and only crack (Figure 8), beyond which the specimen rapidly underwent collapse. Once this crack had formed, stress transfer between matrix and textile became highly ineffective; consequently, the system was unable to develop an effective multi-cracking stage or any significant stress redistribution along the reinforcement. Failure therefore occurred almost immediately after first cracking, followed by telescopic rupture of the filaments, according to a mechanism fully consistent with that also observed in the conditioned textiles.

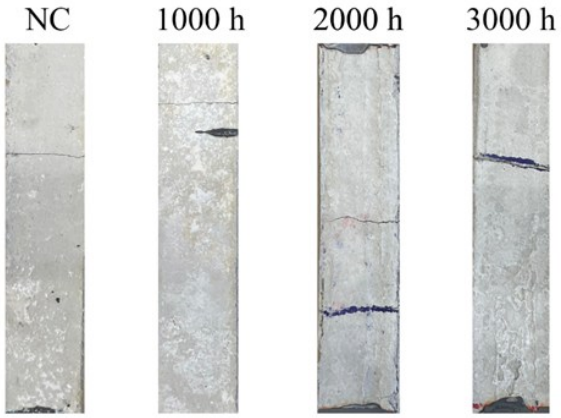

Figure 8 – Failure mode observed in the tensile tests on AR glass specimens

In light of this, the apparently smaller influence of alkaline conditioning on the response of the composite compared with that observed for the dry fibres may reasonably be attributed to the fact that, in this specific FRCM system, the global performance was already strongly limited, from the outset, by the poor quality of the fibre–matrix interaction. In other words, since coupon failure was governed mainly by the early loss of

effectiveness of stress transfer after first cracking, the further degradation induced by the alkaline treatment on the fibres played a relatively less significant role in the overall mechanical response of the composite. As a result, the behaviour of the system appears to be governed more by the intrinsic weaknesses of the stress-transfer mechanism between dry textile and matrix than by reinforcement degradation due solely to the alkaline environment.

4. Conclusions

The present study investigated the alkaline durability of inorganic-matrix FRCM systems, with particular focus on composites reinforced with AR-glass textiles embedded in a cement-based matrix, considering both bare fibres and FRCM coupons subjected to different conditioning procedures. The results showed that alkaline exposure had a markedly detrimental effect on the dry fibres, causing a severe re-duction in tensile strength already after the first 1000 h of conditioning, whereas the elastic modulus exhibited a more limited decrease. This behaviour suggests that degradation was mainly associated with the progressive alteration of the surface of the elementary filaments, leading to a loss of fibre integrity and a rapid reduction in tensile capacity. At the composite level, the effect of alkaline conditioning was significantly less pronounced. FRCM specimens directly immersed in the alkaline solution exhibited smaller reductions in tensile strength than those observed for the bare fibres, although with some experimental scatter and a non-monotonic trend. Similarly, coupons manufactured with previously conditioned textiles showed a progressive decrease in tensile performance with increasing pre-conditioning time, but the overall strength loss remained lower than that recorded for the isolated reinforcement. The overall interpretation of the results indicates that, in the investigated FRCM system, the global mechanical response was not governed exclusively by fibre degradation, but also by the quality of the fibre–matrix interaction. In particular, the absence of a surface treatment in the Glass textile led to a markedly brittle response, characterised by the formation of a first and only crack followed by almost immediate failure, without the development of an effective multi-cracking stage. Consequently, the limited stress-transfer capability after first cracking appears to be the main factor controlling the composite response, thus reducing the apparent influence of alkaline-induced fibre degradation on the overall behaviour of the coupon. Overall, the results confirm the relevance of alkaline environments as a degradation agent for FRCM systems, while also showing that the composite response must be interpreted by jointly considering reinforcement durability and the effectiveness of the fibre–matrix stress-transfer mechanism. In this perspective, the findings contribute to a clearer understanding of the limits and potential of accelerated ageing procedures and provide useful indications for the development of more reliable FRCM systems, characterised by improved internal bond and greater robustness under aggressive environmental conditions.

Resumo: O betão branco de elevado desempenho (HPC) é amplamente utilizado em aplicações arquitetónicas contemporâneas, sobretudo em elementos esbeltos, onde são exigidos elevados níveis de resistência mecânica, durabilidade e qualidade estética. No entanto, o elevado teor de cimento associado a este tipo de materiais levanta preocupações ambientais relevantes, tornando necessária a otimização das matrizes cimentícias utilizadas em aplicações arquitetónicas exigentes.

Este estudo apresenta o desenvolvimento de um HPC branco eco-eficiente, baseado na otimização da matriz cimentícia através da substituição parcial do cimento Portland por adições minerais convencionais, como o fíler calcário, e não convencionais, como o pó de vidro finamente moído. Esta abordagem permite reduzir o consumo de cimento e o impacto ambiental associado, promovendo simultaneamente a valorização de resíduos industriais, sem comprometer o desempenho global do material.

A matriz foi formulada sem agregado grosso e com reduzidas relações água/ligante, visando a obtenção de uma argamassa compacta e adequada a elementos arquitetónicos expostos. A caracterização experimental incluiu ensaios no estado fresco, resistência mecânica à compressão e à flexão e resistividade elétrica, permitindo avaliar o comportamento das misturas em termos de trabalhabilidade, desempenho mecânico e durabilidade potencial.

Os resultados obtidos evidenciam o potencial do HPC branco desenvolvido como material para aplicações arquitetónicas exigentes, conciliando elevados níveis de desempenho mecânico e propriedades associadas à durabilidade com uma abordagem mais sustentável no desenho das matrizes cimentícias.

Palavras-Chave: Betão de elevado desempenho, sustentabilidade, pó de vidro, cimento branco, durabilidade.

1. Introdução

O desenvolvimento de novas matrizes cimentícias tem sido impulsionado pela crescente procura mundial de habitação e infraestruturas, bem como pela evolução da estética arquitetónica, que privilegia estruturas cada vez mais esbeltas e estruturalmente eficientes. Em contrapartida, diversos estudos demonstram que a produção de cimento Portland liberta para a atmosfera uma quantidade de dióxido de carbono (CO_2) e de outros gases com efeito de estufa (GEE) aproximadamente equivalente à massa de ligante produzido, contribuindo de forma significativa para as alterações climáticas globais [1].

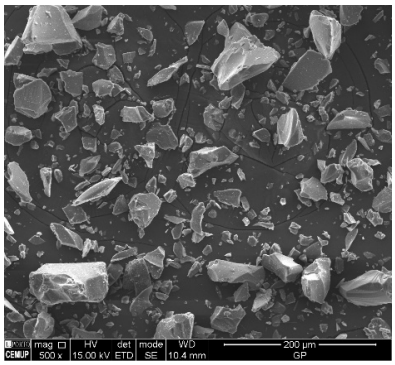
Neste contexto, o betão de elevado desempenho (HPC) e o betão de ultraelevado desempenho (UHPC) afirmam-se como soluções de engenharia particularmente promissoras. Estes materiais distinguem-se pelos elevados níveis de resistência à compressão e pela sua fluidez, aliados a uma elevada durabilidade, permitindo assegurar a longevidade das estruturas por períodos superiores a um século [2]. Paralelamente, a redução do impacto ambiental associado a estes materiais pode ser significativamente otimizada através da substituição parcial do cimento Portland por materiais cimentícios suplementares, nomeadamente pó

de vidro finamente moído [3]. Esta solução permite valorizar resíduos de vidro, que representam uma fração relevante dos resíduos sólidos produzidos a nível mundial e que, devido à complexidade técnica dos processos de reciclagem, são frequentemente encaminhados para aterro [4]. A incorporação deste tipo de resíduos no HPC contribui, assim, para a redução do consumo de matérias-primas convencionais e dos custos logísticos associados ao seu transporte, promovendo simultaneamente princípios de economia circular e o desenvolvimento de novos modelos de negócio [5].

Os resíduos industriais de vidro finamente moído devem apresentar dimensões de partículas similares ou inferiores às do cimento, de modo a garantir uma maior reatividade. Embora seja classificado como material pozolânico de acordo com os requisitos químicos definidos pelas normas ASTM C618 e NP 4220, o seu teor de álcalis (Na_2O) tem suscitado preocupações relacionadas com o potencial desenvolvimento de reações álcalis-sílica [6], [7]. Mais recentemente, o pó de vidro foi formalmente reconhecido como adição para betão nos Estados Unidos da América e no Canadá, através das normas ASTM C1866 e CSA A3000, respetivamente.

Contudo, a literatura indica que a reação pozolânica do pó de vidro ocorre de forma mais precoce do que a reação álcalis-sílica, o que limita a disponibilidade de álcalis livres necessários ao desenvolvimento de efeitos deletérios expansivos [4], [7]. Neste contexto, a dimensão das partículas assume um papel crucial na mitigação de eventuais efeitos adversos [7], [8]. Embora sejam geralmente recomendadas partículas com dimensão inferior a 300 µm, estudos demonstram que partículas inferiores a 38 µm apresentam um comportamento pozolânico mais acentuado, enquanto partículas no intervalo entre 38 µm e 75 µm evidenciam uma atividade significativamente reduzida [9]. Adicionalmente, diversos trabalhos reportam melhorias consistentes da durabilidade das matrizes quando o pó de vidro substitui parcialmente o cimento Portland, promovendo igualmente ganhos de resistência em idades mais avançadas e garantindo a estabilidade dimensional do material [10], [11]. Assim, o presente trabalho tem como objetivo principal o desenvolvimento e a otimização de misturas ternárias de betão branco de elevado desempenho (HPC), incorporando materiais cimentícios suplementares, nomeadamente pó de vidro e fíler calcário, como substituição parcial do cimento Portland branco. Pretende-se avaliar de forma sistemática a influência das principais proporções da mistura no comportamento no estado fresco, no desempenho mecânico e nas propriedades associadas à durabilidade, recorrendo a uma metodologia de Desenho de Experiências. O estudo visa, em particular, identificar combinações de parâmetros de mistura que permitam conciliar elevados níveis de fluidez, resistência mecânica e resistividade elétrica, contribuindo para o desenvolvimento de soluções estruturalmente eficientes e mais sustentáveis para elementos arquitetónicos esbeltos sujeitos a flexão moderada.

2. Metodologia da investigação



2.1 Materiais constituintes

Para desenvolvimento de HPC, foi produzido em laboratório um ligante ternário constituído por cimento Portland branco CEM II-AL 52,5 N br, fíler calcário de origem, com dimensão máxima de 20 µm e massa volúmica de 2750 kg/m^3, e pó de vidro, com máxima dimensão de 80 µm e massa volúmica de 2600 kg/m^3. Este material, obtido através de resíduos industriais portugueses, e revela-se uma adição promissora para o HPC devido ao elevado teor de sílica amorfa e pozolanicidade. Para a produção deste HPC foi utilizada uma areia natural de quartzo de grãos arredondados, com dimensões entre 0 mm e 1 mm e absorção de 0,5%. Para assegurar a fluidez da mistura face à reduzida relação água/ligante, utilizou-se um superplastificante à base de éteres de policarboxilato (PCE), em conformidade com a norma NP EN 934-2.

A Figura 1 retrata o pó de vidro e a morfologia das partículas através do microscópio eletrónico de varrimento (MEV), respetivamente.

a)

b)

Figura 1 – a) Pó de vidro; b) fotografia das partículas do pó de vidro obtida por microscopia eletrónica de varrimento.

2.2 Planeamento de Experiências

Foi implementado um desenho experimental do tipo superfície de resposta, utilizando um plano fatorial fracionado (uma metade do plano fatorial 2^5) construído a partir de um plano fatorial a dois níveis com cinco fatores quantitativos (as proporções da mistura), complementado com seis pontos centrais (designados Ci) e dez pontos axiais (designados CCi). O plano perfaz um total de 31 ensaios. Para garantir a rotatividade do desenho, os níveis dos fatores foram codificados como −2 (pontos axiais), −1, 0, +1 e +2 (pontos axiais) para cada uma das variáveis [4], [12]. A Tabela 1 apresenta a correspondência entre os níveis codificados e os valores reais de todos os parâmetros da mistura, nomeadamente, a relação volume de água/finos (Vw/Vp), em que os finos são o cimento, o fíler e o pó de vidro; relação em massa água/cimento (w/c); relação em massa superplastificante/finos (Sp/p); relação em massa pó de vidro/cimento (GP/c); relação volume de areia/argamassa (Vs/Vm). Os intervalos dos fatores foram definidos com base na literatura relevante [4], [12] e em ensaios preliminares, uma vez que se trata de uma tarefa não trivial. Foram selecionados intervalos de modo a gerar respostas informativas sem produzir misturas impraticáveis e em regiões onde seria expectável encontrar materiais com desempenho mais próximo do alvo. Nos ensaios preliminares foi adotada uma banda de espalhamento alvo de 100 a 350 mm (Tabela 2). Para calcular as composições, utilizou-se a equação abaixo:

$$Vs + Vp + Vw + Vsp + Va = 1{,}0m^3 \quad (1)$$

em que Vs representa o volume de areia, Vp é o volume de finos (cimento, fíler calcário e pó de vidro), Vw é o volume de água, Vsp é o volume de superplastificante e Va é o volume de ar. Conhecendo as massas volúmicas dos materiais constituintes, apresentadas na secção 2.1, e os rácios apresentados na Tabela 1, é possível determinar as quantidades de cada constituinte em kg/m^3.

Tabela 1 – Identificação das variáveis independentes, níveis e valores codificados e valores reais.

Fatores de design	Unidades	Axial (-2)	Fatorial (-1)	Central 0	Fatorial (+1)	Axial (+2)
Vw/Vp	-	0,42	0,44	0,46	0,48	0,50
w/c	-	0,33	0,36	0,38	0,41	0,43
Sp/p	%	3,45	3,48	3,50	3,53	3,55
GP/c	-	0,20	0,25	0,30	0,35	0,40
Vs/Vm	-	0,35	0,40	0,45	0,50	0,55

2.3 Medição das respostas (variáveis dependentes)

Neste estudo foram produzidas 31 amassaduras de betão branco de elevado desempenho (HPC), procedendo-se à moldagem de provetes prismáticos com dimensões de 40 × 40 × 160 mm³. O procedimento de mistura adotado para a produção das diferentes composições encontra-se esquematizado na Figura 2. As amassaduras foram realizadas recorrendo a uma misturadora normalizada, em conformidade com a norma NP EN 196-1, garantindo a repetibilidade e a uniformidade do processo experimental.

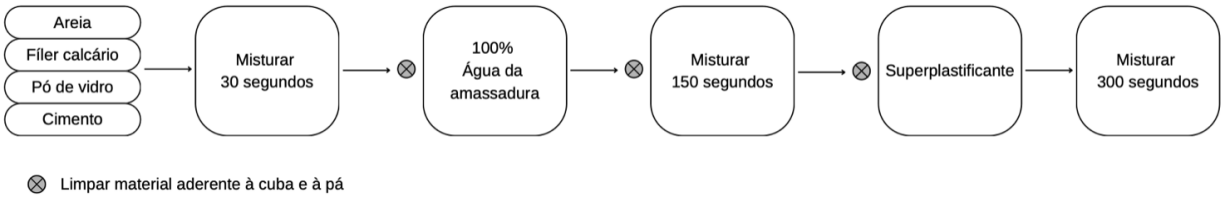


Figura 2 – Procedimento para produção de HPC em laboratório.

A caracterização no estado fresco teve como objetivo a avaliação da trabalhabilidade das matrizes imediatamente após a mistura, assegurando níveis adequados de fluidez, conforme ilustrado na Figura 3. Esta caracterização foi efetuada através do ensaio de espalhamento, de acordo com as recomendações da EFNARC. O valor do espalhamento foi determinado a partir da medição de dois diâmetros perpendiculares, sendo considerado como resultado final o valor médio obtido.

A resistividade elétrica do HPC foi monitorizada como um parâmetro indicativo da compacidade da matriz e da durabilidade potencial do material, recorrendo ao método dos dois elétrodos. Neste procedimento, duas redes de aço inoxidável foram embebidas nas extremidades dos provetes ainda no estado fresco, garantindo o contacto elétrico com a superfície do material. Nas idades estabelecidas, foi aplicada uma corrente elétrica com uma frequência de 100 Hz, medindo-se a diferença de potencial, conforme exemplificado na Figura 4. Este ensaio foi realizado em três provetes por composição do plano experimental, sendo o acompanhamento efetuado até aos 90 dias de idade.

O desempenho mecânico das misturas foi avaliado através de ensaios de resistência à flexão e à compressão, realizados de acordo com a norma NP EN 196-1, aos 28 e aos 90 dias de idade. Os ensaios de compressão foram efetuados sobre os meios provetes resultantes do ensaio de flexão, permitindo uma caracterização consistente e comparável do comportamento mecânico das diferentes composições.

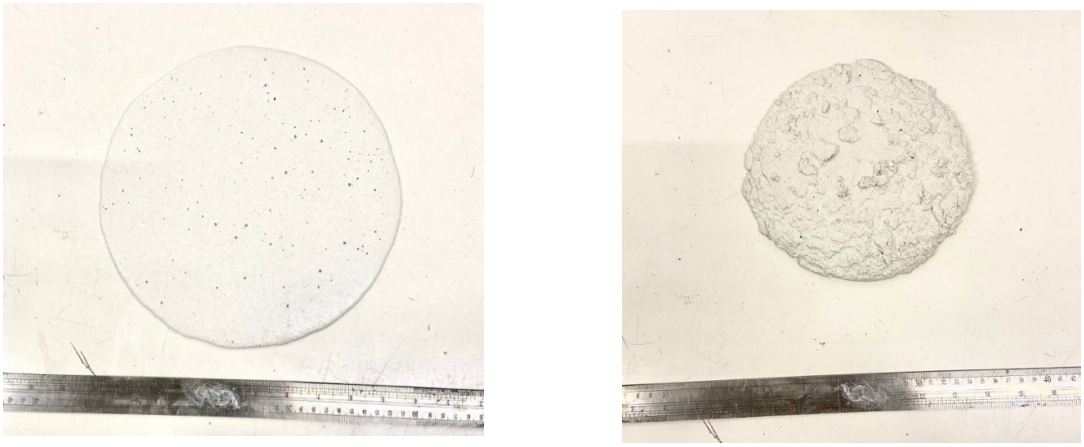

Figura 3 – Espalhamento de duas composições distintas.

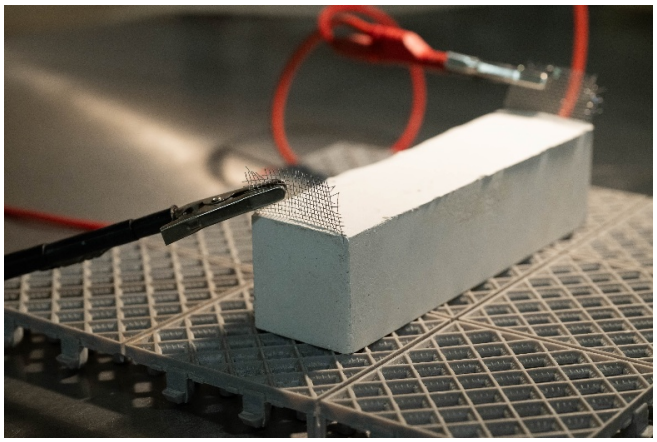

Figura 4 – Ensaio de resistividade elétrica (método dos 2 elétrodos) num provete de HPC.

3. Resultados e Discussão

3.1 Sumário dos resultados experimentais

Os resultados correspondentes ao conjunto integral das 31 misturas, bem como ao subconjunto dos pontos centrais (cinco misturas), encontram-se sumarizados de forma estatística na Tabela 2. Segue-se uma análise sucinta dos principais resultados experimentais obtidos.

As misturas evidenciam valores de fluidez compreendidos entre 100 mm e 321 mm, cobrindo um intervalo alargado de espalhamento. Ao longo do estudo observa-se que, como seria expectável, a diminuição da razão entre o volume de areia e o volume de argamassa (Vs/Vm), bem como o aumento da razão volume de água/volume de pasta (Vw/Vp), resultam em maiores diâmetros de espalhamento. A análise da variabilidade do ensaio de espalhamento (Dflow) mostra que os seis ensaios realizados no ponto central do plano experimental apresentam um coeficiente de variação (CV) de apenas 1,9 %, evidenciando uma variabilidade muito reduzida nessa região do espaço experimental. Em contraste, o coeficiente de variação calculado para o conjunto global das 31 misturas é significativamente superior (24,0 %), conforme indicado na Tabela 2, refletindo a maior dispersão associada às composições localizadas fora da região central, o que pode introduzir desafios adicionais no processo de ajuste de modelos estatísticos.

Relativamente à resistividade elétrica aos 28 dias de idade, os valores observados variam entre 50,85 Ω·m e 97,93 Ω·m, evidenciando diferenças na compacidade da matriz e na conectividade da rede porosa em função das proporções da mistura.

Quanto à resistência à compressão aos 28 dias, os resultados situam-se entre 59,58 MPa e 84,05 MPa, demonstrando que diferentes níveis de desempenho mecânico podem ser alcançados. Estes resultados indicam um adequado desenvolvimento da estrutura resistente da matriz cimentícia, compatível com os requisitos associados a betões de elevado desempenho.

Para além da análise do resumo estatístico da resistividade e da resistência à compressão, nas Figuras 5 e 6 é possível analisar os valores das 31 amassaduras em diferentes idades.

Tabela 2 – Resumo estatístico dos resultados para os pontos centrais e para o conjunto de todas as misturas do plano experimental fracionário.

		Dflow (mm)	Resist_28d (ohm)	Rc_28d (MPa)
Pontos centrais	Média	254,88	68,96	74,94
	Máximo	258,00	71,59	75,94
	Mínimo	251,50	66,76	73,78
	Desvio Padrão	2,66	2,14	1,10
	Coef. Variação (%)	1,04	3,10	1,47
Todos os pontos do plano fatorial	Média	246,29	68,47	74,65
	Máximo	321,00	97,93	84,05
	Mínimo	100,00	50,85	59,58
	Desvio Padrão	53,84	10,17	5,84
	Coef. Variação (%)	21,86	14,86	7,83

Figura 6 – Valores da resistência à compressão aos 28 e 90 dias de idade.

3.2 Ajuste dos modelos

Com base no desenho fatorial (fracionário) definido neste trabalho, a cada variável de resposta, foi ajustado um modelo de superfície de resposta polinomial de segunda ordem (quadrático), conforme expresso na equação (2):

$$Y = \beta_0 + \sum_{i=1}^{k} \beta_i X_1 + \sum_{i=1}^{k} \beta_{ii} x {X_i}^2 + \sum_{i<j} \sum \beta_{ij} X_i X_j + \varepsilon \quad (2)$$

em que y representa a resposta analisada, x_i representa a i-ésima variável independente, β_0 é o termo constante, β_i, β_{ii} e β_{ij} são os coeficientes associados, respetivamente, aos efeitos lineares, quadráticos e de interação entre dois fatores, e ε designa o termo de erro aleatório.

Os modelos foram ajustados com a ajuda do software Design Expert. O enquadramento metodológico do Desenho de Experiências (Design of Experiments, DoE) permite proceder a uma análise simultânea dos efeitos individuais dos diferentes fatores e das suas interações sobre cada resposta, apoiando a tomada de decisões no desenho de misturas e reduzindo o número de ensaios laboratoriais necessários para alcançar níveis de desempenho predefinidos [13]. Na avaliação da significância estatística foi considerado um nível de significância de 5 %. Foram efetuados diagnósticos aos resíduos e uma avaliação da adequação dos modelos. Usaram-se critérios como o coeficiente de determinação ajustado, BIC, AICc, PRESS e -ln L. Informações adicionais sobre a abordagem metodológica adotada encontram-se descritas em trabalhos anteriores dos autores [12], [14], bem como em referências especializadas sobre DoE [15].

Os modelos estatísticos obtidos para todas as variáveis de resposta estão sintetizados na Tabela 3, formulados com base em fatores codificados. Para cada resposta, os dois coeficientes dos termos com maior impacto são destacados a negrito, enquanto o coeficiente dominante é igualmente sublinhado. Os termos estatisticamente não significativos aparecem identificados pela sigla “NS”.

3.2.1 Modelo de espalhamento (Dflow)

A análise dos coeficientes do modelo evidencia que a razão entre o volume de areia e o volume de argamassa (Vs/Vm) é o parâmetro da mistura mais influente em termos de fluidez da argamassa, com impacto negativo e não linear. Logo a seguir, em termos de importância do efeito, vem a razão volume de água/volume de pasta (Vw/Vp), que atua no sentido oposto. Consequentemente, podemos dizer que o aumento de Vw/Vp promove a fluidez, ao passo que incrementos de Vs/Vm conduzem a uma redução acentuada do espalhamento. Foi igualmente identificada uma interação negativa estatisticamente significativa entre Vw/Vp e Vs/Vm. Quando Vw/Vp e Vs/Vm assumem valores elevados em simultâneo, verifica-se uma diminuição da fluidez relativamente ao efeito positivo esperado do aumento isolado de Vw/Vp.

O modelo de melhor ajuste para o *Slump* (reportado na Tabela 3 em termos de variáveis codificadas), apresenta um coeficiente de determinação ajustado de 94,4%. O modelo correspondente em valores reais é dado por:

$$\text{Slump} = -3340{,}3 + 3568{,}2\ \text{Vw/Vp} + 6568{,}7\ \text{w/c} - 123{,}7\ \text{GP/c} + 7226{,}5\ \text{Vs/Vm} - 6468{,}7\ \text{Vw/Vp} * \text{Vs/Vm} - 8242{,}9\ (\text{w/c})^2 - 6060{,}7 * (\text{Vs/Vm})^2 \quad (2)$$

As curvas de nível da superfície de resposta (Figura 7) identificam uma região operacional em que se atingem os valores desejados de *Slump*, aproximadamente definida pelos intervalos Vw/Vp ∈ [0,44, 0,48] e Vs/Vm ∈ [0,40, 0,50].

Tabela 3 – Modelos ajustados em termos de fatores codificados.

	Dflow (mm)	**1/√Resist_28d (√Ωm)**	**Rc_28d (MPa)**
Intercept	255,38	0,1223	74,27
Vw/Vp	13,15	0,0018	1,44
w/c	7,60	**0,0057**	**-4,99**
sp/p	NS	NS	0,45
GP/c	-6,19	-0,0022	NS
Vs/Vm	**-60,19**	**-0,0074**	**-3,98**
Vw/Vp x Vs/Vm	-6,47	NS	NS
w/c x sp/p	NS	NS	1,05
$(w/c)^2$	-5,15	NS	NS
$(Vs/Vm)^2$	**-15,15**	-0,0013	NS
R^2	0,96	0,9440	0,91
R^2 ajustado	0,94	0,9330	0,89
excluídos (outliers)	nenhum	nenhum	run 29

* A designação NS identifica os fatores que não apresentam significância estatística no modelo, considerando um nível de significância α = 0,05.

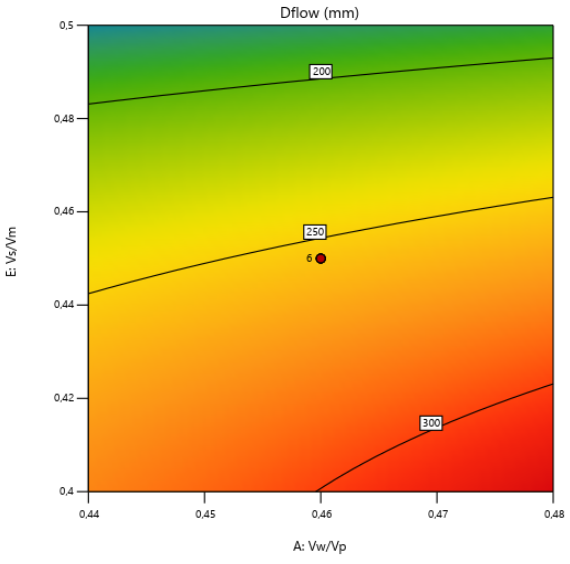

Figura 7 – O espalhamento em função de Vw/Vp e Vs/Vm.

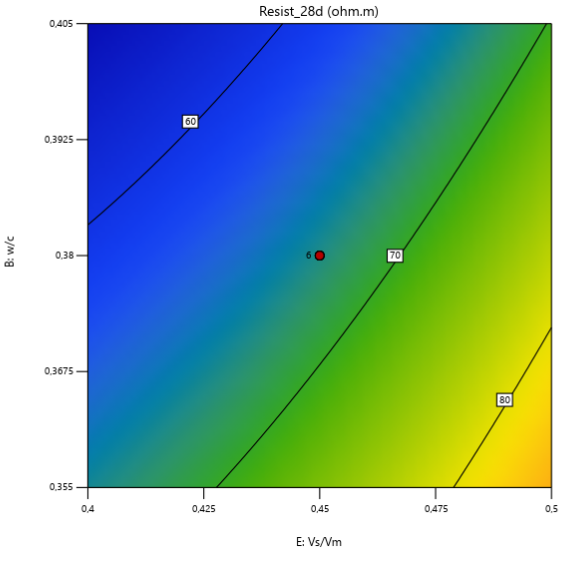

Figura 8 – Resistividade aos 28 dias em função de Vs/Vm e w/c.

3.2.2 Modelo de resistividade elétrica

A análise dos coeficientes do modelo ajustado para 1/Resist_28d evidencia que a razão (Vs/Vm) é o parâmetro da mistura mais influente na resposta em termos de resistividade do material, exercendo um efeito negativo pronunciado. Segue-se, em termos de importância, a razão água/cimento (w/c), que apresenta um efeito positivo significativo. Uma vez que a resposta foi modelada em termos do inverso da raiz quadrada da resistividade, estes resultados indicam que um aumento de Vs/Vm conduz a um acréscimo da resistividade elétrica, enquanto que o aumento de w/c promove uma redução da resistividade aos 28 dias. Para além destes efeitos, a razão volume de água/volume de pasta (Vw/Vp) apresenta um contributo positivo significativo, embora de menor magnitude, sugerindo que níveis mais elevados deste parâmetro da mistura tendem igualmente a reduzir a sua resistividade. O teor de pó de vidro (GP/c) surge com um efeito negativo significativo, indicando um aumento da resistividade associado ao aumento do teor de pó de vidro. Verifica-se ainda a presença de um termo quadrático significativo associado a Vs/Vm, revelando um efeito não linear deste fator na resposta em termos de resistividade. Não foram identificadas interações estatisticamente significativas entre os fatores considerados.

O modelo que melhor se ajusta à resistividade aos 28 dias (apresentado na Tabela 6 em termos de variáveis codificadas) exibe um coeficiente de determinação ajustado elevado (r_{adj}^2=93,3 %), indicando uma boa capacidade explicativa do modelo, sem necessidade de exclusão de ensaios experimentais. Em termos dos valores originais, o modelo é descrito pela equação (3):

$$1/\sqrt{(\text{Resist_28d})} = \text{-0,02798} + 0{,}08890\ \text{Vw/Vp} + 0{,}22917\ \text{w/c} - 0{,}04397\ \text{GP/c} + 0{,}30519\ \text{Vs/Vm} - 0{,}50300\ \text{Vs/Vm}^2 \quad (3)$$

As curvas de nível da superfície de resposta (Figura 8) permitem identificar regiões do espaço experimental associadas a valores mais elevados de resistividade elétrica, correspondendo tipicamente a combinações de valores mais elevados de Vs/Vm e mais reduzidos de w/c. Estas tendências estão em consonância com resultados previamente reportados na literatura, os quais sustentam que a resistividade elétrica é fortemente influenciada pela compacidade da matriz e pela conectividade da rede porosa [16], [17].

3.2.3 Modelo de resistência à compressão

A análise dos coeficientes do modelo ajustado para a resistência à compressão aos 28 dias evidencia que a razão água/cimento (w/c) é o fator mais influente, exercendo um efeito negativo pronunciado, estatisticamente significativo. Este resultado confirma que o aumento de w/c conduz a uma redução significativa da resistência mecânica, em linha com o comportamento para materiais cimentícios. A razão (Vs/Vm) surge igualmente como um parâmetro relevante, apresentando igualmente um efeito significativo negativo sobre Rc_28d. Este efeito sugere que incrementos excessivos de teor de agregado relativamente à fração argamassa conduzem a uma diminuição da resistência mecânica.

Contrastando com estas constatações, a razão volume de água/volume de pasta (Vw/Vp) apresenta um efeito positivo mais moderado na resistência aos 28 dias, embora estatisticamente significativo, indicando que, dentro do intervalo estudado, níveis mais elevados deste parâmetro da mistura podem favorecer uma hidratação mais eficiente ou uma melhor dispersão dos constituintes, sem penalizar significativamente o desempenho mecânico. O teor de superplastificante (sp/p) surge igualmente com um contributo positivo significativo, embora de menor magnitude, refletindo o papel deste adjuvante na melhoria da trabalhabilidade e da homogeneidade da mistura, com impacto indireto na resistência final.

Foi ainda identificada uma interação positiva estatisticamente significativa entre w/c e sp/p, o que revela que a presença de superplastificante pode mitigar parcialmente o efeito negativo do aumento de w/c sobre a resistência mecânica. Não foram observados termos quadráticos significativos para esta resposta, sugerindo um comportamento essencialmente linear da resistência à compressão no intervalo de variação considerado.

O modelo de melhor ajuste para Rc_28d (apresentado na Tabela 3 em termos de variáveis codificadas), apresenta um coeficiente de determinação ajustado de 89,0 %, após exclusão de um ensaio considerado atípico (run 29), revelando ter uma capacidade explicativa adequada para descrever matematicamente esta resposta mecânica. Em termos dos valores originais, o modelo é descrito pela equação (4):

$$Rc_28d = +2332{,}9 + 71{,}93750\ Vw/Vp - 6104{,}2\ w/c - 622{,}88\ sp/p - 79{,}508\ Vs/Vm + 1687{,}0\ w/c * sp/p \quad (4)$$

As curvas de nível da superfície de resposta para a resistência à compressão aos 28 dias (Figura 9) evidenciam a influência dominante da razão água/cimento (w/c) e da razão sólido/argamassa (Vs/Vm). Valores mais elevados de resistência são obtidos para combinações caracterizadas por baixos valores de w/c, sendo este efeito particularmente marcado em todo o domínio experimental analisado. Para um dado valor de w/c, incrementos de Vs/Vm conduzem a uma redução progressiva da resistência, em consonância com o efeito negativo identificado para este parâmetro da mistura. O efeito positivo do superplastificante (sp/p) manifesta-se sobretudo para níveis intermédios a elevados de w/c, refletindo a interação positiva significativa w/c × sp/p identificada no modelo, a qual permite atenuar parcialmente a perda de resistência associada ao aumento do teor de água. Em contraste, a razão Vw/Vp apresenta um impacto mais moderado na configuração das curvas de nível, não alterando significativamente a tendência global da resposta. De um modo geral, as superfícies de resposta indicam que o domínio de maiores resistências mecânicas se encontra associado a misturas com baixa razão água/cimento e valores controlados de Vs/Vm, sendo este resultado coerente com o comportamento clássico de materiais cimentícios e com observações previamente reportadas na literatura [4], [12], [14].

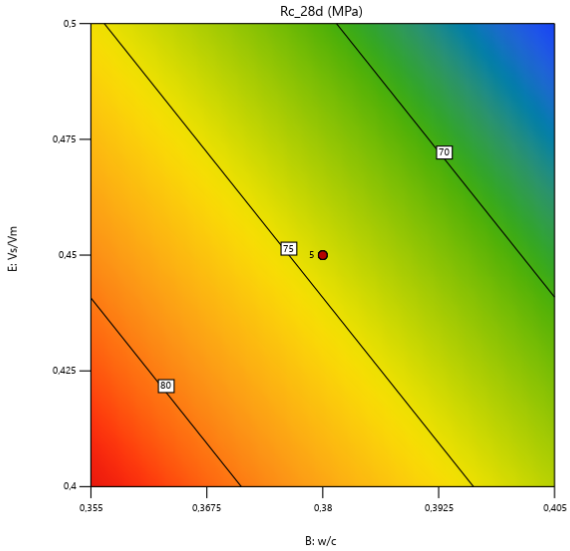

Figura 9 – Resistência à compressão aos 28 dias em função de Vs/Vm e w/c.

3.3 Consequências para o design de misturas

Em síntese, as razões sólido/argamassa (Vs/Vm) e volume de água/volume de pasta (Vw/Vp) assumem-se como os principais parâmetros de controlo do comportamento no estado fresco, devendo ser consideradas de forma integrada no processo de otimização da mistura, de modo a assegurar a fluidez requerida, preferencialmente entre 280 e 300 mm. Em particular, o aumento de Vw/Vp promove a fluidez, enquanto incrementos de Vs/Vm conduzem a uma redução acentuada do espalhamento, sendo ainda identificada uma interação negativa entre estes dois parâmetros.

No que respeita ao comportamento no estado endurecido, avaliado através da resistividade elétrica aos 28 dias, os resultados indicam que a razão sólido/argamassa (Vs/Vm) emerge igualmente como um parâmetro de elevada influência, embora com um efeito de sinal oposto ao observado para a fluidez. Em particular,

valores mais elevados de Vs/Vm conduzem a um aumento da resistividade elétrica aos 28 dias, sugerindo uma matriz mais compacta e uma menor conectividade da rede porosa, mas estão simultaneamente associados a uma redução da resistência à compressão. Este comportamento evidencia que o aumento do teor relativo de sólidos, embora benéfico do ponto de vista da durabilidade potencial, pode penalizar o desempenho mecânico quando excede determinados limiares.

A razão água/cimento (w/c) emerge como o principal parâmetro de controlo da resistência mecânica, apresentando um efeito negativo pronunciado sobre a resistência à compressão aos 28 dias, em linha com o comportamento clássico de materiais cimentícios. Adicionalmente, valores mais elevados de w/c conduzem a uma redução da resistividade elétrica, refletindo uma microestrutura mais permeável. A interação positiva identificada entre w/c e o teor de superplastificante (sp/p) indica, no entanto, que o uso adequado de adjuvantes pode mitigar parcialmente a perda de resistência associada ao aumento do teor de água.

De um modo geral, os resultados obtidos evidenciam a existência de compromissos claros entre desempenho no estado fresco, resistência mecânica e propriedades associadas à durabilidade. Parâmetros da mistura que favorecem a fluidez tendem a penalizar a resistividade e a resistência, enquanto misturas mais ricas em sólidos promovem o desempenho elétrico à custa da trabalhabilidade e, em certos casos, da resistência mecânica. Assim, o desenho de misturas deve assentar numa otimização conjunta de Vs/Vm, Vw/Vp e w/c, explorando o espaço de projeto identificado através das superfícies de resposta, de forma a satisfazer simultaneamente os requisitos no estado fresco e desempenho no estado endurecido.

4. Conclusões

A metodologia baseada em Desenho de Experiências permitiu avaliar de forma sistemática a influência das principais proporções da mistura no comportamento no estado fresco, no desempenho mecânico e nas propriedades associadas à durabilidade potencial. Os resultados evidenciaram que a fluidez das misturas é fortemente condicionada pelas razões volume de areia/volume de argamassa (Vs/Vm) e volume de água/volume de pasta (Vw/Vp), enquanto a razão água/cimento (w/c) assume um papel determinante na resistência à compressão aos 28 dias. A resistividade elétrica mostrou-se igualmente sensível às variações das proporções da mistura, refletindo diferenças na compacidade da matriz e na conectividade da rede porosa.

Os níveis de resistência à compressão obtidos, compreendidos entre aproximadamente 60 MPa e 84 MPa aos 28 dias, confirmam a adequação das matrizes desenvolvidas para aplicações em elementos arquitetónicos esbeltos sujeitos a flexão moderada, para o que será necessário introduzir fibras numa fase posterior deste estudo. Paralelamente, os valores de fluidez alcançados demonstram que é possível compatibilizar elevados requisitos de trabalhabilidade com elevados níveis de desempenho mecânico, através de uma seleção adequada dos parâmetros de mistura.

De um modo geral, os resultados evidenciam a existência de compromissos claros entre desempenho no estado fresco, resistência mecânica e propriedades associadas à durabilidade, reforçando a importância de uma abordagem integrada no dimensionamento das composições. As matrizes ternárias de HPC branco desenvolvidas apresentam, assim, um elevado potencial para aplicações arquitetónicas avançadas, conciliando desempenho mecânico, durabilidade potencial e sustentabilidade ambiental.

Agradecimentos

Este trabalho foi financiado por: UID/04708 da Unidade de Investigação CONSTRUCT - Instituto de I&D em Estruturas e Construções - financiada pela Fundação para a Ciência e a Tecnologia, I.P./ MCTES, através de fundos nacionais; e pela FCT-Fundação para a Ciência e a Tecnologia através do Estímulo ao Emprego Científico 2021.01765.CEECIND (chamada individual). Os autores agradecem às empresas Secil, Omya, Sika, FibreXL e Chryso Portugal. Os autores gostariam também de agradecer o apoio do Laboratório de Estruturas do DECG-FEUP, nomeadamente, à Engenheira Paula Silva e ao Técnico Cláudio Ferraz.

Abstract: The construction sector consumes a substantial share of global resources and contributes significantly to greenhouse gas emissions. Therefore, more sustainable approaches are needed not only in new construction, but also in the repair of existing buildings. In this context, natural-fiber-based composites represent a promising alternative for strengthening brick masonry buildings, offering the potential to reduce environmental impact while improving structural performance. This paper explores the modification of natural fiber reinforcements via a graphene/polyurethane coating protocol for as-received hemp intended for use in inorganic matrix composite manufacturing for the structural strengthening of masonry walls. The aim is to improve the tensile behavior of hemp fibers with different diameters, particularly their strength and elastic modulus. Finally, the implementation of this coating protocol resulted in an approximately 500% increase in the initial elastic modulus.

Abstract: Composite-reinforced mortar (CRM) systems are increasingly adopted for the strengthening of masonry structures; however, their reliable design and implementation remain constrained by the limited availability of systematic mechanical data and insufficient understanding of their interaction with masonry substrates. This challenge is particularly critical, as many masonry structures require repair or strengthening due to ageing and deterioration, as well as extreme actions such as earthquakes, necessitating strengthening solutions that extend service life while preserving structural integrity and architectural value. Within this context, CRM systems have emerged as a promising externally bonded technique, with previous studies reporting improvements in both load-bearing capacity and deformation performance. Nevertheless, CRM remains a relatively recent technology, and the available literature still lacks comprehensive, multi-scale experimental evidence addressing the mechanical response of its constituent components and the structural behavior of strengthened masonry assemblies. To address this gap, the present study employs an experimental program to characterize the tensile response of bare fiber grids and to evaluate the structural effectiveness of CRM strengthening through tensile coupon tests. The results provide a consistent multi-scale mechanical characterization of the CRM system, contributing to a more reliable basis for assessment, design, and implementation of CRM strengthening interventions in masonry structures.

[3] CERIS, Instituto Superior Técnico, University of Lisbon, Lisbon, Portugal, 1049-001, ines.flores.colen@tecnico.ulisboa.pt

Abstract: Since the beginning of the 21st century, the European Union has focused on reducing greenhouse gas (GHG) emissions and improving energy efficiency, with buildings accounting for 36% of these emissions. Portugal has committed to achieving carbon neutrality by 2050, focusing on urban rehabilitation and reducing energy poverty, supported by the Recovery and Resilience Plan. This study characterizes the construction sector in the European Union and Portugal, with emphasis on the Autonomous Region of the Azores, by analysing energy consumption and measures to mitigate energy poverty and climate change. The research included a survey targeting architects, engineers, and contractors from the islands of São Miguel, Terceira, Pico, and Faial. The results indicate that the lack of financial resources was the main barrier to energy rehabilitation (reported by 60% of respondents). Priority interventions include external thermal insulation (19%) and improvements in rainwater drainage systems (23%). Expanded polystyrene (EPS) was identified as the most widely used, followed by mineral wool and extruded polystyrene (XPS). All respondents reported experiencing climate change-related events, and 53% expressed confidence in the feasibility of implementing mitigation measures, with recycling the most frequently cited action (70%). Regarding the importance assigned to reducing environmental impact, the production and end-of-life phases were considered the most relevant. Given the region's geographical location, the use of local materials is highlighted as essential to minimize the environmental impact associated with the production of construction materials. It is concluded that the implementation of thermal insulation solutions in the region will enhance the energy efficiency of buildings, contributing to the reduction of energy poverty and the mitigation of construction pathology (reported by 84% of respondents).

Keywords: Sustainability, insulation materials, alternative materials, climate change, autonomous regions

1. Introduction

Since the early 21st century, the EU has set goals to reduce Greenhouse Gas Emissions (GGE) and improve energy efficiency, and promote the use of renewable energy as part of its broader commitment to environmental sustainability (Parlamento Europeu e do Conselho 2018). In alignment with the Paris agreement and related policy frameworks, Portugal has committed to achieving carbon neutrality by 2050. To support this objective, the country implemented the National Energy and Climate Plan 2021-2030.

In the residential sector, improving thermal comfort, particularly through passive measures such as thermal insulation, has been identified as a priority. However, the current housing stock presents significant challenges: approximately 80% of dwellings have low energy performance ratings, and around 75% lack adequate thermal insulation (Ogut, 2023). Although the adoption of insulation solutions has increased since the 1990s, largely driven by European legislation and technological advancements (Resolução do Conselho de Ministros n.º 53/2020), substantial gaps remain.

European policies, such as the Energy Performance of Buildings Directive (EPBD), have played a central role in promoting building rehabilitation. These policies aim to reduce energy consumption, address energy poverty, and accelerate the transition to renewable energy, with the overarching goal of achieving a decarbonized building stock by 2050. In Portugal, urban rehabilitation efforts have focused on enhancing thermal comfort and indoor air quality, with an emphasis on thermal insulation (ADENE 2024).

This regulatory framework has evolved progressively. Directive 2002/91/EC introduced the energy certification system, which was transposed into Portuguese legislation in 2006 through the creation of the National Energy Certification System and Indoor Air Quality (SCE) (Decreto-Lei n.º 78/2006; Freire, 2015). Subsequent updates, including Directive 2010/31/EU and its transposition via Decree-Law n.º 118/2013, reinforced energy efficiency requirements and introduced stricter standards for building systems. More recently, Decree-Law n.º 101-D/2020, transposing Directive (EU) 2018/844, established the current regulatory framework governing the energy performance of buildings in Portugal, including specific adaptations for the Autonomous Region of the Azores.

According to the 2021 Census (INE, 2021), the Azores and Algarve regions experienced growth in their housing stock, with increases in the number of buildings and dwellings. The Azores, with a population of approximately 250,000, face distinct challenges due to their geographical isolation and strong dependence on imported energy (around 60%) (European Commission n. d.). To reduce this dependency, the region has invested in renewable energy sources, particularly geothermal energy, which accounted for 20.5% of electricity generation in 2022, mainly on the islands of São Miguel and Terceira (DRAAC, 2023).

The residential sector in the Azores is particularly significant, representing 20% of total energy consumption and constituting the largest source of CO_2 emissions (European Commission n. d.). As an autonomous region, the Azores must adapt national energy policies to its specific socio-economic and geographic context. Consequently, emission-reduction targets differ from those of mainland Portugal, reflecting regional characteristics, such as the prominence of the agricultural sector (Furtado et al., 2023).

Energy poverty remains a pressing issue in the region. According to Eurostat (2024), 31.4% of the population is at risk of poverty or social exclusion, exceeding the national average. This situation is exacerbated by the age and inefficiency of the housing stock, with a large proportion of buildings constructed before 2000. In response, the Recovery and Resilience Plan (RRP) allocates €67.5 million to improve housing conditions, focusing on both new energy-efficient construction and the renovation of existing buildings.

These initiatives include demonstration projects and financial support mechanisms to increase energy efficiency, reduce energy consumption, and mitigate energy poverty. Among the available solutions, façade thermal insulation is particularly relevant, as it improves building performance, reduces emissions, and enhances indoor comfort (Governo dos Açores, 2024).

The Azorean climate highlights the need for appropriate building design. Mild temperatures, high humidity, and frequent precipitation challenge thermal comfort and durability. With an average annual temperature of 17.5 °C, low thermal variation, and relative humidity around 80%, context-specific solutions such as bioclimatic design and effective insulation are essential (Governo dos Açores, 2019; Azevedo, 2002).

Climate change mitigation is a priority under the Regional Programme for Climate Change (PRAC), which promotes renewable energy, efficiency, and sustainable mobility, emphasizing adaptation and mitigation measures in residential and service sectors to reduce energy demand and environmental impacts (Decreto Legislativo Regional n.º 30/2019/A).In this context, this study analyses energy consumption patterns and thermal insulation solutions in the Azores, based on a survey of stakeholders in the architecture, engineering, and construction (AEC) sector. The objective is to understand professionals' perceptions and contribute to developing more effective communication strategies to improve thermal comfort and overall well-being.

2. Methodology

The present study was conducted by disseminating a structured survey to a range of stakeholders, including professionals from the AEC sector and residents of the Autonomous Region of the Azores. A total of 19 valid responses were collected. The statistical population comprises residents and sector-related stakeholders within the Azores region.

The survey is organized into several thematic sections. It begins with the characterization of respondents, gathering information on their sector of activity, geographic location, and personal and professional profiles. This is followed by a section on housing characteristics, covering ownership status, building condition, renovation history, thermal insulation, and ventilation practices. Subsequently, the survey explores participants' perceptions of energy performance, including the perceived need for energy rehabilitation, awareness of governmental support programs, and familiarity with tools for assessing energy consumption.

A dedicated section on thermal insulation examines respondents' knowledge of available solutions and their preferences between passive and active strategies for achieving thermal comfort. It also evaluates perceptions of insulation materials across multiple dimensions, technical, environmental, economic, and safety-related, with particular emphasis on durability, sustainability, and fire performance.

Finally, the survey addresses respondents' views on climate change and the environmental impact of insulation solutions, considering a life-cycle perspective and their potential contribution to climate change mitigation.

3. Results

3.1 Characterization of Respondents

The survey for this study was conducted in the Autonomous Region of the Azores, involving participants residing on the islands of São Miguel, Terceira, Pico, and Faial in 2023. Data collection was primarily conducted through face-to-face interviews (14 respondents), while the remaining participants responded via email (19 participants). Of the participants, 89% are men, and 11% are women, all residing in coastal areas. Most of the respondents work in the AEC sector, and generally have an intermediate level of professional experience, with the majority falling within the 25 to 49-age range.

3.2 Characterization of the Respondents´ Homes

Of the participants, 11 are homeowners, and eight are tenants. Out of the 19 respondents, only three reported no visible presence of mold inside their homes. Around 42% of respondents live in buildings constructed after 2006 (Figure 1), with 89% confirming the presence of thermal insulation.

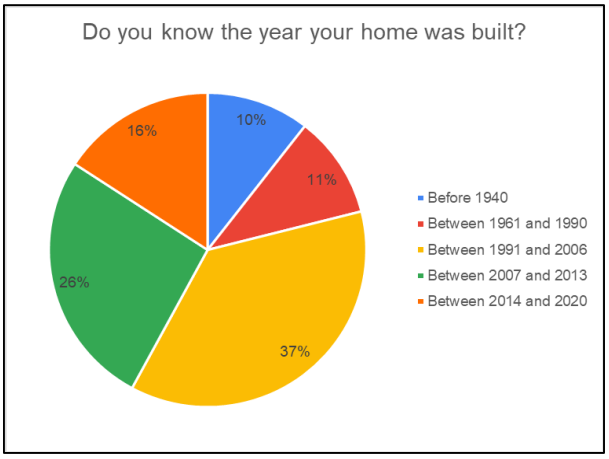

Figure 1 – Distribution of construction year classes of respondents' homes

Among those who reported not having insulation or were unsure, mold and dampness were the most cited reasons for needing energy rehabilitation (Figure 2). However, 92% of those identifying these issues had never carried out rehabilitation works, primarily due to a lack of financial resources.

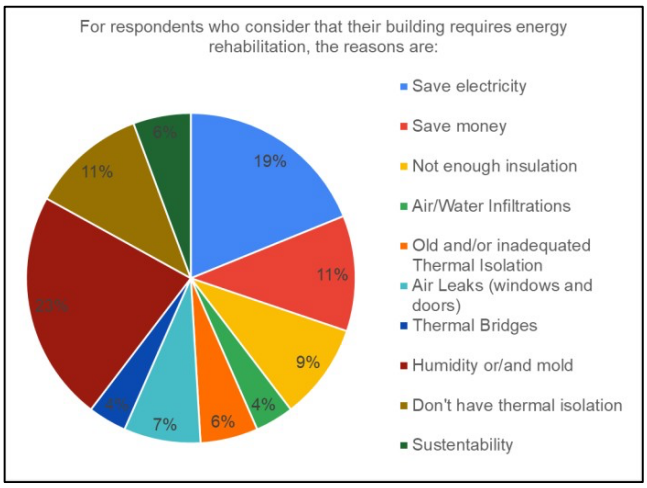

Figure 2 – Selected reasons justifying the need for energy rehabilitation in their respective homes

Approximately 89% of respondents stated they would seek government financial support for energy rehabilitation, aligning with the objectives of the RRP. All participants agreed that investing in rehabilitation is worthwhile, with a focus on improving energy efficiency ratings. Investment in rainwater drainage systems was identified as the top priority due to the region’s climatic conditions, followed by the application of insulation material on walls (Figure 3).

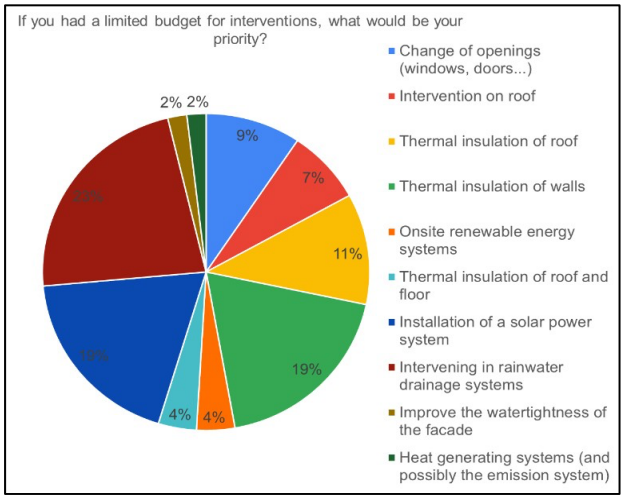

Figure 3 – Type of intervention selected, which respondents would prioritize if they had the available budget

Poor ventilation was not identified as the main cause of mold, as most respondents regularly ventilate their homes (Figure 4). Finally, 63% of participants stated they had no clear understanding of the costs involved in maintaining environmental comfort in their homes.

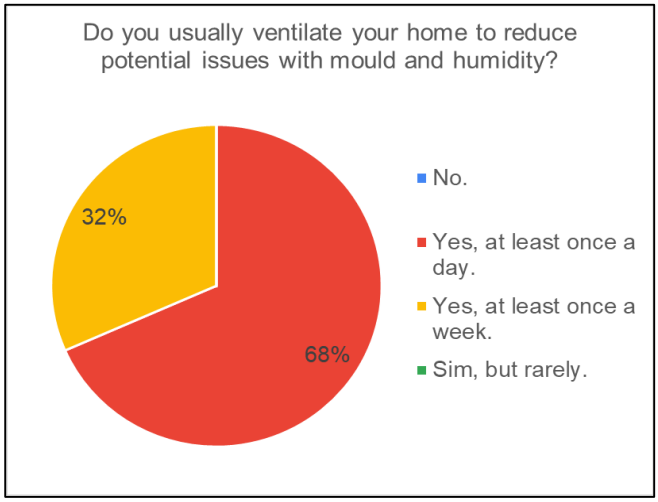

Figure 4 – Frequency with which respondents ventilate their homes to reduce potential issues with mould and humidity

3.3 Characterization of Thermal Insulation

The survey revealed that 15 out of the 19 respondents were knowledgeable about the criteria for selecting and classifying thermal insulation materials (Figure 5), adding credibility to their responses. All respondents stated that expanded polystyrene (EPS) is the most widely used and longest-applied insulation material in the region, which explains the regional perception of its “superior” durability compared to other insulation materials. On the other hand, tenants reported having low knowledge regarding green façades and natural fiber solutions, which are rarely used in the region. The greater commercialization of EPS in the region, compared to other insulation materials, also justifies the fact that it has the lowest market price, followed by mineral wool and extruded polystyrene (XPS), which, according to the respondents, are also among the most commercially available insulation materials.

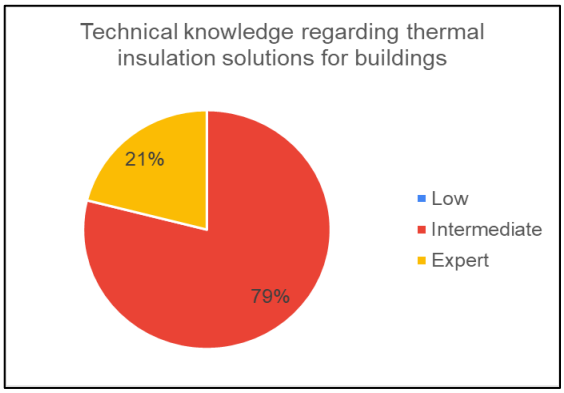

Figure 5 – Percentage of respondents by level of technical knowledge of thermal insulation solutions

The respondents' perception regarding the materials with the greatest maintenance needs, the highest potential for biological growth and the lowest CO_2 emissions converges towards natural materials, such as natural fibers and green façades.

In Figure 6, average values of the classifications obtained for synthetic-origin materials are presented, in Figure 7, for natural-origin insulation materials, and in Figure 8, for mineral wool.

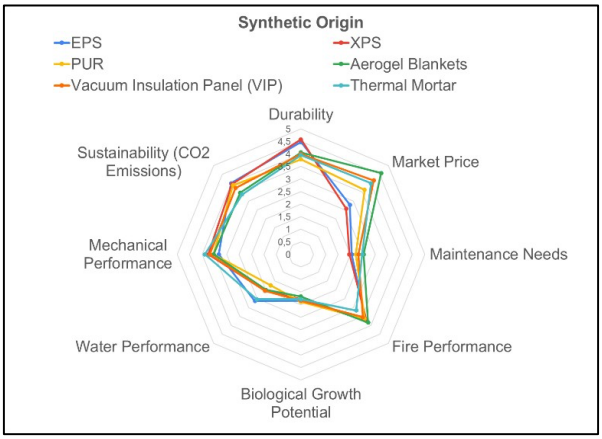

Figure 6 – Average values of the classifications obtained for the various synthetic-origin insulation materials, relative to the criteria under study

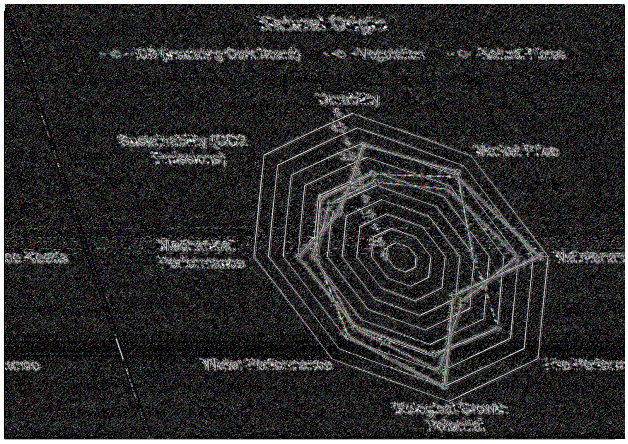

Figure 7 – Average values of the classifications obtained for the various natural-origin insulation materials, relative to the criteria under study

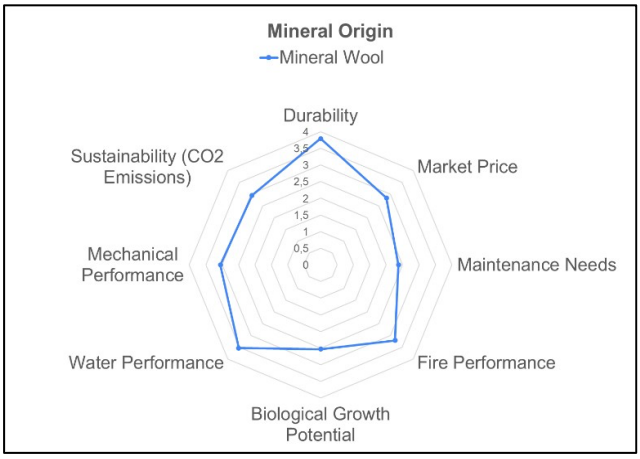

Figure 8 – Average values of the classifications obtained for the various mineral-origin insulation materials, relative to the criteria under study

By analyzing Figures 6 to 8, it can be observed that synthetic-origin materials, compared to materials of other origins, are generally perceived as having better characteristics in various aspects, such as: greater durability, lower maintenance needs, reduced potential for biological growth, and better performance in relation to water, i.e., less water retention. On the other hand, based on the respondents' answers, natural-origin materials stand out for their superior characteristics in terms of fire behavior and sustainability, with lower CO_2 emissions.

Regarding the constructive characteristics that can influence the choice of thermal insulation materials, the most prominent feature was the application of thermal insulation on the exterior of the façade. This solution was perceived by the respondents as a rapidly growing option in the region (proving to be very competitive when compared to other common solutions), associated with quick installation and homes that provide a high level of environmental comfort.

Passive solutions, the balance between these and active solutions, and heating and cooling systems were the options that received the highest percentage of responses as the most suitable for achieving indoor thermal comfort.

Heat pump systems were the solution with the highest response rate. According to the respondents' explanations, this high percentage is due to an incentive system for the production and storage of energy from renewable sources, promoted by the Regional Directorate of Energy. This system allows the investment in heat pumps, both for climate control and Domestic Hot Water (DHW), to be subsidized as a non-repayable grant by the government of the Azores (Direção Regional da Energia 2024).

Approximately 84% of respondents expressed a willingness to choose more sustainable solutions, even if they are more expensive, to reduce CO_2 emissions. The production and end-of-life phases of materials were considered the most important for reducing environmental impact, particularly due to logistical challenges in the Autonomous Region of the Azores. Key environmental goals highlighted by respondents include promoting the circular economy, increasing the use of green energy, and reducing CO_2 emissions. The data collected will be further analyzed in relation to the socioeconomic and environmental context of the Azores.

4. Discussion

All the rehabilitation of the housing stock is a pressing issue in the European Union and Portugal, with energy inefficiency exacerbating energy poverty. Approximately 40 million Europeans, including 17.5% of

the Portuguese population, are unable to adequately heat their homes. The European Union and Portugal have committed to reducing GHG emissions and increasing energy efficiency by 2030 and 2050, with various initiatives underway, such as the RRP (Resolução do Conselho de Ministros n.º 53/2020).

In the Azores, the RRP allocates €67.5 million to improving housing conditions, with a focus on energy efficiency and combating energy poverty (Governo dos Açores 2024). The study's respondents, primarily residents of homes without thermal insulation, identified mold and humidity as critical problems, exacerbated by the region's climatic conditions. Financial constraints were cited as the main barrier to carrying out energy rehabilitation, but 89% of respondents indicated that they would undertake these interventions with government support.

Respondents prioritized the installation of external thermal insulation on façades and improving rainwater drainage systems to address the effects of climate change, which include extreme weather events and rising temperatures, particularly in summer.

Comparative analysis of the results from the present study (Soares, 2023) and those obtained from surveys conducted as part of the EFFICACY project (Bartels et al. 2023) on the use of thermal insulation solutions in building façades on mainland Portugal, reveals several key findings. The EFFICACY data were based on a sample of 127 respondents collected between November 2022 and February 2023 (Parracha et al. 2024; Loura, 2023), and provide a useful benchmark for contextualizing the results presented here.

- In both studies, most of the respondents work in the sector of AEC, allowing for a similar validation of responses.
- In the present study, 63% of respondents reported being satisfied with the comfort level of their homes, compared to 80% on mainland Portugal.
- In both studies, over 62% of respondents, aware of government incentives for energy rehabilitation of homes, deemed these supports inadequate, suggesting that, as in mainland Portugal, the support measures planned for the Azores region should be reassessed to better meet the population's needs.
- Both in the Azores and mainland Portugal, the percentage of respondents indicating the need for additional equipment/devices to improve indoor comfort exceeds 76%, revealing that, in the respondents' view, passive solutions are insufficient to ensure adequate environmental comfort in homes. This high percentage in both studies may explain why most respondents consider investing in an energy rehabilitation intervention worthwhile (as noted by more than 79% of respondents in the mainland Portugal study and all respondents in the present study).
- Reviewing the results from mainland Portugal, 58% of respondents indicated that they either do not believe in climate change or chose not to respond. This contrasts with the present study, in which all respondents reported believing in climate change and having already perceived its effects.
- All Azorean respondents agreed that climate change can influence indoor comfort in buildings and, consequently, affect energy consumption. There was also unanimous agreement that summer is the season most likely to be impacted by climate change. Additionally, they were asked about the approach they would adopt in response to this issue. The predominant response was a reaction/action approach. Respondents justified this choice by stating that climate change is an inevitability whose effects are likely to worsen soon, making it essential for populations to take measures to help reduce its impacts.
- The use of locally sourced Azorean materials was identified as a solution to reduce environmental impacts, considering the significant role the production phase plays in the life cycle of imported materials. Respondents expressed particular concern about the production phase, noting that the region's geographical location logistically constrains the acquisition of products and materials, as a considerable portion depends on long- distance transport (by sea and air).

- Among construction characteristics influencing insulation material choice, external façade insulation was the most frequently chosen option. This preference aligns with the high commercialization of EPS in the Azores region and may reflect the growing trend towards external insulation in Portugal in recent years.
- For solutions considered most effective in improving thermal comfort at home, Azorean respondents highlighted passive façade solutions and a balance of active and passive solutions. Lower percentages associated with heating and cooling systems may be due to the mild temperatures in the region during the whole year. Among active solutions, heat pump systems were favored. In addition to being supported by government incentives in the Azores, their popularity may be linked to increased availability in recent years.

The results presented in Table 1 reflect respondents' perceptions of insulation material performance rather than measured or experimentally validated properties. As such, the findings should be interpreted as indicative of market preferences and professional judgment.

- XPS and polyurethane-based materials (PUR/PUX) are perceived as advantageous in maintenance needs, water resistance, and resistance to biological growth, suggesting that respondents associate these materials with reliability in moisture-prone conditions.
- Thermal insulating mortars are consistently rated highest for fire resistance and mechanical performance in both regions. This may reflect confidence in their compliance with safety regulations and structural robustness.
- The identification of aerogel blankets in the Azores for biological growth resistance suggests awareness of high-performance materials among respondents, although their limited market penetration indicates that such perceptions may not be based on widespread practical application.
- For the sustainability criterion (CO_2 emissions), responses diverge between regions. In the Azores, insulation cork board is perceived as the most sustainable option, likely due to its natural origin and association with low environmental impact. In mainland Portugal, vegetation systems (green walls) are perceived as the most sustainable

Table 1 – Thermal insulation materials with the highest average rating, by performance criterion, for the Azores Autonomous Region (RAA) and mainland Portugal , derived from survey-based studies (Parracha et al. 2024; Parracha et al. 2023: Loura 2023)

Performance Criterion	Best-Rated Insulation Material (Azores)	Best-Rated Insulation Material (Mainland Portugal)
Durability	EPS	Cork insulation board
Market Price	EPS	EPS
Maintenance Needs	XPS	Insulation corkboard
Fire Resistance	Thermal insulating mortars	Thermal insulating mortars
Biological Growth Resistance	Aerogel blankets	PUX/XPS/EPS
Water Resistance	Polyurethane foam (PUR)	XPS
Mechanical Performance	Thermal insulating mortars	Thermal insulating mortars
Sustainability (CO_2 Emissions)	Insulation cork board	Vegetation – green walls

In addition to the information presented in the previous table, respondents indicated that EPS, followed by mineral wool and XPS, are the most widely marketed and applied insulation materials in the Azores. XPS is used for both internal insulation of façades within simple masonry combined with light cladding and in air gaps of double walls and external applications (ETICS). This widespread use makes it more competitively priced compared to other insulation solutions.

5. Conclusion

The results highlight that material selection is influenced by perception, familiarity, and market presence, and may not fully align with quantitative performance data or life-cycle assessments. Considering the results of this study and its scope, the following developments are proposed:

- Conduct a similar study periodically to keep the information in the database promoted by the EFFICACY project up to date.
- Expand the dissemination and development of the survey used in this study to reach a larger number of respondents, making the sample more representative and thus enhancing statistical validity.
- Compare the results of this work with other studies conducted in regions with geographic characteristics like those of the Azores to understand the extent to which the impact of climate change is perceived similarly by respondents and to assess their perspectives on this phenomenon.
- Monitor the use of endogenous materials from the autonomous region of Azores in the construction industry to gather feedback on the classification criteria used in this study.

Abstract: A preservação de edifícios antigos é essencial para a manutenção do património histórico e cultural. Estas estruturas evidenciam estilos arquitetónicos únicos, promovem a sustentabilidade através da reutilização de materiais e permitem a melhoria do desempenho e do valor dos edifícios pela integração de tecnologias modernas e energeticamente eficientes. A caracterização mecânica da alvenaria resistente em Portugal apresenta desafios significativos devido à elevada heterogeneidade dos métodos construtivos e dos materiais utilizados ao longo do tempo. Nos últimos anos, foram realizados numerosos ensaios com macacos planos em todo o país, com especial incidência no centro histórico de Lisboa, abrangendo edifícios civis e monumentos históricos. De acordo com a tipologia de alvenaria apresentada no EC8-3, a alvenaria ensaiada foi classificada e a determinação das propriedades mecânicas da alvenaria, nomeadamente a tensão de compressão, o módulo de elasticidade e o módulo de distorção, foi obtida através de 83 ensaios in situ com macacos planos. Os resultados indicaram valores médios de resistência à compressão de 1,6 MPa, módulo de elasticidade secante entre 1170 MPa e 2404 MPa e módulo de distorção de 375 MPa. De forma geral, os resultados apresentam boa concordância com os intervalos propostos por referências internacionais e estudos anteriores, embora evidenciem valores de rigidez superiores aos recomendados pelo Código Italiano e pelo projeto de revisão do EC8-3. Estes resultados contribuem para o estabelecimento de valores de referência para a alvenaria tradicional portuguesa e fornecem informação relevante para a avaliação sísmica e calibração de modelos numéricos de edifícios existentes.

Keywords: Ensaios de Macacos Planos, Alvenaria Ordinária, Ensaios In Situ, Caracterização Mecânica

1. Introdução

A preservação dos edifícios antigos é essencial para manter vivo o nosso património histórico e cultural. Estes edifícios apresentam frequentemente estilos arquitetónicos únicos e técnicas construtivas tradicionais que testemunham diferentes épocas da história. A conservação destas estruturas permite não só preservar a autenticidade arquitetónica e estética, mas também promover práticas sustentáveis através da reutilização dos edifícios existentes. A reutilização de materiais de construção já incorporados reduz a necessidade de novos recursos e minimiza o impacto ambiental associado à extração e produção de novos materiais. Além disso, a reabilitação de edifícios antigos possibilita a integração de tecnologias modernas e soluções energeticamente eficientes, melhorando o desempenho e o conforto sem comprometer o seu valor histórico. A preservação e valorização do património arquitetónico antigo contribuem para a sustentabilidade ambiental e para a valorização cultural, garantindo que as gerações futuras possam continuar a usufruir da riqueza do património arquitetónico nacional.

A história do património edificado em Portugal é rica e diversificada, refletindo séculos de influências arquitetónicas e culturais. Desde a Antiguidade até à época contemporânea, as construções existentes no território português testemunham a evolução das técnicas construtivas e da expressão estilística de diferentes períodos históricos. O património arquitetónico português integra uma grande variedade de estilos, desde estruturas da época romana até influências mouriscas e, posteriormente, o desenvolvimento dos estilos gótico, renascentista, barroco e neoclássico.

Embora Portugal continental não tenha sido afetado por sismos de grande magnitude nos últimos anos, a sua localização geográfica torna-o suscetível à ocorrência destes fenómenos, como demonstram acontecimentos históricos marcantes, tais como o terramoto de Lisboa de 1755 (Mw = 8.5), o sismo de Benavente de 1909 (Mw = 6.3) e o sismo do Algarve de 1969 (Mw = 7.8) (Salvalaggio et al. 2024). Estes eventos sísmicos provocaram danos extensos, particularmente nas construções em alvenaria (Correia et al. 2015), sendo que uma parte significativa do edificado existente foi construída antes da introdução dos modernos regulamentos de dimensionamento sísmico, apresentando, por isso, deficiências estruturais relativamente ao desempenho sísmico. O Decreto-Lei n.º 235/83 (República 1983), de 31 de maio, classifica a cidade de Lisboa como zona de elevada sismicidade, enquanto a entrada em vigor do Decreto-Lei n.º 95/2019 (República 2019), de 18 de julho, veio incentivar a avaliação das condições de segurança estrutural nos processos de reabilitação urbana, especialmente em zonas de risco sísmico.

Contudo, a caracterização mecânica da alvenaria resistente em Portugal apresenta desafios significativos devido à elevada heterogeneidade dos métodos construtivos e dos materiais utilizados ao longo do tempo. Nos últimos anos, foram realizados numerosos ensaios com macacos planos em todo o país, com especial incidência no centro histórico de Lisboa, abrangendo desde edifícios correntes até monumentos históricos (ver Figura 1). Estes ensaios têm sido desenvolvidos no âmbito de iniciativas dedicadas à conservação e reabilitação do património edificado.

Adotando a tipologia proposta por Candeias et al. 2020 para a alvenaria portuguesa, as estruturas ensaiadas foram classificadas de acordo com os tipos de alvenaria descritos no referido trabalho, acrescentando-se ainda as alvenarias correntes de tijolo furado e as construções em terra (adobe e taipa) (Fonseca et al. 2025).

Face à escassez de informação experimental sobre as propriedades mecânicas das alvenarias tradicionais portuguesas e à necessidade de dados fiáveis para a avaliação sísmica de edifícios existentes, este estudo tem como principal objetivo caracterizar mecanicamente diferentes tipologias de alvenaria através da análise de resultados obtidos em ensaios in situ com macacos planos. Em particular, pretende-se determinar a resistência à compressão, o módulo de elasticidade e o módulo de distorção das alvenarias ensaiadas, analisar a variabilidade destes parâmetros em função da tipologia construtiva e comparar os resultados obtidos com valores de referência propostos por regulamentos e estudos anteriores. Os resultados apresentados visam contribuir para a definição de valores representativos para a alvenaria portuguesa e apoiar futuras avaliações sísmicas e modelos numéricos de edifícios existentes.

Figura 1 - Fachadas de alguns dos edifícios ensaiados

2. Amostra de dados

A determinação das propriedades mecânicas da alvenaria, nomeadamente a resistência à compressão (f_m), os módulos de elasticidade correspondentes a 10%, 30% e entre 30–60% da tensão máxima (ver Figura 2), o módulo de distorção (G), entre outros parâmetros, foi obtida através da realização de 83 ensaios com macacos planos para a tipologia de alvenaria descrita como "alvenaria de pedra irregular, com seixos rolados e unidades pétreas erráticas e irregulares" (Candeias et al. 2020; Italian Building Code 2019; Vanin et al. 2017; CEN 2019; Fonseca et al. 2025).

Esta tipologia encontra-se presente nas paredes dos edifícios ensaiados no município de Lisboa, com especial incidência na Baixa Pombalina e zonas adjacentes, sendo que muitas destas paredes remontam ao período compreendido entre meados do século XVIII e finais do século XIX.

A presente análise pretende contribuir para um melhor conhecimento das propriedades mecânicas deste tipo de alvenaria portuguesa, facilitar a sua classificação e fornecer uma base sólida para as atuais intervenções de conservação e reabilitação, garantindo a preservação do valioso património arquitetónico de Lisboa para as gerações futuras.

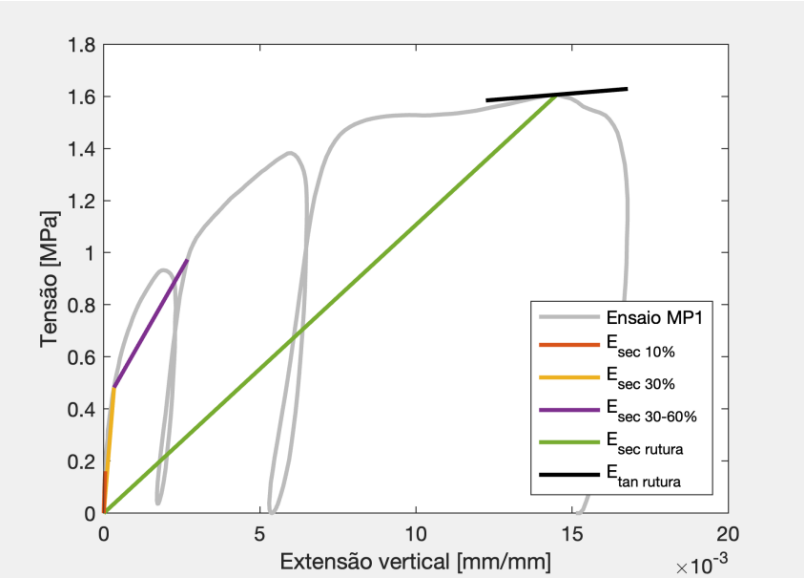

Figura 2 - Módulo de elasticidade determinado através de ensaios com macacos planos

3. Ensaios de macacos planos

Foram realizados ensaios duplos com macacos planos (ver Figura 3), utilizando macacos planos semicirculares com uma área total de 78100 mm², apresentando um valor médio de $k_a$de 0.79 (*DP* = 0.05; *CoV* = 6%) e um valor médio de k_m de 0.79 (*DP* = 0.06; *CoV* = 7.6%), em que *DP* é o desvio padrão e *CoV* o coeficiente de variação. As paredes ensaiadas apresentavam uma espessura média de 0.90 m (*DP* = 039.; *CoV*= 43%).

Para a medição das deformações durante a realização dos ensaios duplos, foram utilizados quatro transdutores de deslocamento: três posicionados verticalmente e um transdutor colocado horizontalmente, conforme ilustrado na Figura 4. A deformação vertical foi calculada considerando a média dos deslocamentos registados pelos três transdutores verticais, traduzindo-se no valor da extensão vertical (ϵ_v).

Para todos os ensaios foram executados ciclos de carga e descarga, tendo estes sido concluídos após a observação, no gráfico Tensão vs. Extensão, da formação de um patamar horizontal, o que indica a capacidade resistente máxima da alvenaria.

A literatura destaca frequentemente o posicionamento dos macacos planos como uma fonte de incerteza, particularmente em alvenarias heterogéneas ou degradadas. Neste estudo, essa limitação foi mitigada através da adoção de uma estratégia sistemática de posicionamento, baseada na configuração geométrica definida na Figura 4. Nas alvenarias correntes, quando as juntas horizontais ou verticais não se encontravam claramente definidas, o posicionamento dos macacos foi sempre determinado de acordo com as dimensões e proporções estabelecidas na Figura 4, privilegiando a repetibilidade do procedimento. Os requisitos de ortogonalidade e espaçamento foram rigorosamente respeitados, assegurando condições consistentes entre diferentes tipologias de parede e configurações de ensaio.

Em alguns casos ocorre a rotura frágil da zona entre macacos planos e, na maioria dos ensaios, é possível observar a abertura de fissuras nessa zona e na região envolvente aos macacos planos (Fonseca et al. 2025). Na presença de argamassas antigas, verifica-se o esmagamento destas na zona envolvente aos macacos, como é exemplo as imagens da Figuras 3c), d) e e).

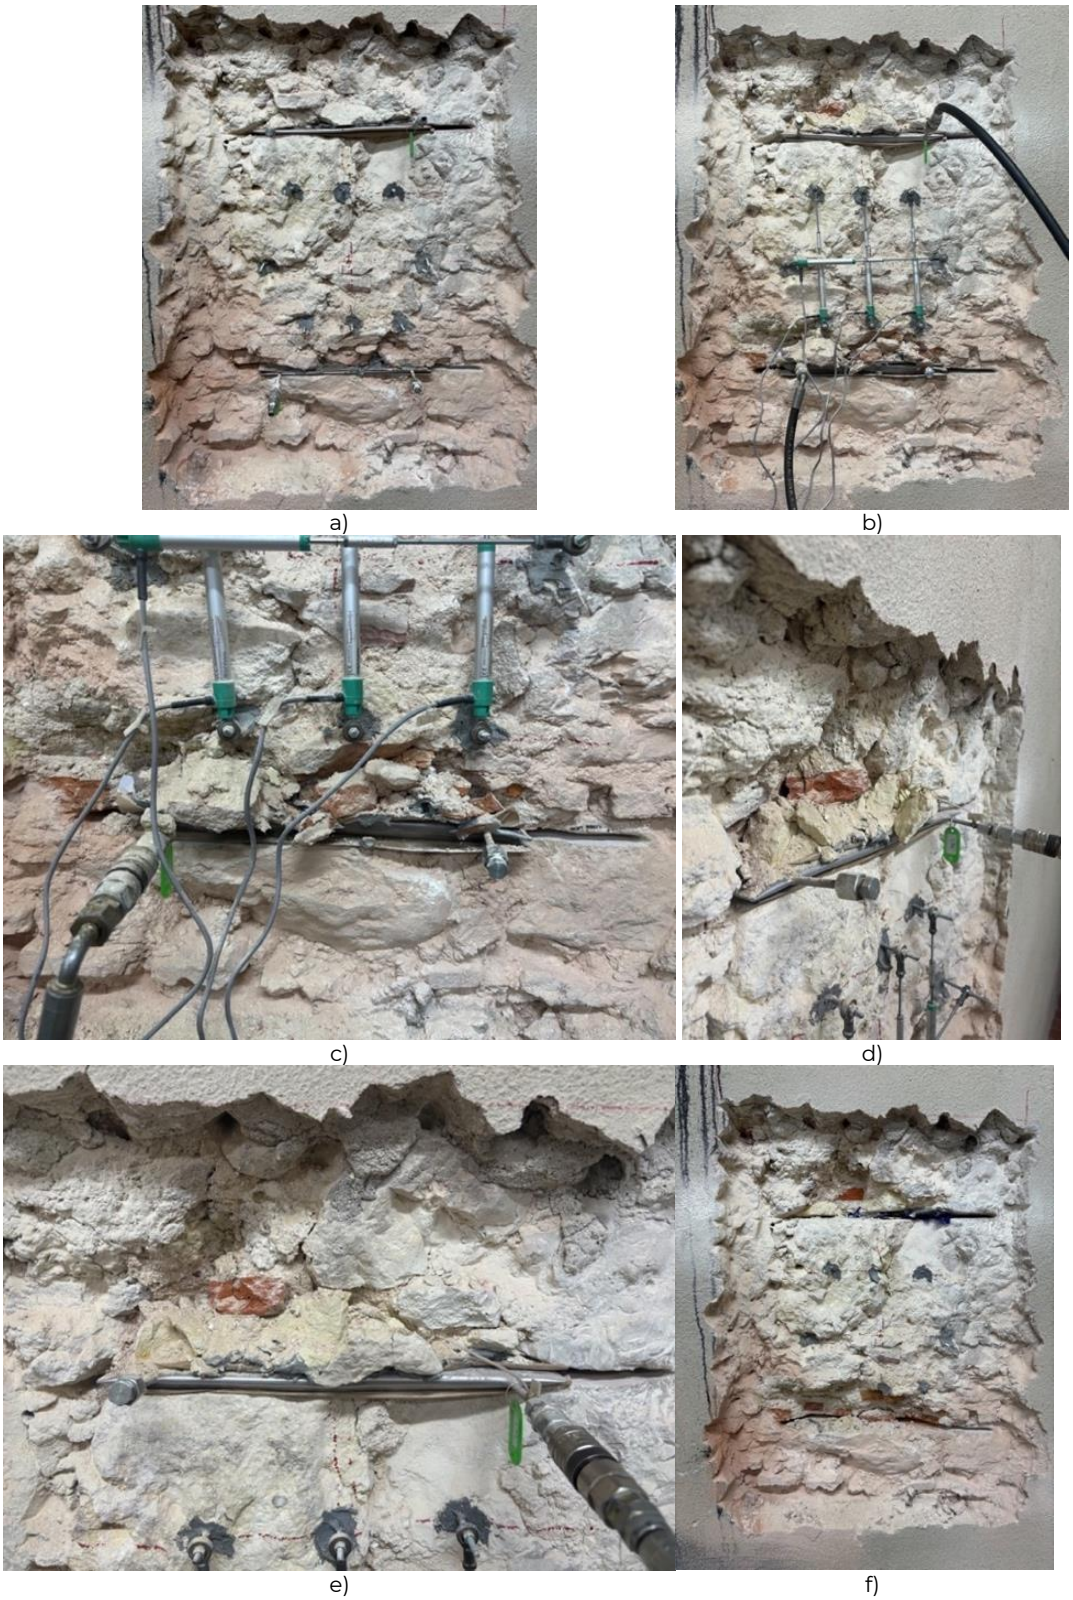

Figura 3 - Ensaio duplo com macacos planos: a) alvenaria após a inserção dos macacos planos; b) alvenaria após a conclusão do ensaio; c) esmagamento da argamassa junto ao macaco inferior; d) e e) esmagamento da argamassa acima do macaco superior; f) alvenaria após a remoção dos macacos.

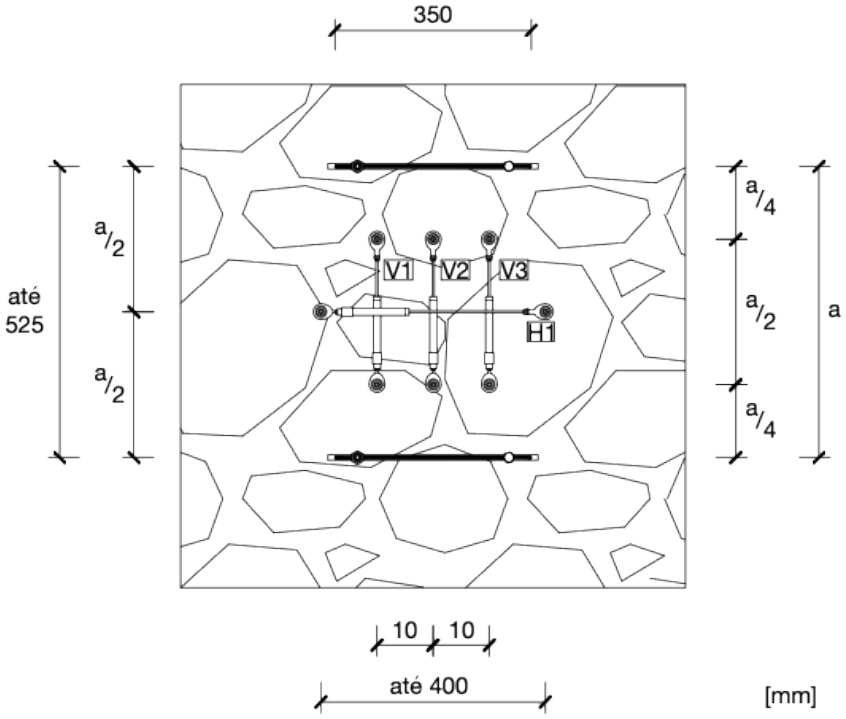

Figura 4 - Configuração geométrica adotada para os ensaios de macacos planos e para os transdutores de deslocamento

4. Caracterização da alvenaria de Lisboa

Para os valores obtidos de resistência à compressão, módulo de elasticidade e módulo de distorção, foram realizados modelos de regressão linear entre as diferentes variáveis determinadas, conforme apresentado na Figura 5.

As regressões entre a resistência à compressão e os diferentes módulos de elasticidade (Figuras 5a), b), c) e d)) apresentaram coeficientes de regressão médios da ordem de 0.65, com exceção da regressão entre f_m e $E_{\text{sec }30-60\%}$. Este modelo foi influenciado pela presença de um valor extremo correspondente a um módulo de elasticidade entre 30% e 60% da tensão máxima significativamente superior aos restantes valores obtidos, claramente identificável na Figura 5c).

A ocorrência destes valores extremos está associada à elevada heterogeneidade da alvenaria, a qual conduz a curvas tensão-extensão atípicas durante os ensaios, originando valores anómalos que podem influenciar os resultados globais das regressões.

A mesma análise pode ser realizada para as relações lineares entre os diferentes módulos de elasticidade, apresentadas na Figura 6. Em particular, nas Figuras 6b) e 6c) identificam-se duas observações extremas associadas a valores elevados de $E_{sec\,30\%}$ e $E_{\text{sec }30-60\%}$, respetivamente. Estas observações refletem a variabilidade inerente às alvenarias tradicionais e estão associadas a diagramas tensão-extensão atípicos obtidos durante os ensaios com macacos planos. Consequentemente, a sua presença afeta o ajuste das regressões lineares e conduz à diminuição dos coeficientes de correlação observados.

Antes do ajuste das distribuições estatísticas, foi realizada uma análise de valores atípicos (outliers) através de diagramas de caixa (boxplots) para cada variável. Foram considerados valores atípicos os resultados situados abaixo de Q1 − 1,5×IQR ou acima de Q3 + 1,5×IQR, sendo Q1 e Q3 o primeiro e terceiro quartis, respetivamente, e IQR a amplitude interquartil. Estes valores foram excluídos apenas da análise das

distribuições estatísticas, de forma a evitar que observações extremas influenciassem significativamente a estimação dos parâmetros das distribuições ajustadas. O número de amostras considerado em cada ajuste estatístico, após a remoção dos valores atípicos, encontra-se indicado nos respetivos gráficos da Figura 7 através do parâmetro N.

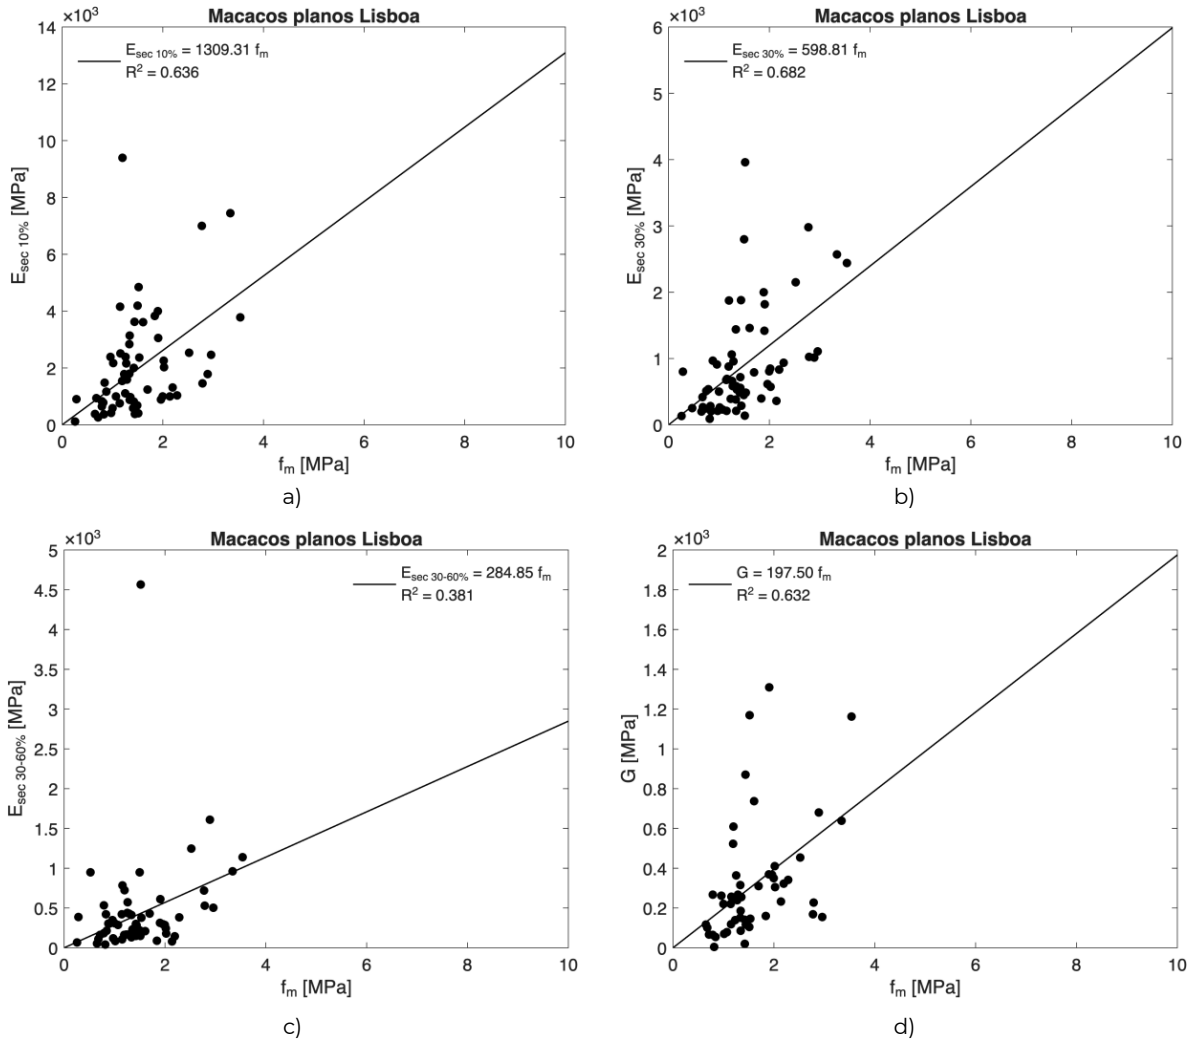

Figura 5 - Análise da rigidez da alvenaria – modelos de regressão linear para: a) $f_m vs. E_{\text{sec } 10\%}$; b) $f_m vs. E_{\text{sec } 30\%}$; c) $f_m vs. E_{\text{sec } 30-60\%}$; e d) $f_m vs. G$.

As distribuições normal e lognormal (ver Figura 7) das variáveis obtidas a partir dos resultados dos ensaios com macacos planos realizados no centro de Lisboa foram determinadas após a exclusão dos valores atípicos identificados através da análise por diagramas de caixa (boxplot), utilizando o critério de 1,5×IQR para cada variável. Entre as cinco variáveis analisadas, a distribuição lognormal apresentou o melhor ajustamento aos histogramas obtidos.

A resistência à compressão (Figura 7a) apresentou uma distribuição aproximadamente normal, indicando uma boa consistência dos resultados obtidos nos ensaios com macacos planos e reforçando a validade desta metodologia para a caracterização da alvenaria. Para os módulos de elasticidade (Figuras 7b), c) e d)) e módulo de distorção (Figura 7e), o melhor ajustamento da distribuição lognormal é explicado pela assimetria positiva dos dados.

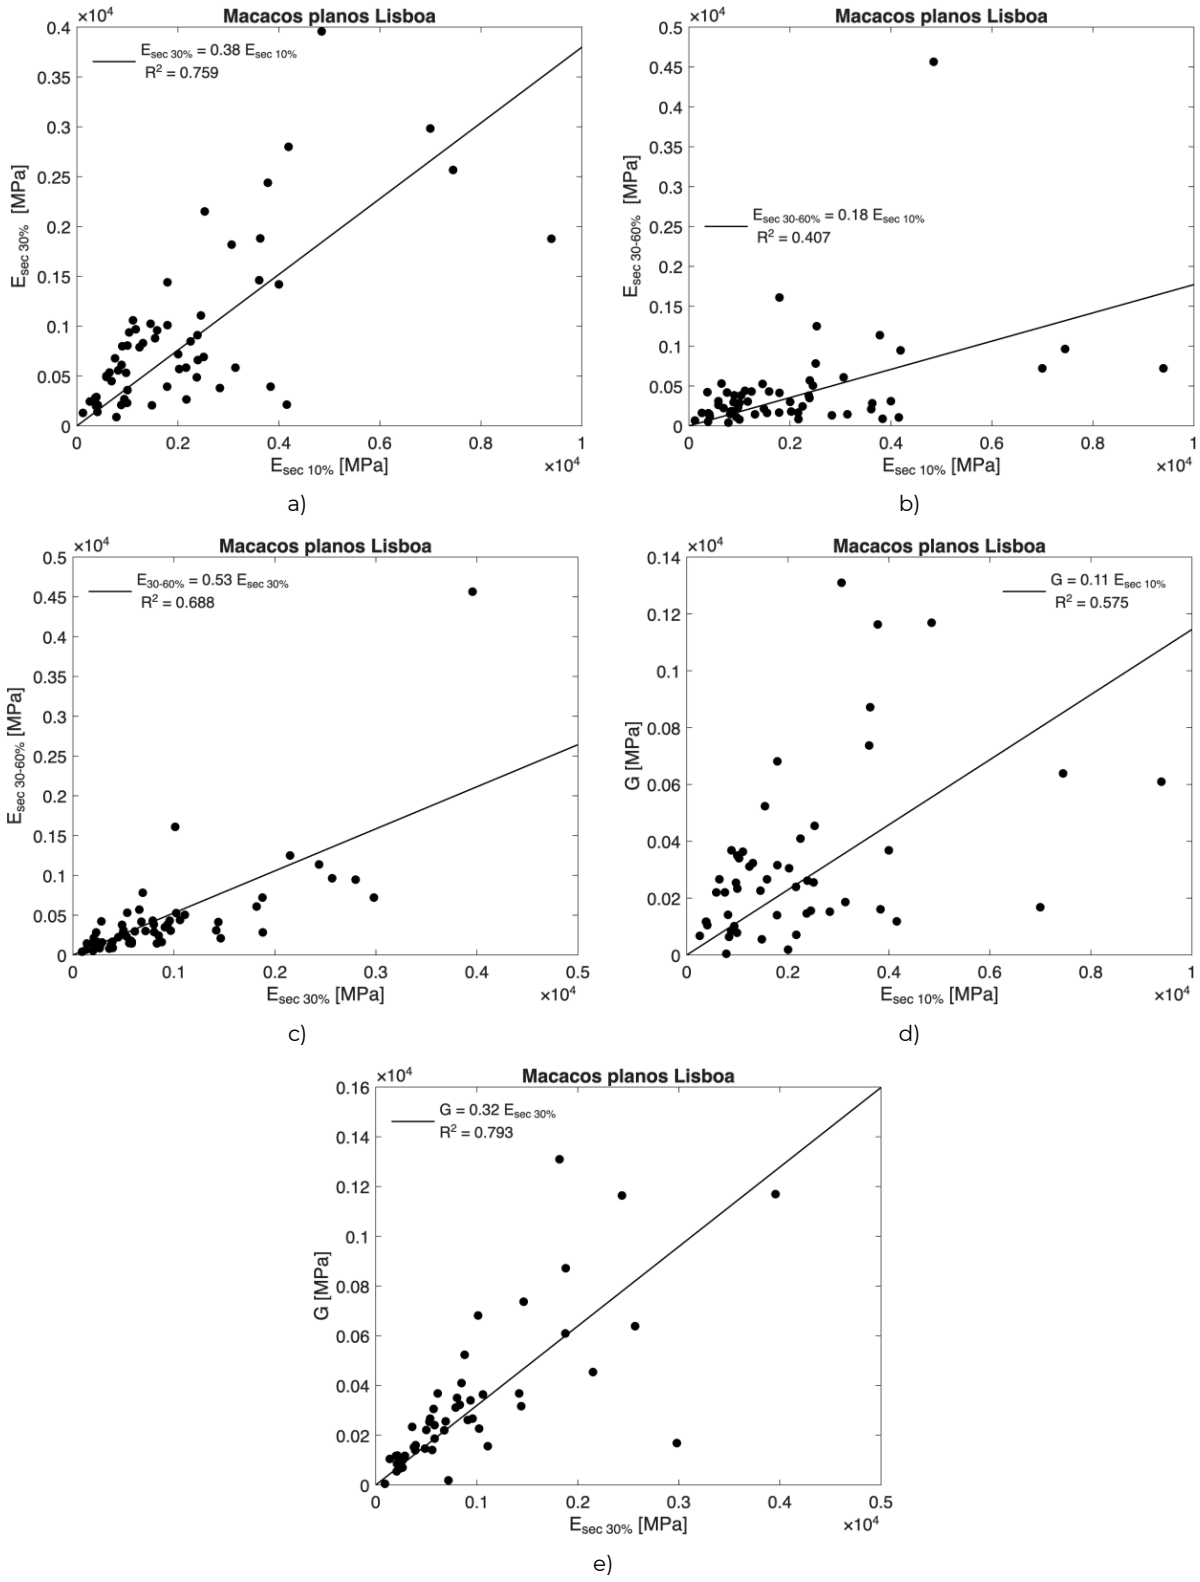

Figura 6 - Modelos de regressão linear dos módulos de elasticidade para diferentes níveis de tensão: a) $E_{\text{sec }10\%}\ vs. E_{\text{sec }30\%}$; b) $E_{\text{sec }10\%-30\%}\ vs. E_{\text{sec }30-60\%}$; c) $E_{\text{sec }30\%}\ vs.\ E_{\text{sec }30-60\%}$; d) $G\ vs. E_{\text{sec }10\%}$; e e) $G\ vs. E_{\text{sec }30\%}$.

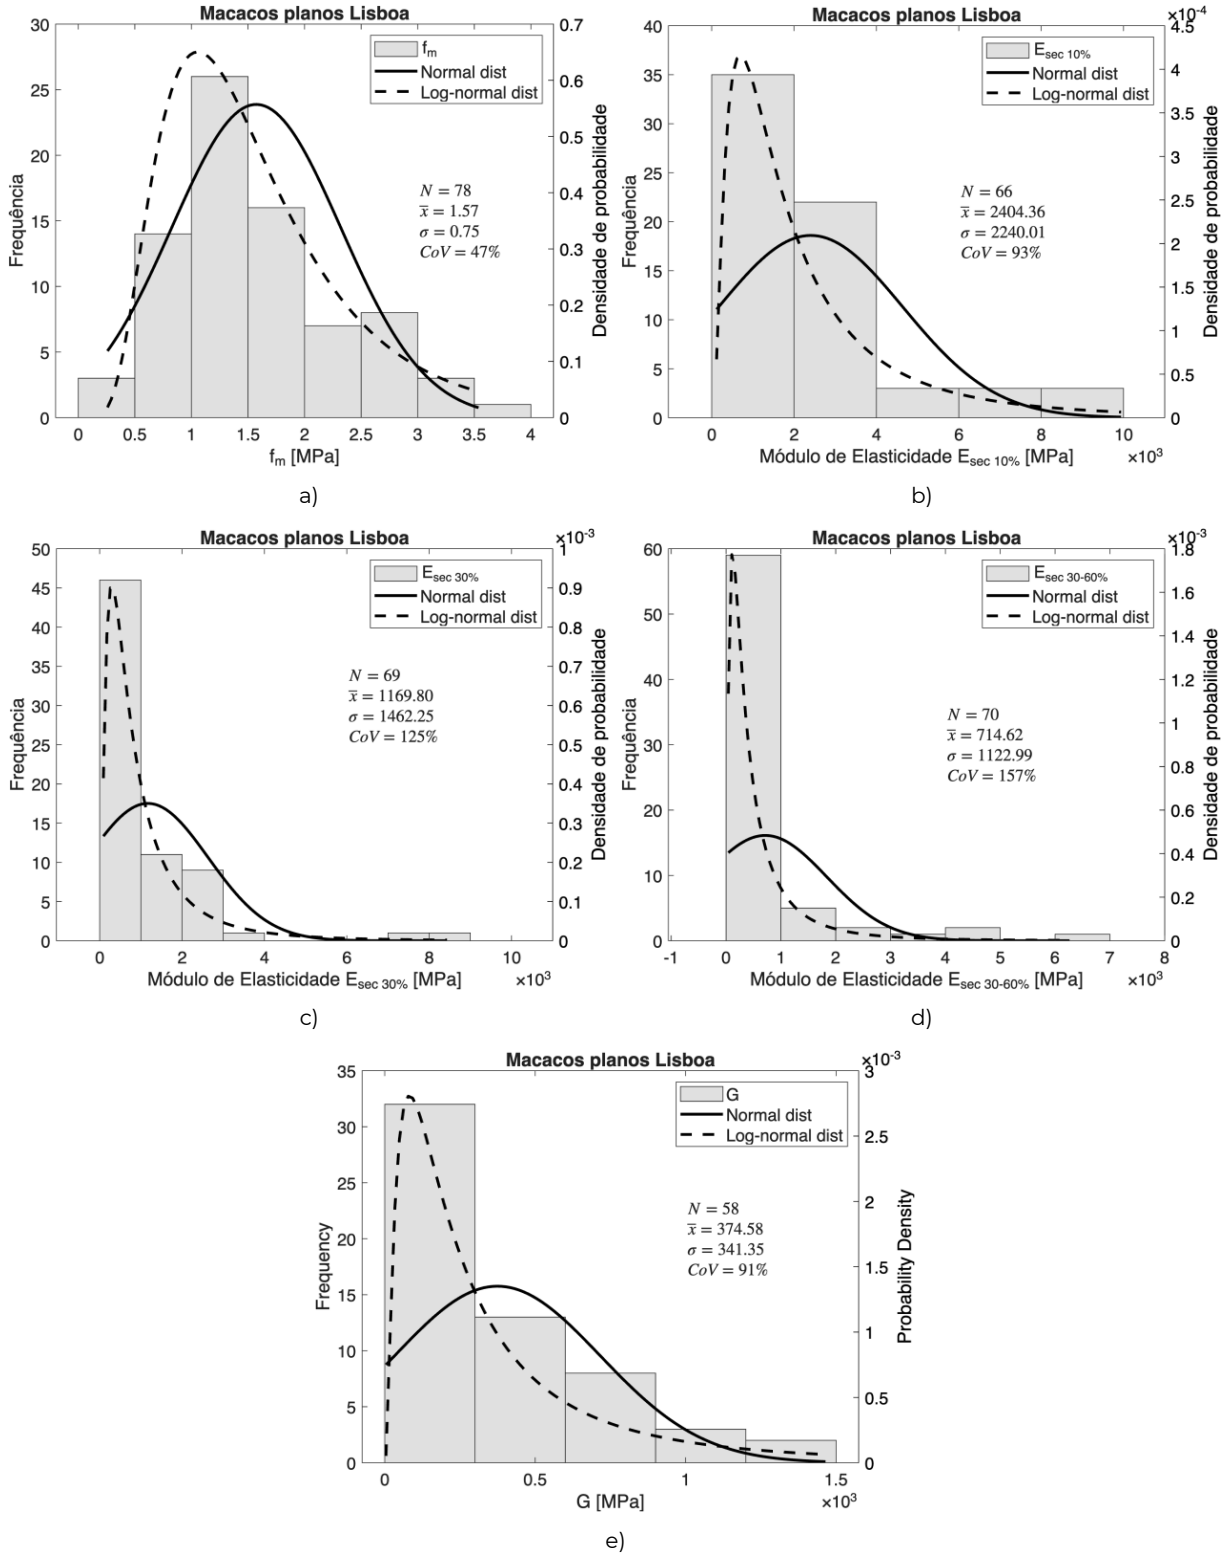

Figura 7 - Histogramas e distribuições de probabilidade de: a) resistência à compressão; b) módulo de elasticidade a 10% da tensão máxima; c) módulo de elasticidade a 30% da tensão máxima; d) módulo de elasticidade entre 30% e 60% da tensão máxima; e e) módulo de distorção.

A Tabela 1 apresenta uma comparação entre os valores médios obtidos através dos ensaios com macacos planos e os valores reportados na literatura para o mesmo tipo de alvenaria considerado neste estudo. Para esta comparação, foram considerados os valores do módulo de elasticidade correspondentes a 10% e 30% da tensão máxima obtidos nos ensaios com macacos planos, tendo em conta a variabilidade ainda existente e o debate em curso relativamente ao valor mais adequado a adotar para o módulo de elasticidade da alvenaria.

Tabela 1 - Comparação das propriedades mecânicas obtidas através dos ensaios com macacos planos no centro histórico de Lisboa com os valores reportados por outros autores.

	f_m **[MPa]**	***E*** **[MPa]**	***G*** **[MPa]**
Macacos planos	1.6	-	375
Macacos planos ($E_{sec10\%}$)	-	2404	-
Macacos planos ($E_{sec30\%}$)	-	1170	-
Candeias et al. 2020	1.1 - 1.9	900	300
Italian Building Code 2019	1.0 - 2.0	690 - 1050	230-350
CEN 2019	1.5	870	290

Os valores obtidos nos ensaios com macacos planos para as propriedades mecânicas da "alvenaria de pedra irregular, com seixos rolados e unidades pétreas erráticas e irregulares" (Candeias et al. 2020; Italian Building Code 2019; Vanin et al. 2017; CEN 2019; Fonseca et al. 2025), presente nos edifícios ensaiados, apresentam resultados médios muito próximos dos reportados por outros autores e dos valores indicados nos regulamentos considerados.

Os valores médios de resistência à compressão obtidos encontram-se dentro dos intervalos propostos na literatura e em documentos normativos. No entanto, os módulos de elasticidade determinados, em particular $E_{\sec 10\%}$, apresentam valores superiores aos valores de referência considerados, evidenciando a importância da caracterização experimental in situ para a definição de parâmetros mecânicos representativos da alvenaria tradicional portuguesa.

5. Conclusões

Os resultados deste estudo evidenciam não apenas a importância da reabilitação dos edifícios antigos em alvenaria, mas também reforçam que as técnicas construtivas tradicionais continuam atuais, constituindo uma abordagem válida e sustentável para a construção contemporânea. A preservação e valorização das estruturas históricas permitem não só salvaguardar o património cultural, mas também reconhecer a relevância contínua destas práticas construtivas. A utilização de materiais naturais, renováveis e recicláveis, como a terra, o adobe, a taipa e o tijolo, reduz a pegada ambiental e promove a sustentabilidade nas novas construções. A integração destas técnicas ancestrais em projetos contemporâneos representa não apenas uma solução eficiente, mas também um compromisso com os princípios ecológicos, contribuindo para um ambiente construído mais resiliente e ambientalmente responsável. Em última análise, a adoção de práticas construtivas tradicionais constitui um contributo relevante para a construção sustentável e para a preservação do planeta para as gerações futuras.

Os resultados obtidos a partir dos 83 ensaios com macacos planos permitiram determinar valores médios de resistência à compressão da ordem de 1,6 MPa, módulos de elasticidade secantes compreendidos entre 1170 MPa e 2404 MPa e módulo de distorção de 375 MPa. De forma geral, estes valores apresentam boa concordância com os intervalos propostos na literatura e em documentos normativos, contribuindo para o estabelecimento de valores de referência para a caracterização da alvenaria tradicional portuguesa.

Por outro lado, o ensaio com macacos planos permite o estudo *in situ* da alvenaria, possibilitando a sua caracterização mecânica sem introduzir danos excessivos nos elementos estruturais. Quando combinado com outras técnicas menos intrusivas, como os ensaios sónicos, os resultados podem ser otimizados, permitindo a determinação das propriedades mecânicas e a calibração de modelos numéricos mais eficientes e representativos das estruturas de alvenaria existentes. Os resultados obtidos nos ensaios evidenciam a importância deste tipo de metodologia na caracterização da alvenaria, demonstrando um excelente desempenho na avaliação do seu comportamento mecânico.

A dispersão observada nas propriedades mecânicas determinadas é consistente com a elevada heterogeneidade característica das alvenarias tradicionais portuguesas. Esta variabilidade pode ser atribuída a diferenças nos materiais constituintes, técnicas construtivas, épocas de construção, estado de conservação e intervenções de reabilitação realizadas ao longo da vida útil dos edifícios. Adicionalmente, a natureza local dos ensaios com macacos planos e a irregularidade geométrica das alvenarias históricas contribuem para a variabilidade observada nos resultados experimentais.

Do ponto de vista prático, os resultados apresentados constituem uma base de referência para a caracterização mecânica de alvenarias tradicionais portuguesas, podendo apoiar engenheiros e técnicos de conservação na avaliação da segurança estrutural de edifícios existentes. Os valores obtidos podem ser utilizados na definição de parâmetros mecânicos para modelos numéricos e em análises de vulnerabilidade sísmica, contribuindo para reduzir a dependência de valores de referência provenientes de regulamentos e estudos realizados noutros países. Adicionalmente, os resultados reforçam a importância da realização de ensaios in situ como suporte aos processos de diagnóstico e à definição de estratégias de reabilitação mais adequadas e fundamentadas.

Agradecimentos

Os autores agradecem o apoio financeiro da Fundação para a Ciência e a Tecnologia, através do projeto UID/6438/2025 da unidade de investigação CERIS.

Jorge Fonseca manifesta o seu agradecimento à Fundação para a Ciência e a Tecnologia (FCT) pelo apoio concedido através da bolsa de doutoramento com a referência 2022.13794.BD, "Influência do nível de conhecimento na avaliação e reforço de edifícios tradicionais de alvenaria de acordo com o Eurocódigo 8", a qual recebeu o DOI https://doi.org/10.54499/2022.13794.BD.

Abstract: Advances in Structural Health Monitoring (SHM) have led to the development of self-sensing composites capable of strain monitoring through piezoresistive behavior. Traditional applications of these smart composites rely on metallic components, such as copper electrodes, to perform electrical measurements. However, integrating metallic elements into cementitious or clay matrices poses architectural and mechanical challenges. This paper introduces a novel approach utilizing a 3D-printed highly conductive cementitious mortar to form embedded electrodes for smart bricks. The fabrication process involved the incorporation of chopped carbon microfibers (CCMF) into the printed cementitious matrix to establish a highly conductive material. Electromechanical cyclic compression tests were conducted to evaluate and compare the performance of the proposed 3D-printed electrodes against conventional copper tape configurations and a combined electrode approach. The results demonstrate an high sensitivity of all the configurations: while the copper tape yielded a higher overall sensitivity compared to the printed electrodes, the standard size smart brick with both 3D-printed electrode and copper tape achieved an intermediate gauge factor of around 215 and the highest linearity among all configurations, reaching a coefficient of determination of 0.84. This approach demonstrates the feasibility of utilizing highly conductive 3D-printed cement mortar as effective electrodes, providing enhanced linearity in smart brick elements.

Keywords: 3D-printed concrete, smart bricks, electrodes, conductive cement mortar, additive manufacturing.

1. Introduction

Damage assessment is a fundamental objective of Structural Health Monitoring (SHM) (Puncello and Caprili, 2023; Rossi and Bournas, 2023), particularly for mitigating the impact of severe hazards such as earthquakes (H. Zhang *et al.*, 2024). Masonry structures are highly vulnerable to seismic events due to their non-homogeneous composition and brittle failure mechanisms (Formisano *et al.*, 2018; Nazimi *et al.*, 2024). Consequently, continuous and systematic monitoring is essential for early damage detection in these structures (Soleymani, Jahangir and Nehdi, 2023). Although well established, traditional SHM systems typically rely on discrete, surface-attached sensors, which can be expensive when deployed in large numbers and may provide only indirect information about the internal condition of structural elements (Laflamme *et al.*, 2023).

To address these limitations, self-sensing construction materials have emerged as a promising alternative for SHM, as they integrate both structural and sensing functions within the constructed element (Wang *et al.*, 2024). These composites can be lime-based (Drougkas *et al.*, 2023), cement-based (J. Zhang *et al.*, 2024; Wang *et al.*, 2024), clay-based (Meoni, Triana Camacho and Ubertini, 2026), among others, and are typically fabricated by incorporating conductive fillers, such as carbon fibers, carbon nanotubes, graphite, or steel fibers into the matrix [(Frąc and Pichór, 2020; Ding *et al.*, 2023; Hao *et al.*, 2023; Li *et al.*, 2023; Rama *et al.*, 2024). The sensing capability of these materials relies on their piezoresistive behavior, which is enhanced near the electrical percolation threshold (D'Alessandro *et al.*, 2016). In contrast, for overpercolated systems, this piezoresistive sensitivity reduces and is replaced by high electrical conductivity, driven by the formation of a dense, continuous network of conductive pathways within the matrix (Laflamme *et al.*, 2023).

Within the framework described above, smart bricks function as masonry-compatible sensing units designed to replicate conventional clay bricks (Meoni, D'Alessandro and Ubertini, 2020). These advanced units possess enhanced piezoresistive capabilities that allow strain characterization through changes in their electrical properties. As embedded sensors, they offer improved structural integration compared to externally attached sensing systems. Typically, copper plates or tapes are utilized as electrodes for electrical measurements (Meoni, D'Alessandro and Ubertini, 2020; Meoni, Triana Camacho and Ubertini, 2026). However, their installation presents distinct technical and architectonic challenges. For instance, Meoni et al. (Meoni *et al.*, 2023) reported unexpected mechanical behavior during testing, which they attributed to mechanical weaknesses developing at the contact interfaces between the mortar layers and the insulating tape used to secure the copper plates.

To overcome these limitations, additive manufacturing technologies, such as 3D concrete printing (3DCP), have emerged as a promising alternative, with advantages in terms of standardization and scalability (Liu *et al.*, 2025; Zhang *et al.*, 2025). Consequently, extruding a highly conductive cementitious mortar directly above the smart brick presents a potential solution for achieving structurally compatible electrode integration, with a good mechanical interface resulting in sensing systems suitable for an easier application in masonry. This paper introduces this novel approach utilizing 3D-printed conductive mortar as an embedded electrode. The study evaluates the electromechanical performance under cyclic compressive loading, comparing the sensitivity and linearity against conventional copper tape configurations and a combination between both types of electrodes in smart bricks.

2. Background

2.1 Smart bricks

Two types of samples were fabricated for this study: a small-sized smart brick with nominal dimensions of 70 × 50 × 50 mm^3, and a standard size smart brick measuring 260 × 120 × 55 mm^3. The composite material was prepared by manually mixing fresh clay with R.STAT/S conductive stainless-steel microfibers at a concentration of 0.25% by mass of the clay. To ensure uniform fiber dispersion, the procedure involved repeatedly flattening the clay matrix, adding the steel microfibers, and folding the mixture ten times. The samples were then cast into wooden molds, pre-sprinkled with sand to prevent clay adhesion, and subsequently demolded. After an initial resting period of 24 h, the bricks underwent a two-stage thermal treatment: a drying phase (2.5 h at 50 °C, followed by 6.5 h at 90 °C) and a subsequent firing phase at 900 °C for 6 h. For the electromechanical characterization, copper tape electrodes were applied to opposite faces of the bricks, and copper wires were soldered to ensure reliable metallic contact. Figure 1 illustrates the small smart brick with copper tape electrodes.

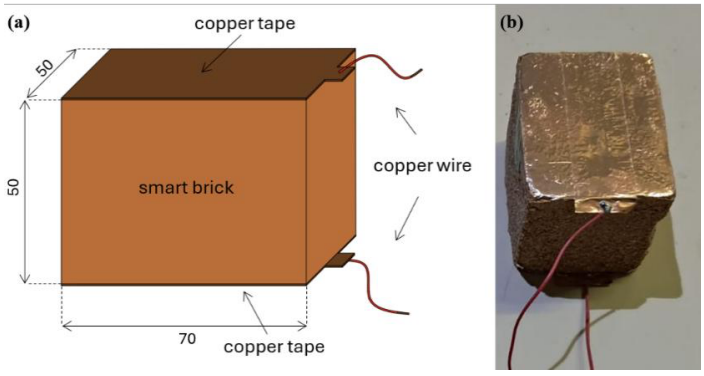

Figure 1 – Schematic representation of the small smart bricks with (a) copper tape electrodes; (b) sample with copper tape electrodes. Units in mm.

2.2 Printed electrodes

A highly conductive cement-based mortar was developed for 3D printing applications. The mix consisted of Portland cement CEM II/B-M (P-LL) 42.5R, siliceous river sand (maximum particle size of 1 mm), and tap water. To induce electrical conductivity, chopped carbon microfibers (CCMF), supplied by SIGRAFIL®, were incorporated at a dosage of 0.4% by mass of cement. To improve printability, based on previous studies, the sand-to-cement and water-to-cement ratios were fixed at 1:1 and 0.55, respectively. Sample fabrication was performed using a WASP 40100 LDM 3D printer equipped with a manually fed extruder. The mixture was designed to ensure that the electrical resistance of the hardened printed electrode remained below 1.0 kΩ. Properties of the utilized CCMF are presented in Table 1.

Table 1 – Properties of chopped carbon-microfibers.

Typical properties	**C C6-4.0/240-G100**
Density	1.80 g/cm³
Mean fiber length milled	6 mm
Filament diameter	7 μm
Tensile strength	4.0 GPa
Tensile modulus	240 GPa
Elongation at break	1.70%
Single filament resistivity	15 μΩm
Bulk density	-
Sizing type	glycerin
Sizing mass content	4.0 %
Compatible with	water-based systems

The mixing procedure started with the manual dry mixing of all solid materials: cement, sand, and CCMF. Subsequently, water was introduced in two distinct stages: initially, 60% of the total volume was added, followed by the remaining 40%. After achieving a homogeneous consistency, the mixture was transferred into the continuous manual-feeding extruder, as illustrated in Figure 2. The printing process involved the extrusion of the fresh conductive mortar at a printing speed of 25 mm/s and an extrusion rate of 864 mm³/s, maintaining a standoff distance of approximately 4 mm. The layers were deposited using an 8 mm nozzle, producing a layer thickness and width of approximately 6 mm. At this stage, the copper tape was removed to enable the printing of the cementitious material in the same region. Prior to printing, the sample was immersed in water to enhance the adhesion between the mortar and the brick surface.

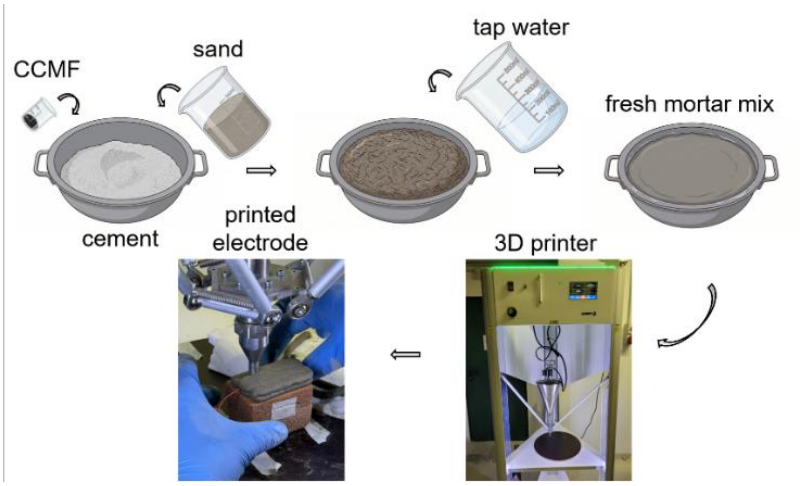

Figure 2 – Fabrication process of the conductive cement-based mortar

Figure 3(a) displays the scheme of the sample with printed electrodes, where copper wires were embedded between the mortar layers during the printing process to establish a reliable electrical connection with the internal conductive networks. Figure 3(b) presents the actual printed electrodes on the fabricated sample. Figure 4(a) illustrates the schematic representation of the standard size smart brick. The different surface configuration is displayed in Figure 4(b), which shows the copper tape electrodes, and Figure 4(c), which presents the printed electrode layers on the smart brick surface.

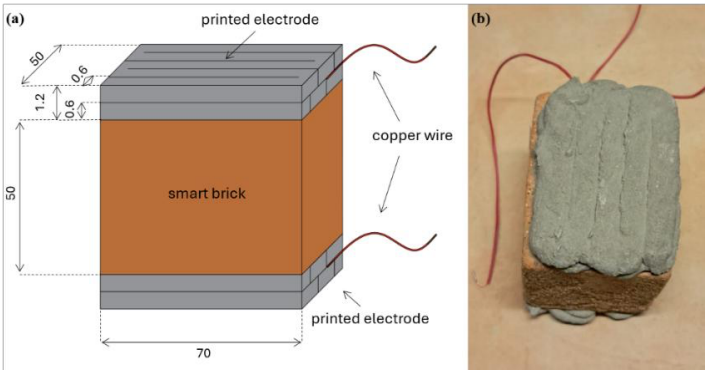

Figure 3 – Schematic representation of the small smart bricks with (a) printed electrodes. (b) Photo evidence of a smart brick sample with printed electrodes. Units in mm.

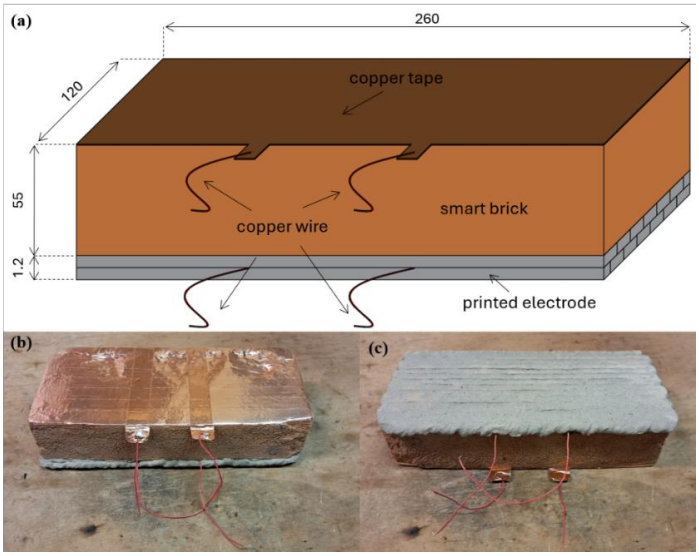

Figure 4 – (a) Representation of the regular size smart bricks sample; (b) view of the top region of the smart brick, with copper tape electrodes; and (c) view of the bottom region of the smart brick, with printed electrodes. Units in mm.

3. Instruments and tests

Electrical measurements were conducted using an NI PXIe-1071 DAQ system equipped with an NI PXIe-4313 module utilizing two channels. A RIGOL DG-1022 function generator supplied a ±10 V square wave input at a frequency of 1 Hz (Downey *et al.*, 2017). A shunt resistor was connected in series with the samples, and the voltage drops across both the resistor and the sample were recorded. The electrical current (i) was calculated using Ohm's law (Equation 1), enabling the estimation of the sample's electrical resistance (R). For the small sample, two-electrode measurements were performed. In contrast, a four-electrode configuration was deployed for the standard size brick due to its geometric scale.

$$R = \frac{V(t)}{i} \tag{1}$$

where, R is the resistance of the sample, i is the current, and $V(t)$ is the voltage.

Electromechanical tests were conducted on two samples to evaluate the piezoresistive performance of the material: (i) a small smart brick, which was tested first with copper tape and subsequently with 3D-printed electrodes; and (ii) a standard size brick, which featured a combined configuration of both printed and copper tape electrodes. Uniaxial cyclic compression tests were performed using an Instron 68TM-50 Universal Testing Machine under load control at a rate of 200 N/s. The experimental setup is presented in Figure 5.

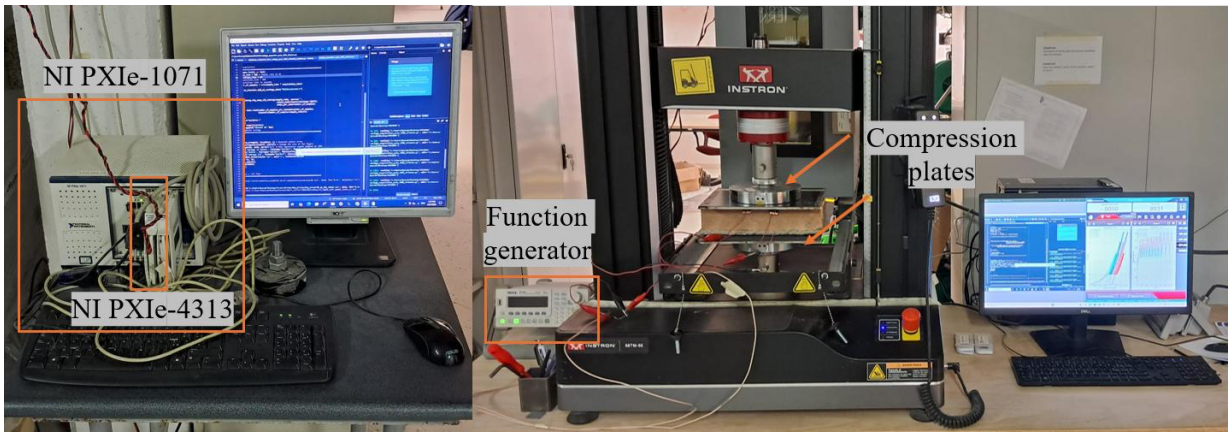

Figure 5 – Test setup for the electromechanical test.

The test initiated with a preliminary 1 kN step ramp followed by a 10-second constant load period as a pre-load phase. Subsequently, the cyclic loading protocol was applied, consisting of 12 cycles divided into three stages of 4 cycles each, with peak loads of 3 kN, 4 kN, and 5 kN, respectively. To ensure uniform load distribution on the standard size brick, an additional metallic platen was placed, which was not required for the small samples. Electrical insulation between the samples and the machine platens was achieved by applying a Kapton layer. Finally, fractional change in resistance (*FCR*) was estimated using Equation 2, following the loading profile illustrated in Figure 6, while the Instron machine displacement data were utilized to determine the axial strain (ε) through Equation 3.

$$FCR = \frac{R - R_0}{R_0} \tag{2}$$

where R_0 is the initial measured resistance, with

$$\varepsilon = \frac{L - L_0}{L_0} \tag{3}$$

where, L is the deformed length of the sample, and L_0 is the initial measured length.

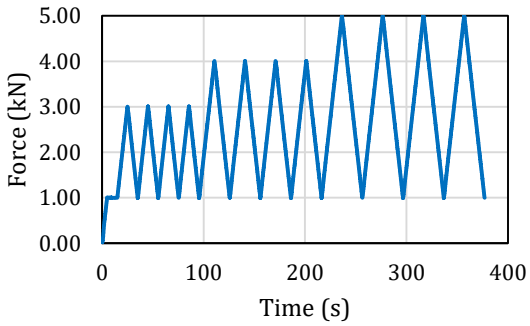

Figure 6 – Applied loading method

The gauge factor (λ), which quantifies the sensitivity of the material, was defined by the relationship between the *FCR* and axial strain, as expressed in Equation 4. To mitigate experimental noise, the gauge factor was determined as the slope of the linear regression computed using the data from the final four loading cycles.

$$\lambda = \frac{FCR}{\varepsilon} \tag{4}$$

4. Results and discussion

Electromechanical testing was first performed on the small brick samples equipped with copper tape electrodes. Figure 7(a) illustrates the applied cyclic load alongside the time-domain correlation between the axial strain and the FCR, plotted starting from the 15th second from the initiation of the test. The FCR trend inversely mirrors the strain profile, indicating that an increase in compressive strain induces a reduction in FCR. This behavior is attributed to the reduction in distance between conductive fibers and the consequently enhanced formation of conductive networks within the smart brick matrix. Within this stabilized region, the magnitude of the FCR changes proportionally with the applied strain. At the maximum peak load of 5 kN, the sample reached a maximum strain of approximately 0.00065 mm/mm, corresponding to a maximum *FCR* drop of around -58%. Figure 7(b) displays the direct correlation between FCR and strain during the final four loading cycles at 5 kN. The linear regression yields a λ of 522.61 and a coefficient of determination (R^2) of 0.72.

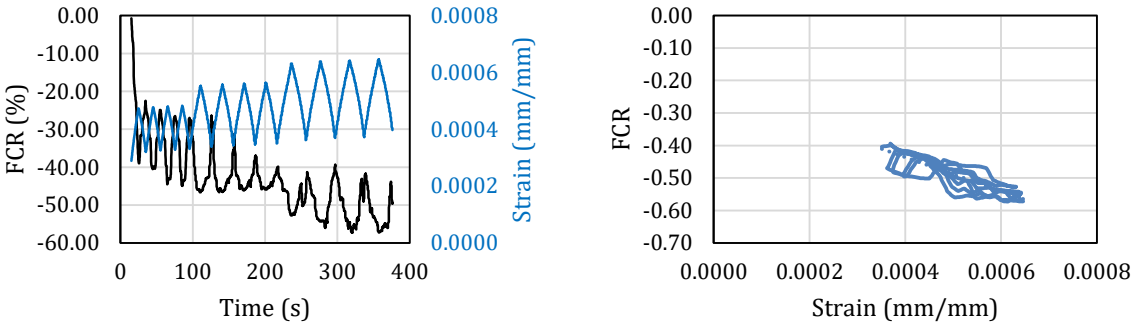

Figure 7 – Electromechanical response of small brick sample dopes with 0.25% with copper tape electrodes: (a) variation of FCR and strain in the time domain; (b) relationship between FCR and strain.

Figure 8(a) presents the time-domain correlation between FCR and axial strain for the small smart brick incorporated with 0.25% steel microfibers and utilizing printed electrodes. As initially expected, the measured strain was slightly higher than that of the reference brick with copper tape electrodes, reflecting an alteration in the overall system stiffness due to the deformability of the new interface configuration. Additionally, a lower FCR magnitude was observed compared to the sample with copper tape, indicating a reduced electrical output. This however came a much better time stability and improved sensing linearity compared to copper tape electrodes. Figure 8(b) displays the FCR and strain relationship during the final four cycles, the linear regression yields a λ of 68.33 and a R^2 of 0.81.

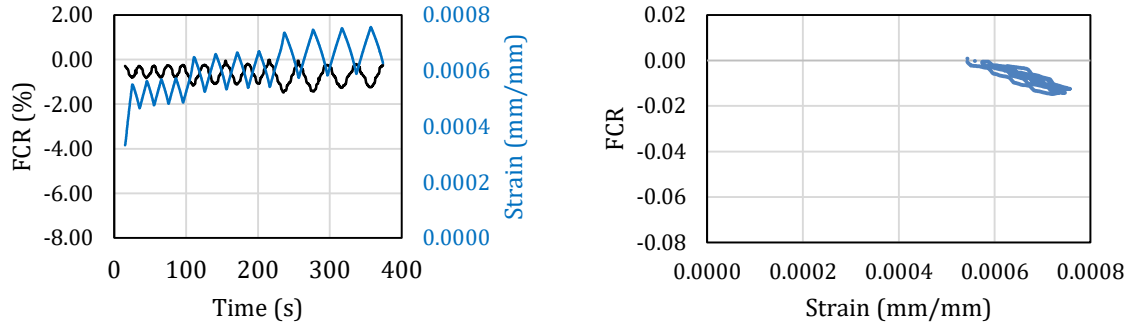

Figure 8 – Electromechanical response of small brick sample doped with 0.25% steel fibers with 3D printed cementitious electrodes: (a) variation of FCR and strain in the time domain; (b) relationship between FCR and strain.

Figure 9(a) presents the time-domain variation of the FCR and axial strain for the standard size brick instrumented with both printed and copper tape electrodes on its surfaces. The electromechanical characterization revealed a maximum peak strain of approximately 0.0004 mm/mm, corresponding to a maximum FCR drop of around -6%. Figure 9(b) illustrates the direct correlation between the FCR and axial

strain during the four final loading stages. The linear regression analysis demonstrates a strong correlation, yielding a gauge factor (λ) of 214.77 and a R^2 of 0.85.

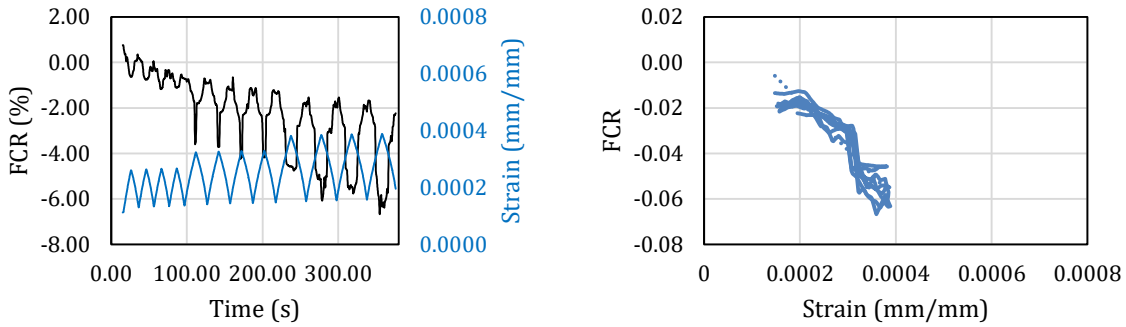

Figure 9 – Electromechanical response of the standard size smart brick sample doped with 0.25% steel fibers and using both 3D printed and copper tape electrodes: (a) variation of FCR and strain in the time domain; (b) relationship between FCR and strain.

The results from the electromechanical tests are summarized in Table 2. For the small smart brick sample, the configuration with copper tape electrodes exhibited a gauge factor 7.6 times higher than the one with printed electrodes, while presenting an 11% lower R^2. On the other hand, the standard size smart brick achieved a gauge factor of 214.77, which is 3.1 times higher than the small brick with printed electrodes but 2.4 times lower than the one with copper tape. Despite this intermediate sensitivity, this larger sample demonstrated the highest linearity among all configurations, with an R^2 of 0.84, representing a 3.7 % increase compared to the small brick utilizing printed electrodes.

Table 2 – Summary of the electromechanical responses for the tested smart bricks (where SSB is small smart brick and StSB represents standard-sized smart brick)

Sample	Type of electrode	λ	R^2
SSB	CT	522.61	0.72
	PE	68.33	0.81
StSB	PE + CT	214.77	0.84

5. Conclusions

This study presented a novel approach for integrating embedded 3D-printed cementitious mortar electrodes into smart bricks. This was achieved by formulating a highly conductive mortar matrix through the incorporation of CCMF. Electromechanical characterizations were performed on small and standard size smart bricks to compare traditional copper tape, the proposed 3D-printed electrodes, and a combination of both.

Electromechanical tests were conducted to evaluate the sensitivity of the smart brick and the performance of the 3D-printed electrodes. For the comparative analysis, the results highlighted a clear trade-off between peak sensitivity and signal reliability. Although the copper tape configuration yielded a higher overall sensitivity, the small-sized smart bricks equipped with 3D-printed electrodes achieved a higher linearity (R^2 = 0.81) and an improved time stability (reduced drift) in comparison to the copper tape. An intermediate gauge factor λ of 214.77 was observed for the standard size sample with copper tape on one face and a printed electrode on the opposite face, while delivering the highest linearity among all tested setups (R^2 =

0.84). Overall, these findings demonstrate that 3D-printed conductive mortar is a viable and structurally cohesive alternative to metallic electrodes, ensuring reliable measurements in smart bricks.

Abstract: This article analyzes the use of aerial surveying as a technical instrument articulated with participatory practices in the process of land regularization and in the affirmation of the right to the city in the Dorothy Stang Occupation, in the Federal District. The research associates aerial photogrammetry procedures conducted in accordance with ABNT NBR 17047:2022 with critical university extension actions, which involved the local community in the processes of reading, validating and interpreting territorial data. The surveying was carried out from fifty-nine control points, registered with the Brazilian Institute of Geography and Statistics (IBGE) and obtained through GNSS RTK, enabling the generation of orthomosaics and digital terrain and surface models with a level of precision compatible with the technical requirements of the formal land regularization processes. The analysis of the results shows that the articulation between technical methods and the knowledge produced by the residents expanded the understanding of the socio-spatial dynamics of the settlement, gave greater visibility to the territorial demands and strengthened the technical bases for dialogue with the public authorities. It is observed that the use of aerial surveying, when associated with inclusive and participatory methodologies, contributes to the reduction of information asymmetries and to the strengthening of collective processes of urban rights claims. It is concluded that this approach expands the reach of aerial surveying beyond its strictly instrumental function, consolidating it as a technical and methodological support for the formulation of urban policies guided by criteria of social justice and territorial recognition.

Keywords**:** Favelas and urban communities; Technical advice; Critical university extension; Solidarity technoscience; Social cartography.

1. Introduction

Urban land regularization in Brazil occurs in a context marked by historical inequalities, territorial disputes, and recurrent processes of invisibility of peripheral populations. In informal territories, such as the Dorothy Stang Occupation, located in the region of Sobradinho in the Federal District, the legal recognition of housing is intertwined with the struggle for dignity, permanence, and active citizenship. Such territories express, in an emblematic way, what Andrade and colleagues call the "struggle against socio-environmental injustice in the search for the right to the city" (Andrade *et al*., 2019, p. 207). In this scenario, aerial surveying emerges not only as a technical tool, but as a strategic instrument for the production of socially oriented

knowledge. The incorporation of drones, GNSS RTK receivers and advanced photogrammetry techniques allows for the expansion of community access to spatial information and the strengthening of processes of solidarity technoscience.

In the case of Dorothy Stang, the aerial photogrammetric surveying followed the guidelines of ABNT NBR 17047:2022, which defines the procedures for cadastral surveys for public registration. The implementation of fifty-nine control points with RTK receivers ensured an average accuracy of eight millimeters, meeting the accuracy parameters established by the standard and enabling their future use in administrative regularization processes.

In addition to the technical dimension, aerial surveying is articulated with participatory practices inspired by critical university extension. Andrade and Loureiro (2020) highlight that the role of the citizen university involves bringing together technical knowledge and popular knowledge, forming socio-technical networks that sustain processes of resistance and emancipation. In the same perspective, Periférico, Sociotechnical Advisory Laboratory has been working in informal occupations and settlements in the Federal District to produce shared diagnoses, strengthen community organizations, and develop mapping methodologies sensitive to the realities experienced by residents (Andrade *et al*., 2022). Thus, this article discusses how the application of aerial surveying, articulated with participatory socio-technical processes and based on technical reference standards, contributes to strengthening the right to the city in the Dorothy Stang Occupation.

2. Historical and territorial contextualization of the Dorothy Stang Occupation

The Dorothy Stang Occupation is located in the administrative region of Sobradinho, in the Federal District, Brazil (Figure 1), in an area marked by strong real estate pressure, land disputes, and discontinuity of housing policies. Its territorial conformation is the result of simultaneous processes of social vulnerability and community resistance, expressing dynamics common to the Brazilian urban peripheries (Caldeira, 2000; Maricato, 2011; Rolnik; Klink, 2011). The occupation was named Dorothy Stang in honor of the missionary murdered in 2005, whose trajectory became a symbol of the struggle for socio-environmental justice, dialoguing with the very history of resistance built by the residents of the settlement.

Figure 1 – Location of the Dorothy Stang Occupation, Sobradinho, Federal District

The territorial expansion of the occupation occurred in 2015 by 544 low-income families initially linked to the National Front of Struggle (Costa, 2017), who sought decent housing conditions amid the absence of effective housing policies in the Federal District. As in other informal settlements in the region, its formation is directly linked to inequalities in access to urban land, real estate speculation and the fragmentation of territorial planning policies (Bringel; Domingues, 2011; Paviani, 2010). The absence of basic infrastructure, adequate public services and legal recognition of the subdivision intensified conflicts with inspection agencies and intensified conditions of socio-spatial precariousness.

In this scenario, the occupation was also consolidated as a space for social mobilization, in which community associations, local collectives and support networks acted in the claim of fundamental rights, including access to housing, land regularization and the implementation of public facilities. This process is in line with analyses of social housing movements in Brazil, which highlight the centrality of popular organization for the achievement of urban rights (Gohn, 2017). The territoriality constructed by the residents articulates material dimensions such as self-construction, opening of roads and conformation of collective spaces and symbolic dimensions, which include bonds of solidarity, narratives of belonging and practices of daily resistance (Caldeira, 2000; Paviani, 2010). Dorothy Stang stands out for the organization in sectors or blocks with local representatives, giving its residents a strong identity that remains to this day in the addresses of the houses.

The inclusion of the occupation in the debate on the Regularization of Social Interest (Reurb-S) in the Federal District reinforces the relevance of socio-technical approaches capable of articulating technical knowledge and community practices. Bearing in mind that the accelerated and disorderly urbanization that has characterized the process of occupation of the territory of the Federal District is synonymous with the environmental degradation of the Cerrado biome, Romero *et al*., (2019), the disputes around the characterization of the area, the limits of the subdivision and the identification of lots and buildings demonstrate the need for high-precision technical instruments, but they also show that regularization processes depend on social legitimacy and the participation of residents. The literature on land policies points out that the security of tenure and the production of well-located housing require joint actions between the State, the community, and civil society (Rolnik; Klink, 2011).

Thus, understanding the origin, context and territorial dynamics of the Dorothy Stang Occupation is fundamental to situate the role of aerial surveying as a sociopolitical instrument in the search for the right to the city. In this territory, the technique does not act in isolation: it interacts with practices of resistance, produces narratives and becomes a strategic element for the recognition and permanence of families in the place they have built.

3. Theoretical foundation

The right to the city, as discussed by Harvey (2003) and Rolnik (2015), transcends physical access to urban territory, translating into the effective ability to participate in decisions that shape the production of space. It is a political, collective and procedural right, permanently stressed, in the Brazilian case, by real estate speculation, by the retraction of the regulatory role of the State and by the advance of neoliberal rationalities that weaken legal instruments aimed at territorial protection and urban justice (Jatobá, 2016). In view of this scenario, critical university extension asserts itself as a transformative practice, capable of repositioning the university as an active agent in the dispute for rights. Andrade and Loureiro (2020) argue that the citizen university should contribute to the political organization of social groups, creating emancipatory conditions for intervention in reality" (Andrade; Loureiro, 2020, p. 293), bringing together scientific production, community action, and decision-making processes.

This perspective converges with the approach of the Law Found on the Street, formulated by Roberto Lyra Filho, according to which the law originates in social practices, in concrete struggles and in the collective action of historically oppressed subjects. In this sense, the right to the city is not only declared; it is built in

the territory, in conflicts and mobilizations that demand recognition and permanence. Similarly, Romero *et al*. (2019) state that pronounced environmental problems require complementary design strategies, in order to minimize certain conflicting features.

The experiences of the Peripheral Laboratory materialize this articulation between technical knowledge and emancipatory praxis. As argued by Andrade *et al*. (2019), working in informal territories requires conflict mediation, strengthening community autonomy, and "reconciling knowledge as the foundation of the territorial transformation process" (p. 192). In the case of the Dorothy Stang Occupation, the authors highlight that socio-technical advice, which began in 2016, played a central role in the preparation of urban proposals later incorporated into Complementary Bill No. 986, of June 30, 2021, which defined the Social Interest Regularization Area, ARIS Dorothy Stang, showing how technical production, when constructed in a participatory way, it directly influences institutional agendas (Figure 2). The advisory also contributed to the community being one of the pilot territories of the public policies of the National Secretariat of Peripheries of the Ministry of Cities with the Periferia Viva Program in 2024 and 2025 and with the Land Regularization Program in 2026 (Figure 3).

Figure 2 – Ceremony of inclusion of Dorothy Stang in the Master Plan of the Federal District

Figure 3 – Periodic participatory technical advisory workshops since 2016

Social and environmental issues are inseparable and are presented as a basic and essential concept for sustainable urban development. The pressure of urban occupation and the increasing impermeabilization of the soil compromise the surroundings, especially the vegetation, lead to the extinction of riparian forests and recharge areas, the contamination of the water table and the reduction of biodiversity in the Cerrado, Romero *et al*. (2019). Pronounced environmental problems require complementary design strategies in order to minimize certain conflicting features.

This theoretical set shows that technologies such as drones, GPS RTK receivers and orthomosaics are not neutral tools. Its emancipatory or excluding potential depends on the political, methodological and community orientation that guides its use. The aerial survey can, therefore, both reproduce inequalities when appropriated in a vertical and technocratic way and subvert them when mobilized in participatory processes that expand territorial visibility, strengthen local autonomy and sustain claims for rights.

4. Methodology of cadastral planialtimetric survey with drone and photogrammetric processing

4.1 Background and objective

The methodology adopted was structured to carry out a planialtimetric cadastral survey in the Dorothy Stang Settlement, located in the Administrative Region of Sobradinho (RA V), Brasília-DF. The main objective was to generate high-resolution cartographic products to support the technical registration of buildings, the road system, infrastructure and land limits in the area. The method integrated aerial survey technologies with remotely piloted aircraft (RPAs), high-precision GNSS tracking and digital photogrammetric processing, ensuring geometric accuracy compatible with urban surveys of a cadastral nature.

4.2 General structure of the methodology

The methodology was organized in three main stages: field survey, geodetic processing of the support points and photogrammetric processing for the generation of cartographic products. These steps were designed in an integrated way, in order to ensure strict geometric control, traceability of the data collected and minimization of operational errors. The articulation between field and office allowed the raw data captured to be converted into structured and technically validated cartographic information.

4.3 Field survey

The field survey began with the implementation of 24 targets strategically distributed throughout the study area, configuring the Ground Control Points (GCPs). These points are fundamental for the geometric control of the photogrammetric model, as they allow linking the three-dimensional model to an official geodetic system, ensuring positional accuracy.

Figure 4 shows the spatial distribution of the control and validation points implemented in the study area. The points were positioned in order to ensure homogeneous coverage of the territory, contemplating the peripheral and central portions of the occupation. This configuration allows to reduce geometric distortions in the photogrammetric process and ensure greater reliability in the generation of the orthomosaic and the digital terrain and surface models.

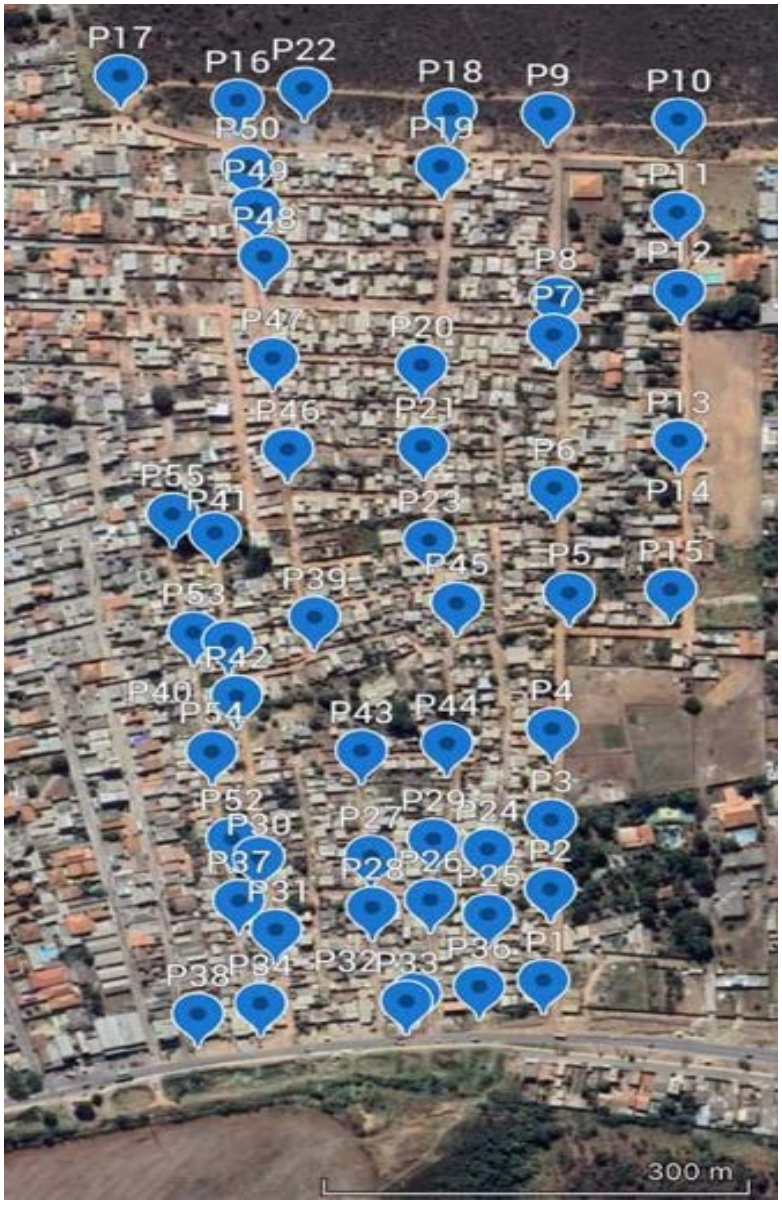

Figure 4 - Spatial distribution of the control and validation points used in the aerial photogrammetric survey in the Dorothy Stang Occupation.

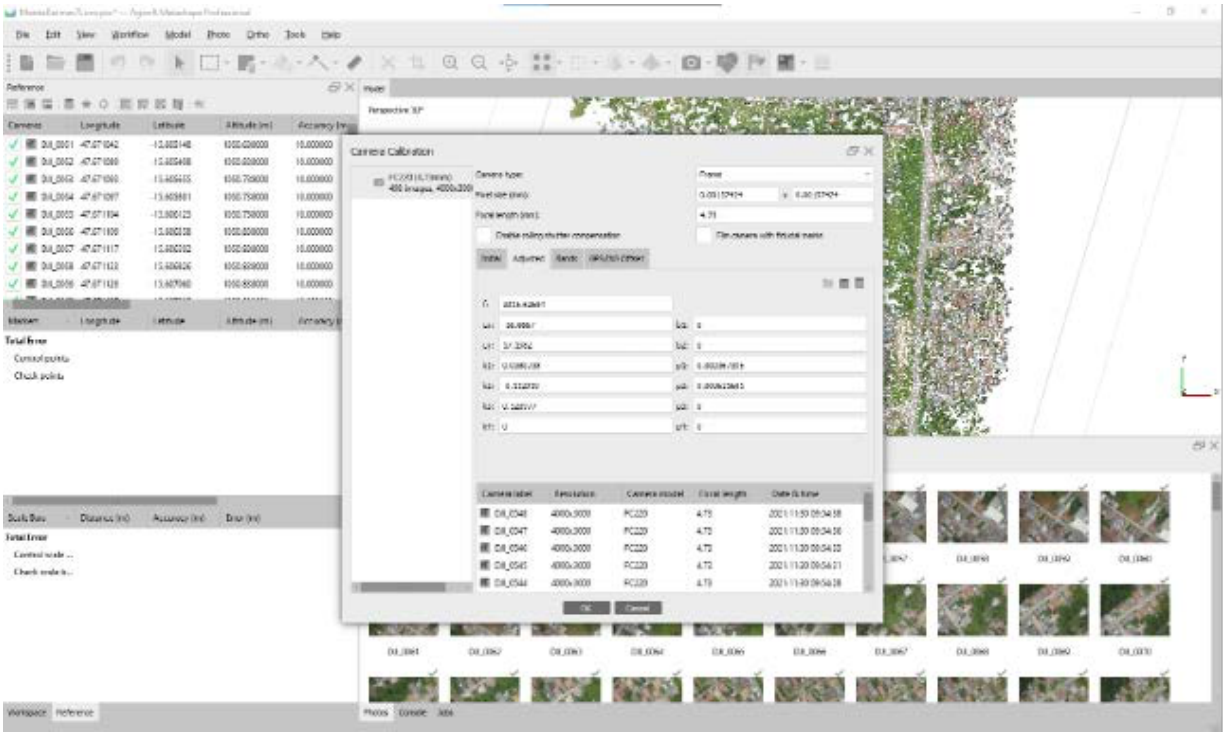
Coordinate tracking was performed with a DJI D-RTK 2 GNSS receiver, compatible with GPS, GLONASS, BeiDou and Galileo systems, with horizontal accuracy of 1 cm + 1 ppm and vertical accuracy of 2 cm + 1 ppm. The observations were later processed by the Precise Point Positioning (PPP) method at the Brazilian Institute of Geography and Statistics (IBGE), using as reference the BRAZ station of the Brazilian Network of Continuous Monitoring (RBMC), in the SIRGAS2000 system (Época 2000.4). This procedure ensured the linkage of the survey to an official and nationally recognized geodetic reference.

The aerial survey was carried out with the DJI Mavic 3 Enterprise Multispectral drone, in a flight carried out on November 13, 2025. The flight planning considered longitudinal and transverse overlap parameters suitable for three-dimensional reconstruction, ensuring that each point of the terrain was recorded in at least six different images. This geometric redundancy is essential for the robustness of the photogrammetric adjustment and for the reliability of the three-dimensional model generated. All data was stored digitally in the equipment, being transferred directly to the computer environment, and thereby eliminating manual transcription steps and reducing potential sources of error.

4.4. Geodetic reference system

The survey was referenced to the Datum SIRGAS2000, adopting geocentric planimetric coordinates and altitudes referred to the Imbituba datum, with a central meridian of 45° WGr., according to the UTM system corresponding to the region. The use of the SIRGAS2000 ensures compatibility with the National Cartographic System and with official cartographic bases, in addition to meeting the technical guidelines applicable to the territory of the Federal District. The link to the RBMC station reinforces the consistency and geodetic traceability of the results obtained.

4.5. Photogrammetric processing



The image processing was performed in the Agisoft Metashape V2.1.2 software, following a structured and sequential workflow. Initially, the photographs were imported with automatic recognition of EXIF metadata, including approximate geographic coordinates. The quality of the images was evaluated, discarding those with an index lower than 0.5, in order to avoid degradation of the final model and optimize the computational performance.

The alignment of the images consisted of determining the position and orientation of the cameras in three-dimensional space. For this, computer vision algorithms were used based on the identification of homologous points (keypoints) and the automatic correspondence between images. The triangulation of these points resulted in the generation of the sparse point cloud, which represents the initial geometric structure of the model. After the preliminary alignment, the internal calibration of the camera was optimized by means of self-calibration, refining the geometric parameters of the adjustment (Figure 4).

Then, the coordinates of the 24 support points processed via PPP were entered. Each point was manually identified in multiple images, ensuring the minimum recommended redundancy of six observations per point. The model was then reprocessed incorporating these controls, significantly increasing the overall geometric accuracy.

From the refined positions of the cameras, the dense point cloud was generated through stereoscopic matching algorithms. Filtering procedures were applied to remove noise and outliers, especially relevant in land surveys. Based on the dense cloud, the Digital Elevation Model (DEM), the Digital Terrain Model (DTM), the three-dimensional grid and the georeferenced orthomosaic were derived. The texture construction was carried out in orthophoto mode, suitable for topographic applications, using mosaic-type blending to maximize sharpness.

Figure 5 – Self-calibration used in Agisoft software

4.6. Precision results

The processing resulted in a Ground Sample Distance (GSD) of 3.48 cm, a reprojection error of 1.25 pixels, and an estimated planimetric error of around 4.35 cm. The photographic coverage demonstrated that all points of the raised polygonal were imaged by at least six photographs, ensuring adequate redundancy for robust three-dimensional reconstruction. The values obtained are compatible with the technical requirements of urban planialtimetric surveys of cadastral character.

4.7. Preparation of the planialtimetric survey

Based on the photogrammetric products generated, the vectorization of the elements of interest in the CAD environment (AutoCAD) was carried out, contemplating buildings, curbs, blocks, walls, fences, lot boundaries and other elements of urban infrastructure. The final survey was organized on boards in A0 format, following the SICAD articulation and the technical guidelines of the competent Secretariat. The set of products generated allowed the consolidation of a detailed and georeferenced cartographic base, able to subsidize land regularization and urban planning actions.

4.8. Methodological considerations

The methodology adopted demonstrated high efficiency by integrating official geodetic control, high-resolution aerial survey and structured photogrammetric processing. The use of support points tracked with high precision, associated with automated digital processing and linking to the SIRGAS2000 system, ensured geometric reliability, technical standardization and data traceability. The method proved to be suitable for applications in land regularization, multipurpose technical cadastre and territorial planning, reconciling precision, operational productivity and scientific consistency.

5. Preliminary results and discussion

The preliminary results demonstrate that the aerial survey contributed decisively to increase the territorial visibility of the community, producing an accurate and socially legitimized spatial representation. As Andrade et al. (2022) point out, the graphic materialization of the territory operates as a device for political affirmation, as it provides residents with concrete instruments to claim presence, institutional recognition, and participation in decision-making processes. In the case of the Dorothy Stang Occupation, the orthomosaic and the derived models worked as mediators capable of revealing the complexity of the settlement before public agencies and external actors.

It is also important to highlight the role of aerial survey tools, especially drone flights, in providing a significant amount of spatial data to support the land regularization process in Dorothy Stang and its related urban planning project. The data produced through the methodology presented in this study serve as the basis for developing urban planning scenarios focused on improving infrastructure in streets and public open spaces, while also supporting in situ surveys of existing housing conditions.In this context, documenting the actual conditions of the area is a fundamental legal step in the land regularization process, as it organizes and consolidates information for each lot and dwelling through identification codes and detailed spatial representation. Moreover, drone flights carried out according to the standards described here provide a reliable and legally compliant database, helping to ensure that the following stages of the regularization process can be conducted more efficiently and securely.

The collective reading of the images allowed the residents to identify elements that would not be captured by isolated technical interpretation, such as informal passages, living areas, conflict zones and symbolic limits that structure the daily life of the occupation. This intersection between the technical knowledge generated by the aerial survey and the territorial knowledge produced by the community experience confirms the dialectic between technical knowledge and social practices described by Andrade et al. (2019). Such articulation proved to be essential to build urban analyses that are more sensitive to the real dynamics of the territory and, therefore, more aligned with emancipatory perspectives.

In addition, the high precision obtained in the survey resulting from the implementation of control points and the application of the parameters defined by ABNT NBR 17047, gives technical robustness to the products generated, making them suitable to support formal stages of land regularization. The reliability of the material reinforces its credibility before public agencies, expanding the potential for using the data both in administrative processes and in political negotiations that involve the recognition and permanence of the community.

6. Final considerations

The experience developed in the Dorothy Stang Occupation shows that the aerial surveying, when articulated with critical university extension practices, is configured as a strategic instrument for the realization of the right to the city. Compliance with the technical parameters defined by NBR 17047 ensures precision and reliability to the products generated, while the active participation of the community confers political legitimacy and expands the transformative reach of the process. This convergence between technical rigor and the collective construction of knowledge is fundamental to face historical inequalities that mark informal territories.

The team of authors of this article, linked to the Peripheral Laboratory of the University of Brasilia, understands the university as a strategic agent in the construction of democratic alternatives for the production of space, acting as a mediator between specialized technical knowledge, social practices and the formulation of public policies. The experience developed in the Dorothy Stang territory evidences this understanding by demonstrating that the use of geospatial technologies, when guided by sensitive,

inclusive and socially committed methodologies, goes beyond the merely instrumental character and consolidates itself as a tool for community strengthening. In this context, the cartography produced ceases to be just a physical record of the territory and begins to assume the role of support for social claims, the construction of collective memory and the practices of territorial resistance.In reality, It contributes to making public policy actions, such as land regularization processes, more democratic by broadening access to technology and ensuring the generation of physical data. As a result for this, experience confirms that the map, far from representing a neutral reality, becomes a political element capable of influencing metropolitan expansion, sustaining struggles for recognition and contributing to the consolidation of fairer territories. In Dorothy Stang, the combination of aerial surveys and active community involvement highlights both the importance and the potential of integrating science, technology, and public participation in the construction of more inclusive and democratically developed cities.

7. Limitations and Future Prospects

Although the results obtained show the relevance of aerial survey associated with participatory socio-technical practices, it is important to recognize some limitations inherent to the process. First, the execution of the survey depends on adequate climatic conditions and specific logistics, which may restrict the frequency of cartographic updates in territories subject to rapid transformations. In addition, the accuracy of the data, although high, does not eliminate the need for continuous validation in the field, especially in areas where the dynamics of occupancy are accelerated and marked by daily changes. It is also worth noting the data processing time, which can take weeks, depending on the power of the computer used.

Another challenge is the sustainability of participatory processes over time. The shared production of territorial knowledge requires continuous involvement of residents, institutional availability of the university and political support for the actions to continue. The absence of permanent public policies that recognize and incorporate socio-technical methodologies hinders the institutionalization of the results and, in certain cases, limits their impact on the administrative processes of land regularization.

Despite these limitations, the study opens up important avenues for future research. The replication of the methodology in other informal territories of the Federal District can contribute to the construction of a collection of social practices and technologies applied to land regularization. From a technical point of view, the advancement of embedded sensors, processing algorithms, and artificial intelligence techniques offers the potential to improve the accuracy of models and automate territorial classification steps. In turn, the expansion of community participation, through continuous training processes, can strengthen local autonomy in the management of spatial data and expand the political impact of social cartography.

Thus, the limitations pointed out here should be understood as opportunities for methodological deepening and expansion of the social and institutional reach of the research, reinforcing the role of the aerial surveying as a strategic instrument in the promotion of the right to the city.

8. Acknowledgments

This work has the support of the National Secretariat of Peripheries, of the Ministry of Cities, in partnership with Fiotec – Fiocruz Support Foundation, FUNAPE – Research Support Foundation and the University of Brasília (UnB), through a public notice of the Deanery of Research and Innovation (DPI).

Abstract:

The accelerated growth of informal urban settlements in environmentally fragile areas has intensified the occurrence of erosive processes and mass movements, increasing the demand for monitoring methodologies capable of providing rapid, accurate, and technically reliable information for risk management. This article presents the results of the monitoring of a gully located in Block 3 of Sol Nascente, Federal District, Brazil. The goal was carried out within the scope of a geotechnological surveillance project aimed at proposing a methodology for the classification and monitoring of geological risk areas. The adopted methodology was based on the use of an Unmanned Aerial Vehicle (UAV), integrated with aerial photogrammetry corrected by Real-Time Kinematic (RTK), enabling the generation of orthomosaics, digital elevation models, topographic profiles, and three-dimensional visualizations from successive flight campaigns conducted throughout 2024. The comparative analysis of the surveys allowed the identification of distinct phases of the erosive process, including periods of reduction in the degraded area associated with landfilling interventions, as well as phases of erosion reactivation related to increased rainfall rates, resulting in the measured expansion of the gully area. The results demonstrated the robustness of the proposed methodology for the temporal monitoring of geological risk areas, contributing to decision-making by civil defense agencies and to the planning of preventive and corrective actions in vulnerable urban contexts.

Keywords: Risk Areas; Gully Erosion; UAV; Aerial Photogrammetry; Geotechnical Monitoring.

1. Introduction

Risk management is a process conducted by multidisciplinary teams with the objective of identifying, analyzing, evaluating, prioritizing, treating, and monitoring risks that may affect the objectives, processes, and outcomes of a project.

According to ISO 31000 (ABNT, 2009), risk is defined as the effect of uncertainty on objectives, that is, possible events that may or may not occur and that, if materialized, may hinder or delay the achievement of the intended results. This topic is directly related to the Desafio DF Program, launched in 2023 by FAP-DF, whose objective is to map environmental risk areas in the Federal District.

Peripheral urban areas of the Federal District present recurrent processes of environmental degradation associated with disordered land occupation, suppression of vegetation cover, and the absence of adequate surface drainage systems. In this context, the occurrence of gullies constitutes one of the main geological

risk factors, with direct impacts on public safety, urban infrastructure, and adjacent environmental systems. These processes tend to intensify in areas characterized by erosion-susceptible soils, rugged topography, and high levels of soil impermeabilization. According to Osterkamp (2008), a gully is defined as a cavity or channel excavated in the soil or in unconsolidated material, generally on slopes, by the action of running water, through which water predominantly flows after rainfall or snowmelt events.

In the Federal District, this investigation becomes particularly relevant, since in 2009 a total of 1,094 ravines and gullies were mapped, occupying a total area of 64.88 hectares, corresponding to approximately 0.01% of the study area (see Figure 1). In addition, processes associated with regional population growth and ongoing climate change have contributed to the intensification and expansion of these erosive features (Oliveira et al., 2009).

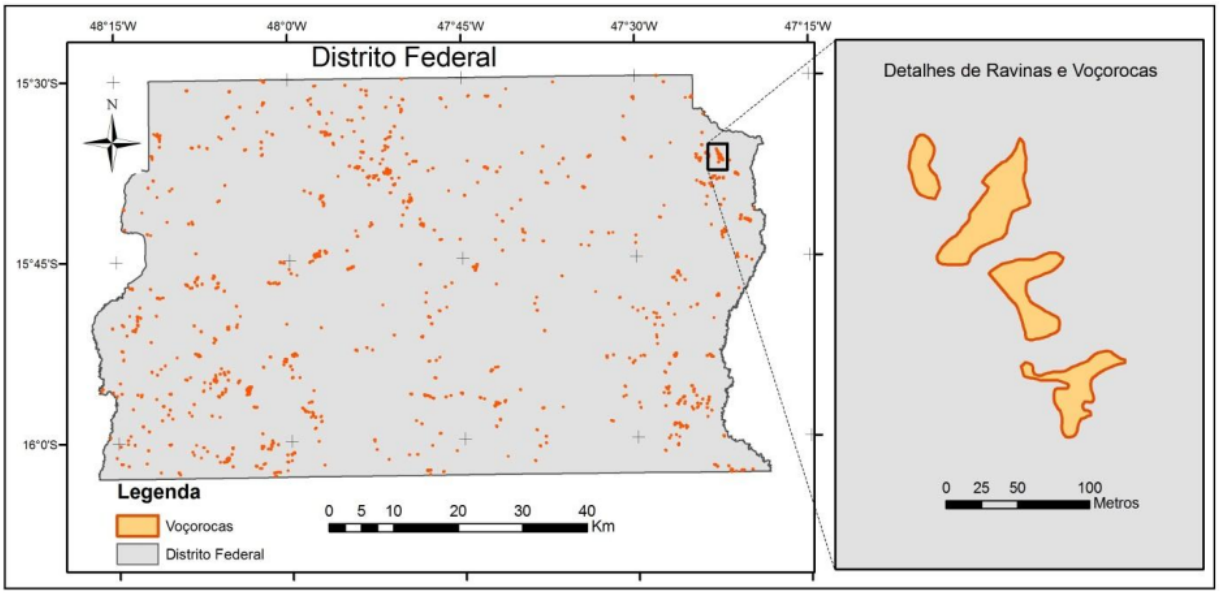

Figure 1: Spatial distribution of ravines and gullies in the Federal District (Oliveira et al., 2009).

Although UAV-based photogrammetry offers numerous advantages, its application in complex terrains also presents challenges. The geometric complexity of areas with steep ravines, dense forests, rocky hills, and intricate urban environments generates a high level of occlusions, variations in lighting and shadows, as well as difficulties in ensuring sufficient image overlap and consistent scale across the surveyed area (Liao, 2025).

As a case study, Chácaras 36 and 74, located in the Administrative Region RA XXXII – Sol Nascente e Pôr do Sol, were selected. These areas were chosen due to their high degree of vulnerability to phenomena such as surface runoff and erosion, as well as their proximity to gullies (SGB, 2022). Furthermore, they present distinct socio-environmental characteristics that require specific mitigation and monitoring approaches (Oliveira et al., 2025). Sol Nascente is part of this context as a territory marked by rapid urban expansion and high socio-environmental vulnerability. The erosive dynamics observed in different sectors of the area highlight the need for continuous monitoring strategies capable of early identification of terrain instability processes and of supporting risk mitigation actions.

Given this context, the present research aims to present and discuss the results of the geotechnological monitoring of a gully located in Block 3 of Sol Nascente, based on successive surveys carried out using UAVs, emphasizing the methodology employed, the products generated, and the comparative analysis of the morphological evolution of the terrain over time.

2. Study Area

The study area corresponds to Block 3 of Sol Nascente, in the Federal District, where a gully has developed associated with the concentration of surface runoff, the exposure of erosion-susceptible soils, and the immediate proximity to densely occupied areas. The erosive process advances toward residential buildings and areas of remaining vegetation, configuring a significant geological risk situation, with potential impacts on the safety of housing and the local population, as presented in Figure 2.

The gully exhibits an irregular geometry, with steep slopes and progressive deepening of the erosive channel, evidencing the combined action of water erosion processes and mass movements. The area is influenced by intense rainfall events, which contribute to the acceleration of erosive dynamics, especially during the rainy season.

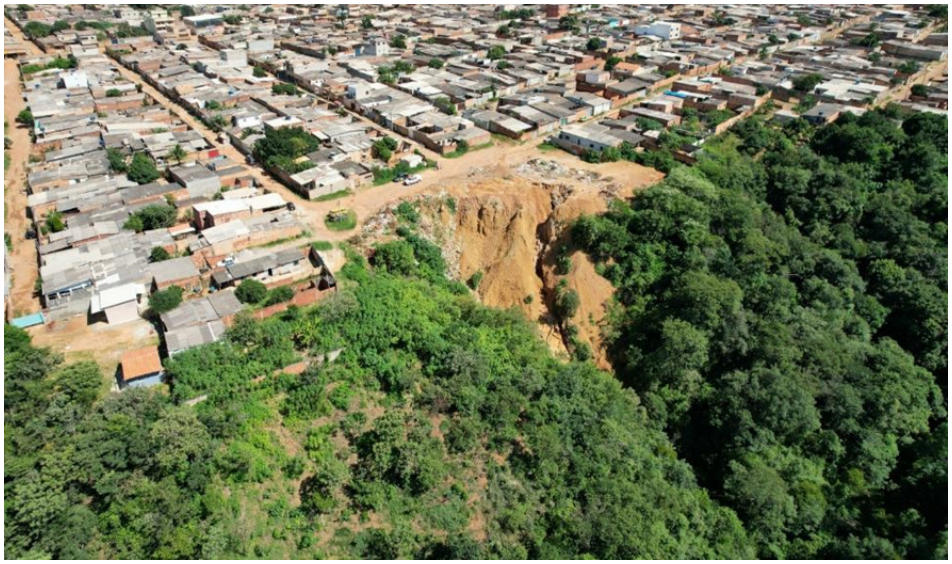

Figure 1: Aerial view from Google

3. Methodology

Once formed, gullies may progressively increase in scale over time. This expansion intensifies hydrological and sediment connectivity, resulting in increased sediment transport and the silting of rivers and reservoirs (Castillo & Gómez, 2016; Poesen, 2018). Due to these changes, continuous monitoring of gullies is necessary to assess the progression of their dimensions and the implications for nearby populations.

The monitoring of the area was carried out through aerial photogrammetry using an Unmanned Aerial Vehicle (UAV), a technique that enables the systematic acquisition of aerial images with high spatial resolution, allowing detailed analyses of terrain morphology and the temporal evolution of erosive processes. The adopted methodological strategy was based on successive flight campaigns, ensuring data comparability over time. Scientific studies, such as the one conducted by Hugenholtz et al. (2013), have demonstrated the effectiveness of using drones in the detection and analysis of gullies.

Throughout 2024, eight flight campaigns were conducted between the months of January and December. For the purposes of analysis in this article, priority was given to the data obtained from the flights carried out in March, August, November, and December, representing different phases of the erosive process observed during the monitoring period. The dates of each field visit are presented in the table below.

Dates of the visits:

1° Field Visits:	31/01/2024
2°Field Visits:	02/29/2024
3°Field Visits:	25/03/2024
4° Field Visits:	25/05/2024
5° Field Visits:	20/07/2024
6° Field Visits:	31/08/2024
7°Field Visits:	09/11/2024
8° Field Visits:	19/12/2024

Table 01: Dates of the visits

Figure 2: High-precision DJI D-RTK 2 GNSS mobile station (compatible with Inspire 3 / Phantom 4 RTK / Matrice 300 RTK and 350 RTK) BR – DJI310

Figure 3: Drone DJI Mavic 3 Thermal

The accuracy of the surveys was significantly improved through the use of a real-time mobile positioning station and an onboard RTK module integrated into the UAV, ensuring higher precision in image georeferencing and in the generation of derived cartographic products (Ekaso et al., 2020). This approach reduced metric uncertainties and provided greater reliability in the analysis of the detected morphological variations.

From the collected aerial images, georeferenced orthomosaics, digital elevation models, contour lines (Figure 06), longitudinal and transverse topographic profiles (Figure 05), as well as three-dimensional models of the monitored area (Figure 07) were generated. For the detailed analysis of the gully, four reference cross-sections were defined and distributed to represent different sectors of the erosive process.

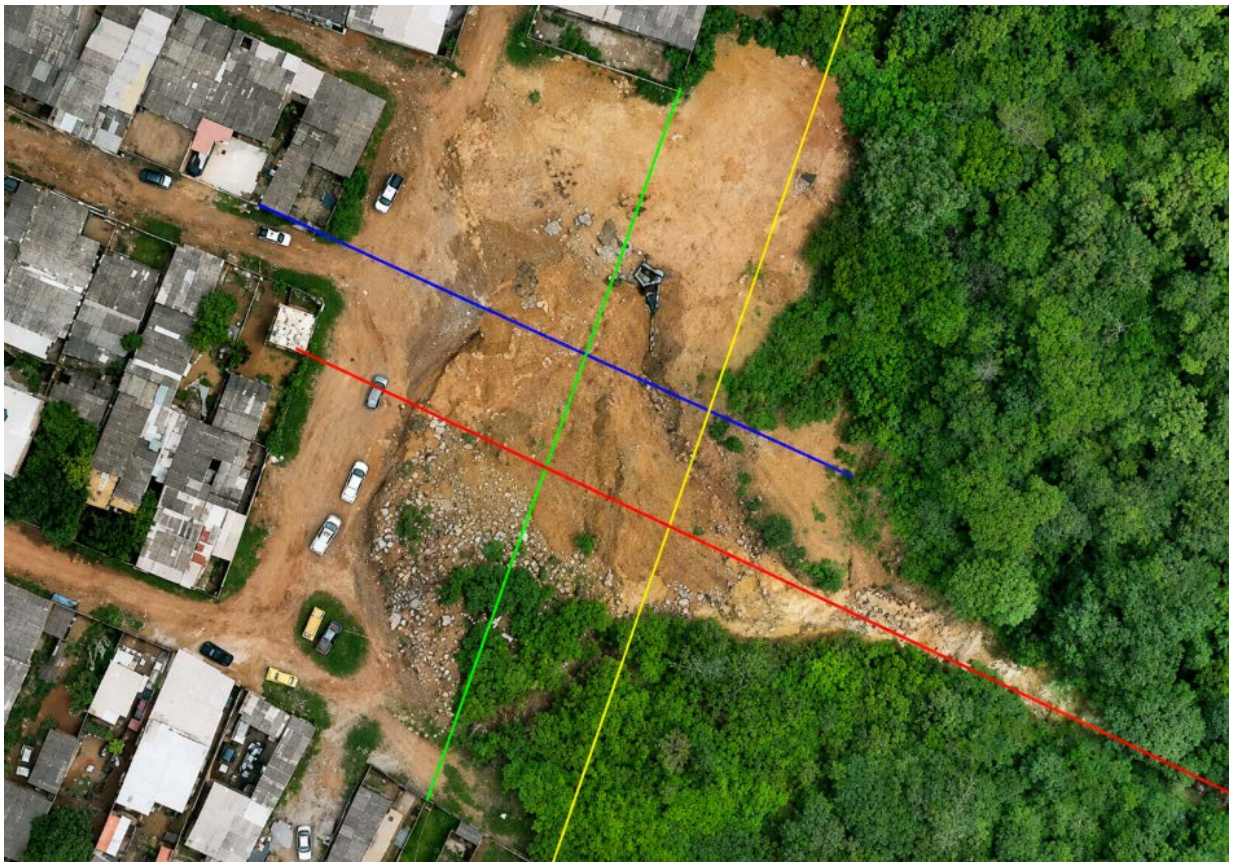

Figure 4: Longitudinal profiles for erosive movement analysis

The results obtained from these cross-sections were organized and graphically represented in Excel spreadsheets, allowing for a comparative visualization of the variations observed between different flight periods. Based on these graphs, it was possible to analyze earth movement over time, identifying changes associated with both erosion and sediment deposition processes.

As a complement to this initial analysis, contour lines with a one-meter interval were also generated for each flight campaign, enabling a more detailed interpretation of the topography of the studied area. In the resulting map, different shades of gray represent the altimetric variation of the terrain, where darker tones indicate greater gully depth. This representation facilitates the understanding of the relief morphology and contributes to the identification of areas with a higher concentration of erosive processes throughout the analyzed period.

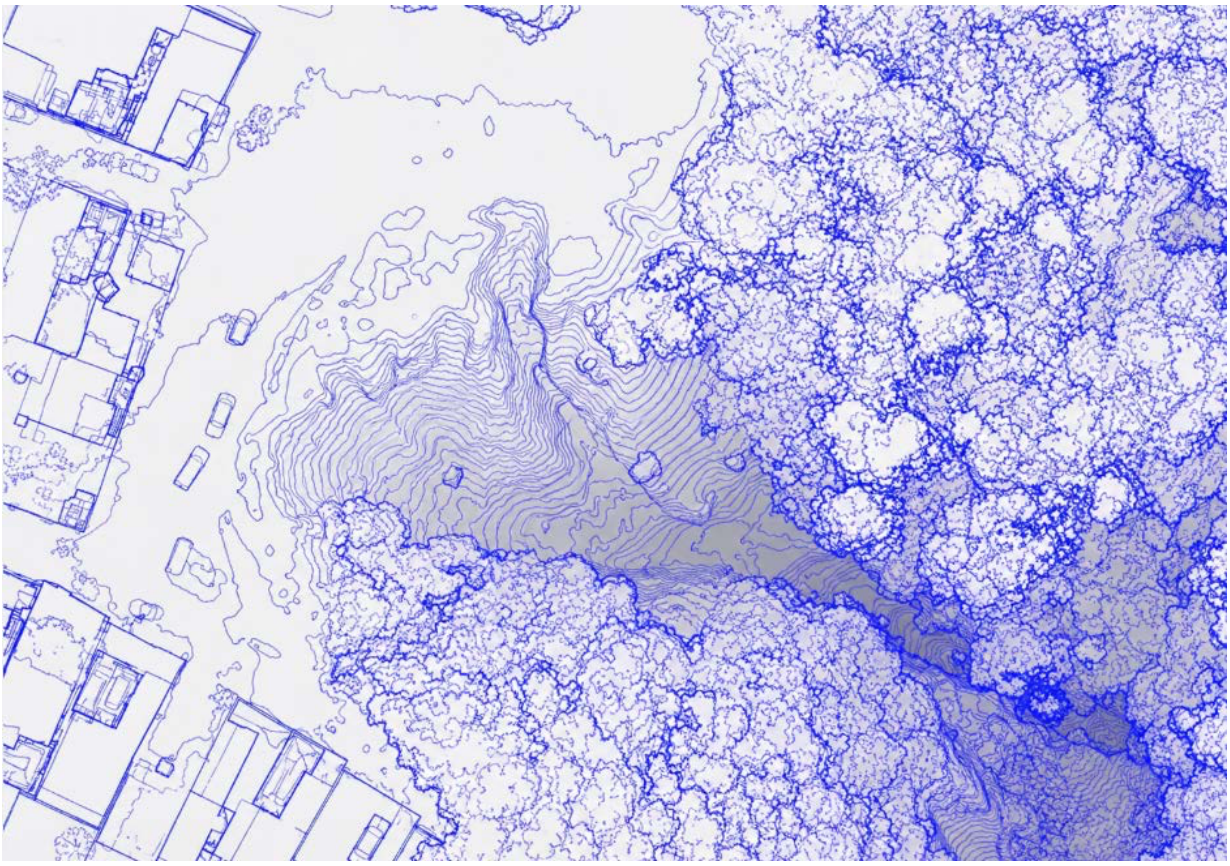

Figure 5: Digital contour model from the survey campaign

The three-dimensional representation images were produced from rectangular cross-sections defined over the terrain, in which the altimetric values extracted from the orthomosaic generated in each flight campaign were applied. This procedure enabled the digital reconstruction of the terrain surface and provided a clearer visualization of height variations and the morphology of the gully throughout the monitoring period.

The comparison between the different 3D models made it possible to identify changes in the terrain, highlighting both deepening processes associated with erosion and modifications resulting from anthropogenic interventions, such as the earth filling carried out in the area. A clear difference can be observed between the first and the fifth field visits, particularly after the execution of the filling process, which resulted in significant modifications to the site's topographic configuration.

These three-dimensional representations contribute to a more intuitive understanding of the gully's evolution, allowing the spatial visualization of the areas with the greatest terrain changes, as illustrated in Figures 07 and 08.

Figure 6 and 8: 3D visualization of the survey campaign

4. Results

The products generated from the flight campaigns clearly demonstrate the spatial and temporal evolution of the gully in Quadra 3 of Sol Nascente. The orthorectified aerial images and digital elevation models made it possible to identify significant changes in the terrain morphology, both in terms of the affected area and the depth of the erosive process.

The comparison between the surveys conducted in March and August indicates a reduction in the eroded area observed in plan view. This decrease is associated with an increase in the volume of material deposited within the gully, characterizing a filling phase. The corresponding topographic profiles reveal the partial infilling of the erosive channel and the temporary smoothing of the slopes, reflecting anthropogenic interference in the natural dynamics of the process.

Figure 9 and 10: Comparative erosion analysis between March (right) and August (left)

In contrast, the comparative analysis between the surveys conducted in August and November reveals the reactivation of the erosive process. During this period, an expansion of the gully area of approximately 461.6 m² was observed, mainly associated with increased precipitation. The topographic profiles indicate a deepening of the channel and a retreat of the slopes, confirming the reactivation of mass movement processes and terrain instability.

Figure 11 and 12: Comparative erosion analysis between August (right) and November (left)

The analysis of the reference cross-sections demonstrates that the morphological variations do not occur uniformly along the gully. Instead, it is possible to identify sectors that are more susceptible to erosion and slope collapse. This heterogeneity highlights the complexity of the erosive dynamics and reinforces the need for detailed monitoring methods capable of capturing the local specificities of the process and understanding the different responses of the terrain to anthropogenic actions and natural conditions.

In this context, the comparative analysis was conducted through the overlay of the gully boundaries obtained from different flight campaigns (Figure 8), combined with the evaluation of variations in planimetric area and the comparison of topographic profiles along the previously defined sections. This integrated approach enabled the identification of changes in slope geometry, as well as the deepening of the erosive channel and the lateral expansion of the degraded area, allowing for a more accurate interpretation of the spatial evolution of the erosive process over time.

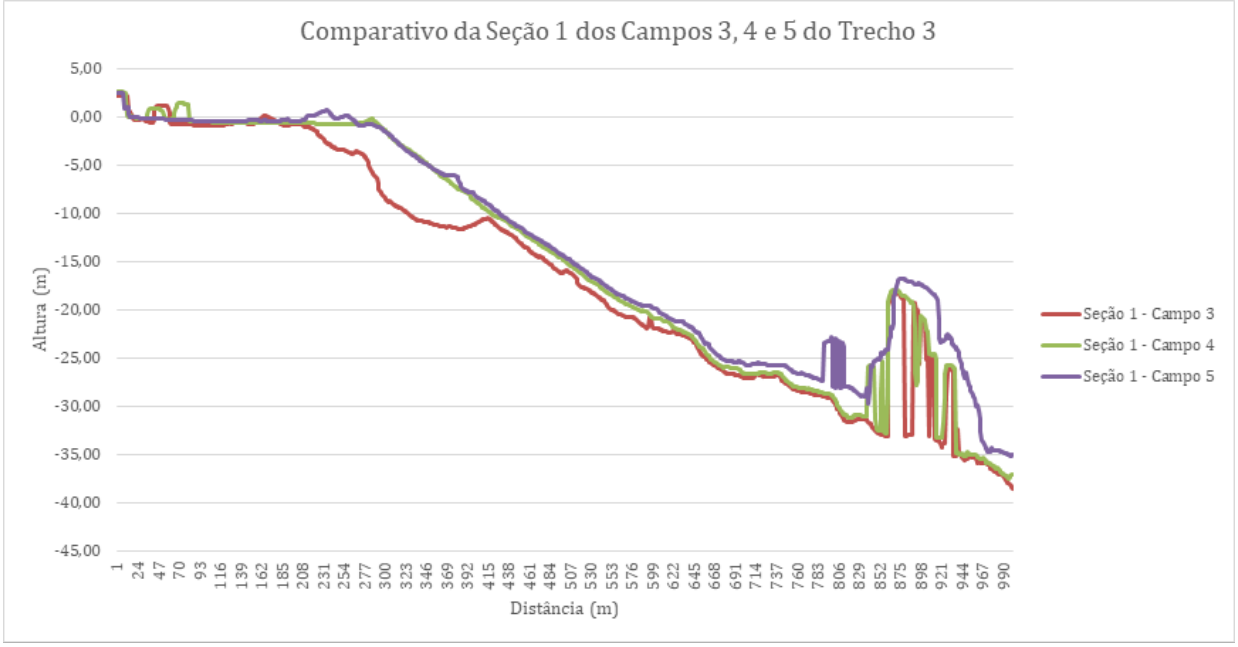

Figure 13: Comparative table of cross-sections from surveys 3, 4, and 5

Another comparative method adopted was the development of maps based on the drone flights, focusing on two main analyses. The first consisted of estimating the expansion of the gully in square meters, visually represented through the overlay of the contours obtained in flights 7 and 8 with those from flights 3 and 6, highlighting the changes that occurred after the onset of the rainy season and following the earth-filling process.

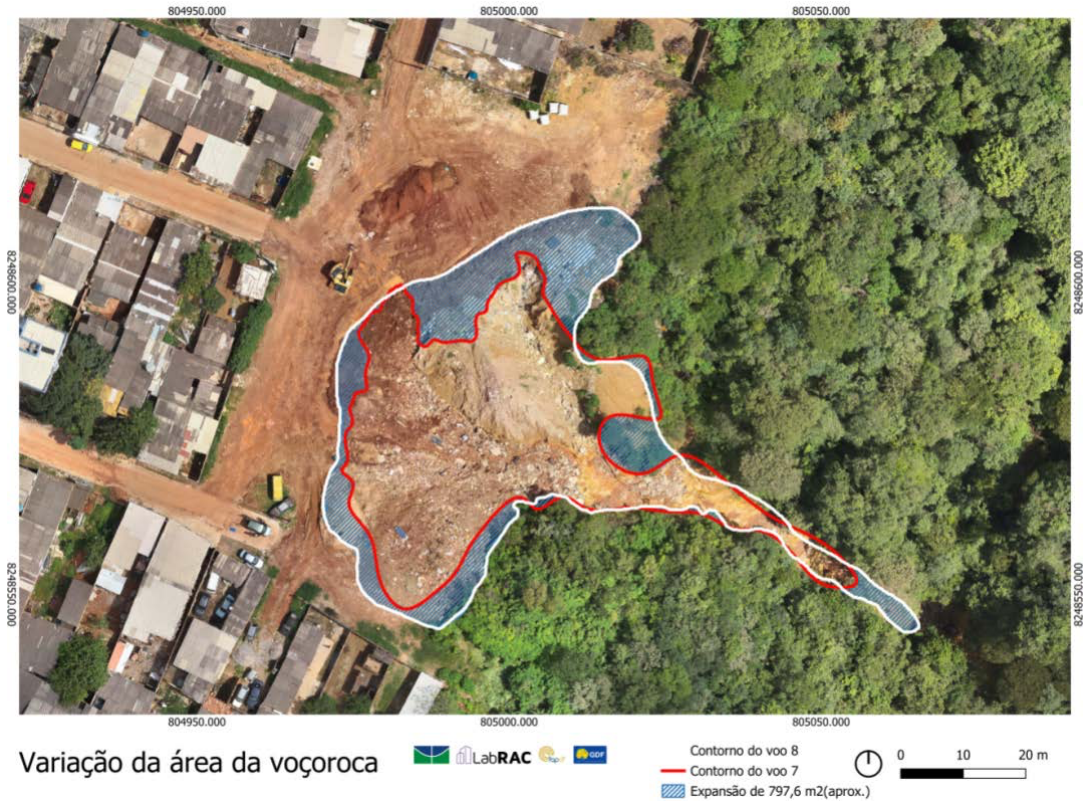

Figure 14: Area variation map from flights 7 and 8

In these comparative maps, the contour corresponding to the most recent flight is shown in red, while the contour from the previous flight is indicated in white, allowing a clearer visualization of the areas where modifications in the gully morphology occurred. The areas highlighted in red represent mass gain resulting from the earth-filling process carried out in the area, whereas the regions shown in blue indicate material loss caused by rainfall and surface runoff. The overlay of these boundaries makes it possible to identify the most dynamic sections of the erosive process, highlighting zones where edge retreat or material deposition occurred. The spatial analysis of these data allowed for the estimation of an approximate variation of 797.6 m^2 in the gully area, demonstrating the significant morphological change that occurred during the analyzed period. Therefore, the comparative maps contribute to understanding the evolution of the erosive process and to identifying the areas most susceptible to continued soil degradation, as illustrated in Figures 09 and 10.

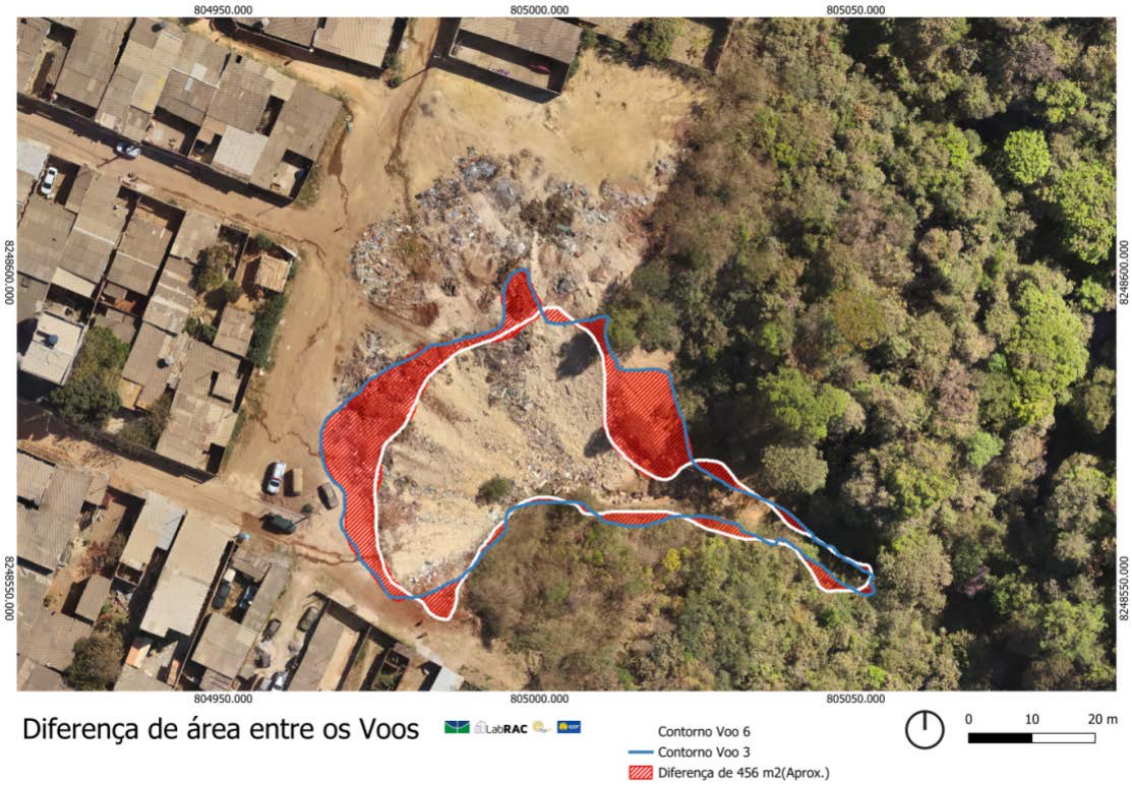

Figure 15: Area variation map from flights 3 and 6

The second analysis refers to the distance between the crater and the surrounding residences, considering the gully boundary and the terrain contour lines, which makes it possible to assess the risk of advancement toward occupied areas, as presented in Figures 11 and 12. For this analysis, measurement axes were drawn perpendicular to the gully boundary toward the nearest buildings, allowing the identification of the shortest distances between the edge of the erosion feature and the residences.

Figure 16: Analysis map – flight 1

The measurements indicate that the proximity of the gully in certain sections represents a potential risk to nearby residences, especially in areas where the topography favors surface water runoff toward the crater. The contour lines included in the map contribute to understanding the relief dynamics by indicating preferential drainage directions and the points most susceptible to the continuation of erosive processes. Thus, the intersection between the gully boundary, the measured distances, and the local topography enables a more accurate assessment of the areas that may be impacted in the event of further advancement of the erosive process.

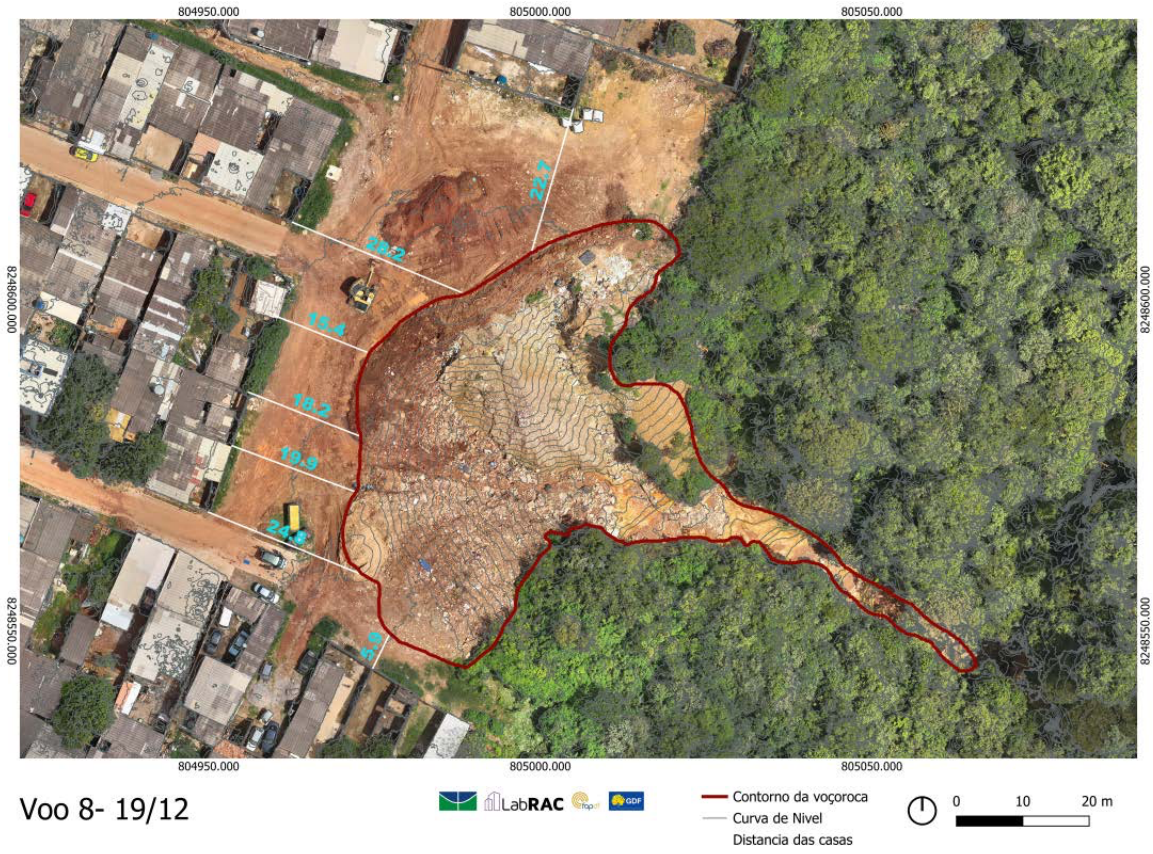

Figure 77: Analysis map – flight 8

The comparison between the first aerial survey (Figure 13) and the most recent monitoring (Figure 14) highlights significant changes in the morphology of the gully throughout the analyzed period. In the first record, a deeper and more continuous configuration of the erosive channel can be observed, with a greater concentration of contour lines within the feature, indicating areas of steeper slopes and deeper terrain incision. In the most recent survey, however, it is possible to identify topographic changes mainly associated with interventions carried out in the area, such as the earth-filling process and the redistribution of material. These modifications resulted in a partial reconfiguration of the internal relief of the gully, reducing its depth in certain sections and altering the surface runoff dynamics.

Furthermore, the comparison between the measured distances from the gully boundary to nearby residences shows minor variations throughout the monitoring period, indicating that although internal modifications occurred within the erosive feature, the lateral advance toward urbanized areas remained relatively limited during the analyzed interval. Therefore, the integrated analysis of the orthomosaics, contour lines, and distance measurements enabled a broader understanding of the spatial evolution of the gully, highlighting both the effects of natural erosive processes and the anthropogenic interventions carried out in the area. This approach contributes to risk assessment and supports the continuous monitoring of the studied site.

5. Discussion

The results obtained highlight the highly dynamic nature of erosive processes in vulnerable urban areas, where localized interventions may produce temporary stabilization effects but do not necessarily interrupt the progression of the phenomenon. The erosive reactivation observed after the filling phase demonstrates the strong influence of climatic conditions—particularly precipitation—on the stability of slopes and the erosive channel.

The use of UAVs combined with RTK correction proved to be fundamental for the accurate detection of these variations, enabling consistent comparative analyses between successive monitoring campaigns. The high spatial resolution of the generated products allowed the identification of subtle morphological changes that would be difficult to detect through traditional field survey methods.

The adopted methodology presents strong potential for application in geotechnological monitoring programs, supporting civil defense agencies, urban planning, and the development of risk mitigation strategies. In contexts of informal settlements and areas with limited accessibility, the use of UAVs represents an efficient, safe, and low-impact alternative for the continuous monitoring of risk-prone areas.

6. Conclusions

The present study aimed to map and monitor geological risk areas in the Federal District. Through the developed methodology, it was possible to identify and characterize risk areas using geological monitoring techniques. The results obtained so far highlight the complexity of the geological and hydrological challenges faced in the region, emphasizing the presence of significant gullies, susceptibility to water erosion, and the direct impact on the safety and well-being of local communities. In the studied areas, anthropogenic factors that aggravate the risks were also identified, such as inadequate waste disposal and the lack of proper drainage infrastructure.

This project contributes to scientific advancement in the field of geotechnological monitoring by providing a replicable methodology for the effective mapping of geological risk areas. Furthermore, the results reinforce the need for integrated public policies that address both the immediate mitigation of identified risks and the prevention of future environmental disasters in the Federal District.

The findings of this study present significant practical implications for the Civil Defense of the Federal District, urban managers, and the scientific community, providing a solid basis for the development of risk mitigation strategies and sustainable urban planning. The applied methodology and the generated data contribute to the development of a geological risk management model adaptable to different urban contexts, promoting community resilience to natural hazards.

The monitoring of the gully located in Quadra 3 of Sol Nascente demonstrated the effectiveness of UAV-based aerial photogrammetry associated with real-time positioning technology as a geotechnological monitoring tool for geological risk areas. The applied methodology enabled the precise identification of different phases of the erosive process, the quantification of area variations, and the understanding of the morphological evolution of the terrain over time.

The results reinforce the importance of continuous monitoring as a tool to support risk management, highlighting the need to integrate this information into public policies aimed at prevention, erosion control, and land-use planning in vulnerable urban areas. The approach presented is replicable in other similar contexts, contributing to the improvement of geological risk management practices in urban environments.

Abstract: The mitigation of impacts due to natural hazards (such as floods and earthquakes) on Urban Built Environments (UBEs) should take into account disaster risk assessment tasks as the fundamental steps to build on reliable, comprehensive and effective emergency scenarios. Assessment should hence integrate hazard conditions and urban-use dynamics, as these together determine the spatio-temporal variability of user exposure and vulnerability. To address these interactions, a multiscale approach is essential, enabling the representation of complex relationships among UBE subsystems and supporting the construction of alternative risk scenarios. In this perspective, building-scale information is aggregated at the level of urban public open spaces (e.g., streets and squares), which act as key elements in everyday activities and as critical assets during emergencies. This study proposes a novel framework using dynamic single-risk assessment in UBEs to provide insights into possible mitigation and emergency planning strategies. It integrates the main components influencing risk (hazard, physical vulnerability, user exposure, and user vulnerability), and is applied to floods and earthquakes as relevant disasters in UBEs. Leveraging the microscale level, data are then aggregated into open-space-level risk indices, allowing the identification of scenario-sensitive hotspots under different spatio-temporal user configurations. The application to the historical UBE of Senigallia (Italy) highlights how variations in urban use significantly influence risk distribution and severity, confirming the relevance of integrating behavioural dynamics within urban-scale assessments. The results provide an operational basis for advancing risk mitigation and emergency planning. The identification of recurrent and scenario-specific hotspots supports the prioritisation of interventions, the optimisation of resource allocation, and the development of targeted, context-specific strategies. In this sense, the proposed framework acts as a bridge between risk diagnosis and risk management, providing decision-makers with actionable evidence to customise mitigation measures and emergency response plans according to specific natural hazard scenarios and user dynamics.

Keywords: Multi-Risk Assessment, Flood Risk, Earthquake Risk, Urban Built Environment, Emergency Planning

1. Introduction

Disasters such as earthquakes and floods represent major threats to Urban Built Environments (UBEs), affecting territories due to both their intrinsic natural and geological characteristics, as in the case of seismic hazards, and the increasing influence of climate change, which is exacerbating extreme precipitation events (Davis et al. 2023; Giuliani, De Falco, and Cutini 2021). These phenomena belong to the category of Sudden Onset Disasters (SUODs), characterised by limited warning times and the rapid escalation of impacts in densely populated urban areas (UNDRR 2019). Their effects on urban systems depend not only on hazard intensity but also on the intrinsic vulnerability of UBEs, which involves both its physical characteristics and the users who inhabit and interact with these spaces. User-related factors, including age, mobility, environmental familiarity, and emergency awareness, significantly influence evacuation processes, behavioural responses, and potential casualty levels (Bernardini et al. 2024; Quagliarini et al. 2023; 2025). UBEs should therefore be understood as complex socio-spatial systems where buildings, infrastructures, public spaces, and users interact dynamically (Sharifi 2023), highlighting the need for disaster risk management approaches that address both structural vulnerability and the spatio-temporal distribution of urban populations.

Disaster risk management encompasses mitigation measures, preparedness strategies, and emergency planning actions (Kelman and Glantz 2015), and relies on disaster risk assessment as a key analytical foundation. However, both assessment and management approaches must move beyond static representations of exposure and vulnerability, since the impacts of many hazards are strongly influenced by the spatial and temporal distribution of people, which varies according to daily mobility patterns, tourism flows, and seasonal fluctuations. Neglecting such heterogeneity may lead to substantial misestimations of urban risk (Guo et al. 2025; Dabbeek et al. 2025; Duan and Fei 2025). At the mesoscale, Public Open Spaces (POSs) - such as streets and squares - represent key elements connecting building-level and urban-fabric scales within UBEs (Sharifi 2019). During emergencies, these spaces become critical interfaces where exposure, vulnerability, and behavioural responses concentrate, particularly during evacuation and early response phases. Defining plausible POS-use scenarios is therefore essential to estimate exposed users and their time-varying vulnerabilities (Frigerio et al. 2016; Romano, Bernardini, and Quagliarini 2025). When integrated with hazard and physical vulnerability parameters, this information enables the identification of critical urban hotspots and supports targeted mitigation and emergency planning strategies within disaster risk management frameworks.

In this context, the present study aims to support disaster risk mitigation, with particular reference to flood and seismic hazards. Applying a multi-layer, single-risk assessment methodology to a real case study (the historic UBE of Senigallia, Italy), the research identifies the most critical hotspots exposed to flood and earthquake risks. Based on these results, hazard-specific mitigation strategies and emergency planning measures are developed. The proposed approach integrates physical and user-related components under dynamic conditions through a POS-centred mesoscale framework, capturing interactions between hazard intensity, physical vulnerability, and spatio-temporal variations in exposure.

2. Methods

The method applied in this study is structured into five main phases, which collectively form an integrated workflow (illustrated in "**Error! Reference source not found.**"). This workflow enables the single-risk assessment for flood and earthquake hazards (Phases 1-4), and subsequently supports the development of risk mitigation strategies (Phase 5). The method is finally applied to a real case study, represented by the city of Senigallia, in order to demonstrate the validity and applicability of the proposed approach.

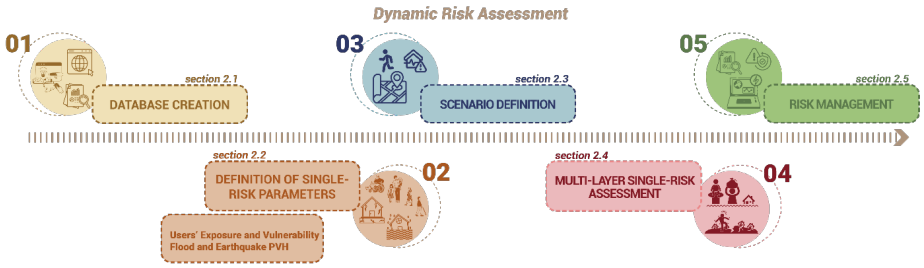

Figure 1 – Workflow

The five phases of the methodology are detailed as follows:

1. *Database creation*. Mesoscale assessment units are represented by POSs linking adjacent buildings and urban functions. A dataset including urban morphology, land use, building features, and hazard parameters supports the risk assessment process (Section **Error! Reference source not found.**);
2. *Definition of Single-Risk Parameters*. The key parameters, hazard, exposure and vulnerability, are assessed at the POS scale for both users and the built environment, including spatio-temporal user dynamics and building characteristics (Section **Error! Reference source not found.**);
3. *Definition of Risk Scenarios.* Single-risk scenarios are defined by combining hazard and vulnerability conditions for floods and earthquakes with shared spatio-temporal user patterns (seasonality, crowding levels, and daily time slots) across risk typologies (Section 2.3);
4. *Multi-layer single-risk assessment*. User exposure, user vulnerability, and *PVH* are integrated into multi-layer single-risk matrices to derive final risk levels for each POS, time period, and scenario. The results are represented as risk maps highlighting worst-case conditions (Section 2.4);
5. *Risk management*. Risk maps identify scenario-sensitive hotspots among the POSs in the UBE; they are compared with current emergency plans to detect conflicts between escape routes and critical areas within the city. Once weaknesses are detected, intervention planning is developed through the identification of new safe routes (Section 2.5).

A real case study was selected to apply the developed method. The city of Senigallia (Ancona, Italy) represents a suitable case study: characterised by significant cultural heritage, it developed along the Misa River and has been affected over time by both riverine floods (major events recorded in 2014 and 2022) and earthquakes (a severe seismic swarm in 1930 and a less intense one in 2022), which in both cases caused extensive damage to buildings, POSs and riverfront areas, compromising urban functionality. Therefore, the city's layout, the high presence of POSs, multi-hazard conditions, and dynamic exposure patterns related to recurrent mass-gathering events hosted in the UBE[1], make Senigallia a suitable case study for analysis, with the ultimate objective of supporting risk mitigation and emergency planning.

2.1 Database creation

A georeferenced database was developed to support the mesoscale POS-centred assessment. The dataset integrates building-level information with open-space characteristics and user-related parameters, enabling the aggregation of micro-scale data to streets and squares.

Building data include construction period, structural typology, number of storeys, and ground-floor use. These attributes were derived from municipal technical cartography[2] and publicly available sources, complemented, where necessary, by field verification and digital platforms (e.g., Google Street View). POSs were mapped and classified according to their geometric configuration, accessibility, and functional role within the urban fabric. Seasonal variability is explicitly considered by distinguishing winter (October-May) and summer (June-September) periods, characterised by differences in tourist presence, opening hours, outdoor uses, and mass-gatherings conditions. Demographic data from the Italian National Institute of

[1] https://www.feelsenigallia.it/en/ (last access: 20.02.2026)
[2] https://www.comune.senigallia.an.it/documento_pubblico/p-p-c-s-senigallia/ (last access: 20.02.2026)

Statistics (ISTAT, 2023 census database[3]) are used to define age-based user categories for exposure and vulnerability assessment. Occupancy loads [persons/m^2] are derived from fire safety regulations for both indoor and outdoor main functions (Ministero dell'Interno 2015). In addition, the theory of pedestrian Levels of Service (LOS) is adopted to model seasonal conditions in outdoor pedestrian areas and mass-gathering scenarios in open spaces (Bloomberg and Burden 2006). This framework was adopted to define the spatio-temporal characterisation of users across the different scenarios, as it has already been validated in previous studies, despite its conservative nature (Quagliarini et al. 2023).

All data were harmonised within a GIS environment to ensure spatial consistency and enable indicator normalisation at the POS scale.

2.2 Definition of single-risk parameters

This study builds upon consolidated approaches for computing hazard, exposure and vulnerability, integrating spatio-temporal urban use patterns with building characteristics (Ferreira and Santos 2020; Bernabei et al. 2021; Quagliarini et al. 2023). These components are expressed through the User Exposure and Vulnerability indices (Section 2.2.1) and the Physical Vulnerability and Hazard indices for flood and earthquake (Section 2.2.2). The response of the built environment to risks is therefore evaluated by combining user-related parameters (exposure and vulnerability), the physical vulnerability of buildings facing each POS, and hazard severity, ultimately describing the effects of flood and earthquake scenarios on public open spaces within the UBE. In detail, Physical Vulnerability (*PV*) reflects intrinsic building characteristics, such as materials, structural configuration, geometry, and conservation state, and is assumed invariant across hazard scenarios. Hazard (*H*) depends on the intensity of the selected event and varies according to the specific flood or earthquake scenario. *PV* and *H* are combined through a matrix-based procedure to derive a synthetic Physical Vulnerability-Hazard (*PVH*) index, which expresses the expected level of damage and its potential effects on adjacent open spaces (Ferreira and Santos 2020).

All indices are finally normalised on a scale from 0 (minimum risk, excluded according to general criteria for risk assessment) to 1 (maximum risk), ensuring mutual comparability and enabling their integration within the multi-layer single-risk assessment framework (see Section 2.4).

2.2.1 Users' Exposure and Vulnerability

User-related indices are derived by combining spatial information on urban functions with time-dependent occupancy assumptions. Users are classified according to their location (indoor or outdoor), type of activity, familiarity with the UBE, and age-related characteristics. Temporal variations in user presence are reconstructed through the intersection of functional schedules and behavioural assumptions, enabling the estimation of the spatio-temporal distribution of users and its aggregation at the POS scale. On this basis, User Exposure (*E*) and User Vulnerability (*UV*) indices are computed as time-dependent factors reflecting both the number of users and their susceptibility under emergency conditions. In detail, four time-dependent parameters are introduced to represent user presence and vulnerability under emergency conditions: Users' Exposure, Age-based User Vulnerability, Familiarity-based User Vulnerability, and Position-based User Vulnerability. These are computed following the methodology described in (Quagliarini et al. 2023; Bernardini et al. 2024). In particular:

- Users' Exposure, *E*, represents crowding levels in POSs under emergency conditions, considering both indoor and outdoor users. It is calculated by aggregating all users associated with a POS and normalising their density against a reference maximum outdoor occupant load;
- Age-based User Vulnerability, *Uva*, reflects the reduced autonomy and emergency response capacity of specific population groups due to age. It is computed as the proportion of age-vulnerable users with respect to the total number of users associated with each open space;

[3] https://demo.istat.it/app/?l=it&a=2023&i=POS (last access 20.02.2026)

- Familiarity-based User Vulnerability, *Uvf*, reflects the limited knowledge of the UBE and its associated risks among non-regular users (e.g., visitors, tourists and occasional users). The indicator is computed as the proportion of low-familiarity users associated with each POS;
- Position-based User Vulnerability, *Uvp*, reflects the location of users within the UBE at the onset of an emergency, which directly influences their exposure to hazard effects. The indicator is hazard-specific: in flood scenarios, vulnerability mainly affects users located outdoors or at ground-floor level due to rising water and flow conditions (Davis et al. 2023), whereas in earthquake scenarios it is primarily associated with users inside buildings because of potential structural damage and falling elements (He et al. 2025).

2.2.2 Flood and Earthquake Physical Vulnerability and Hazard

For both flood and earthquake scenarios, the Physical Vulnerability and Hazard components are combined to quantify the potential impact of hazards on buildings surrounding a POS and the resulting effects on public open spaces.

For flood scenarios, the Flood Physical Vulnerability Index (PV_f) reflects the susceptibility of buildings to flood impact and water ingress, accounting for architectural and structural features with respect to floodwater spreading direction (Miranda and Ferreira 2019). The index is assumed to remain constant across scenarios. The Flood Hazard Index (H_f) represents hazard intensity based on water depth and flow velocity (Davis et al. 2023). PV_f and H_f are combined into the PVH_f index using a matrix-based approach, subdivided into five normalised classes (from negligible to extreme), with numerical values ranging from 0.20 to 1.00 ("**Error!**

Flood PVH_f			Hazard [H = H_f]				
			Negligible [H ≤ 0.75]	Low [0.75 < H ≤ 1.25]	Moderate [1.25 < H ≤ 2.5]	High [2.5 < H ≤ 7.0]	Extreme [H > 7.0]
Flood Physical Vulnerability Index PV_f	Extreme	75 < PV_f ≤ 100	Moderate	High	Extreme	Extreme	Extreme
	High	50 < PV_f ≤ 75	Low	Moderate	High	Extreme	Extreme
	Moderate	25 < PV_f ≤ 50	Low	Low	Moderate	High	Extreme
	Low	PV_f ≤ 25	Negligibile	Low	Low	Moderate	High

Figure 2 - Flood Physical Vulnerability and Hazard matrix

Reference source not found.").

In seismic scenarios, the Earthquake Physical Vulnerability Index (PV_e) is calculated at the building scale by integrating structural and geometrical parameters, conservation state, and the presence of anti-seismic devices (Bernabei et al. 2021). The Earthquake Hazard Index (H_e) is derived from seismic return periods and Peak Ground Acceleration levels, according to national seismic hazard maps and the Limit States of the Italian Building Code (NTC18 Ministero delle Infrastrutture e dei Trasporti 2018). PV_e and H_e are combined into the PVH_e index through a matrix-based procedure linking vulnerability classes to EMS-98 damage grades. PVH_e is normalized from 0 (no damage) to 1 (collapse), representing both structural and non-structural damage potential for buildings facing a POS ("**Error! Reference source not found.**").

2.3 Scenario definition

According to Section 2.1 and Section 2.2 methods for the characterization of user-related factors, different mass-gatherings conditions and spatio-temporal patterns of UBE use can be identified. Nevertheless, for application and demonstration purposes, this study limits the analysis to single-risk assessment (for both flood and earthquake) performed for the most recurring annual scenario, corresponding to a winter working

Earthquake PVH_e			Hazard [Return Periods (years)]			
			[50]	[101]	[475]	[975]
Seismic Physical	Low	PV_e < 0.55	D0	D1	D2	D3

Figure 3 – Earthquake Physical Vulnerability and Hazard matrix

day with outdoors low crowding condition: no mass-gatherings and a density of 0.2 pp/m^2 in the pedestrian areas, corresponding to the condition of LOS A. This scenario was selected for exploratory purposes, as it represents the most frequent typical day, accounting for approximately 66% of the occurrences observed over a year, and it represents an intermediate critical state for both Exposure (*E*) and User Vulnerability (*UV*). To stress the reliability of the framework in capturing daytime variability of risks (i.e., via the user factors), this scenario is analysed across five daily time slots (night-time NT, early morning EM, noon N, afternoon A, evening E) enabling the assessment of temporal risk dynamics. Then, hazard- and vulnerability-specific conditions are selected to derive the indices, that are:

- for flood: moderate hazard level (1.25 $m^2/s < H_f < 2.5$ m^2/s) combined with a PV_f condition of floodwater flowing perpendicularly to the river (conservative assessment);
- for earthquake: moderate hazard level (H_e corresponds to 475-years return period) combined with a PV_e condition of pushing sloped/pitched roof, and anti-seismic devices with poor performance levels (conservative assessment).

These hazard conditions are selected as they represent the most critical situations in which outdoor evacuation process could still be performed by hosted users under both flood and earthquake emergencies (Davis et al. 2023; Bernabei et al. 2021).

2.4 Multi-layer single-risk assessment

The single-risk (*R*) quantifies disaster risk at POSs' scale as a weighted linear aggregation of the indicators described in Section 2.2. For each hazard scenario, risk is computed as in Eq. (1):

$$R = I_{PVH}*PVH + I_{UVp}*UVp + I_{UVa}*UVa + I_{UVf}*UVf + I_E*E \quad (1)$$

where I_i represents the relative importance of each risk factor. These weights are assessed using the Analytic Hierarchy Process (AHP), with distinct schemes for flood and earthquake (Goepel 2013). Experts from the Polytechnical University of Marche (11 for floods, 8 for earthquakes) performed pairwise comparisons of the risk components on a linear 1-9 scale, and the resulting judgments were aggregated into a consensus matrix. Relative priorities were calculated using the Row Geometric Mean Method (RGMM), ensuring that the weights sum to one and that the Consistency Ratio (CR) remains below 10%, validating the comparisons.

The equation is applied separately for flood and earthquake scenarios, producing two single-risk metrics according to the adopted multi-layer single-risk approach. User-related parameters remain consistent across scenarios, whereas *PVH* and *UVp* are hazard-specific. Finally, maps-over-time (MOTs) of the multi-layer single-risk are generated to provide an immediate visualisation of daily risk patterns. Risk levels are classified into five categories: Negligible (0 < index < 0.2), Low (0.2 ≤ index < 0.4), Moderate (0.4 ≤ index < 0.6), High (0.6 ≤ index < 0.8) and Extreme (0.8 ≤ index ≤ 1). This allows the temporal variation of risk across different public open spaces and hazard scenarios to be analysed.

2.5 Risk management: hotspots identification and emergency planning

The multi-layer single-risk assessment introduced in Section 2.4 is employed as an operational tool to support risk management, with specific reference to the evaluation and enhancement of existing emergency planning strategies. In particular, single-risk (*R*) and MOTs are used to investigate the effectiveness of current evacuation layouts by analysing their spatial and temporal consistency with flood and earthquake risk conditions. The procedure is based on the systematic comparison between the official emergency plans and the single-risk MOTs obtained for flood and earthquake hazard scenarios.

Emergency plans identify a set of POSs as designated evacuation paths and safe areas, which essentially do not change over time depending on the use dynamics. These elements are spatially overlaid onto the corresponding risk maps, enabling a direct evaluation of the risk levels associated with the planned evacuation network under different hazard conditions. Through this overlay analysis, hotspots are identified as POSs that are currently designated as evacuation routes or gathering areas but exhibit high risk levels

according to the proposed risk assessment framework. In these locations, relevant levels of potential physical damage, user exposure, or user vulnerability may compromise evacuation safety and emergency response, particularly during daily peak occupancy periods or under unfavourable hazard conditions. As such, hotspots represent critical mismatches between planned emergency functions and risk conditions. The identification of hotspots is performed consistently for both flood and earthquake hazard scenarios, allowing the distinction between recurrent hotspots, which remain critical regardless of time of day, and scenario-sensitive hotspots, whose risk level varies significantly with user dynamics and hazard-specific factors. This distinction is particularly relevant for design-oriented planning, as it supports both long-term mitigation strategies and scenario-dependent emergency measures. Building upon the identification of hotspots, the subsequent step consists of the development of a design-oriented proposal aimed at redefining and integrating alternative evacuation routes within existing emergency plans. These alternative routes are conceived to ensure safer evacuation conditions for the exposed population under both flood and earthquake hazard scenarios.

3. Results and Discussion of the Application to the Case Study of the City of Senigallia

The proposed framework is applied to a representative portion of the historical centre of Senigallia (represented in "Figure 4 – A, B, C").

Figure 4 - Discretization of the historic UBE of Senigallia into buildings, open spaces, links and nodes for the implementation of the proposed framework (A); urban views of Via Portici Ercolani (B, Street View: Google Maps. (2025). [Street View of via Portici Ercolani, Senigallia, Italy]. Retrieved March 9, 2026, from [https://maps.app.goo.gl/ce1wEYEvoKheeJPk8]) and Piazza Roma (C, Street View: Google Maps. (2025). [Street View of Piazza Roma, Senigallia, Italy]. Retrieved March 9, 2026, from [https://maps.app.goo.gl/k9pcztPovTeQVLZy9])

The study area is discretised into a mesoscale urban system ("**Error! Reference source not found.** – A") composed of: (i) POSs (squares and widened street sections), adopted as assessment units; (ii) buildings; (iii) links (street segments); and (iv) nodes (intersections between streets and squares). This representation enables the aggregation of building-scale vulnerability and hazard parameters to the POS level and supports the integration of user-related indices across the urban network. The application of the multi-layer model produces time-dependent single-risk MOTs for both flood and earthquake scenarios, classified into the five risk levels (negligible to extreme). The obtained results are subsequently presented and discussed. Specifically, "**Error! Reference source not found.**" shows flood single-risk MOTs, whereas "**Error! Reference source not found.**" presents the earthquake single-risk MOTs.

In the flood case, risk distribution appears relatively stable across time slots, with low and moderate levels mainly concentrated in POSs located along the riverfront and in its immediate proximity. EM and NT are predominantly low, while N and A are characterized by low-to-moderate risk areas, particularly along the main east-west street axes. This increase corresponds to higher outdoor presence during working hours, amplifying the contribution of users' exposure and vulnerability to the final index. During E, the pattern remains similar to the afternoon configuration, with low-to-moderate risk concentrated along the riverfront and in central connecting links, but without extreme peaks. Overall, the flood MOTs highlight a risk structure strongly influenced by hazard proximity to the river, with temporal variations mainly affecting intensity rather than spatial hierarchy.

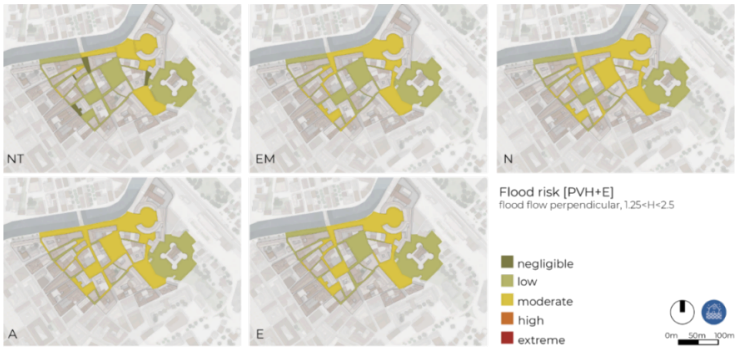

Figure 5 - Maps-over-time of flood risk in moderate H condition (1.25<H<2.5)

In contrast, the seismic MOTs reveal a stronger influence of functional schedules and indoor occupancy, producing sharper temporal fluctuations and localized hotspots with relevant single-risk values. The earthquake maps hence show a more pronounced spatial and temporal variability compared to the flood case, with the emergence of moderate and high-risk values in specific street segments. EM and NT are characterized by elevated risk levels; they appear along the northern riverfront axis and in central street links. Moderate and locally high values are visible even under reduced occupancy, indicating the dominant role of PVH_e. N and A show the most critical configurations. Several central links shift to moderate and high classes, forming a continuous high-risk corridor across the historical fabric. The increase reflects the combined effect of indoor occupancy and position-based user vulnerability under seismic conditions. During E, the spatial pattern becomes more fragmented, also in view of the position of public intended uses (e.g., restaurants, bars, other entertainment buildings) in the UBE, but persistent high-risk segments remain along structurally vulnerable fronts.

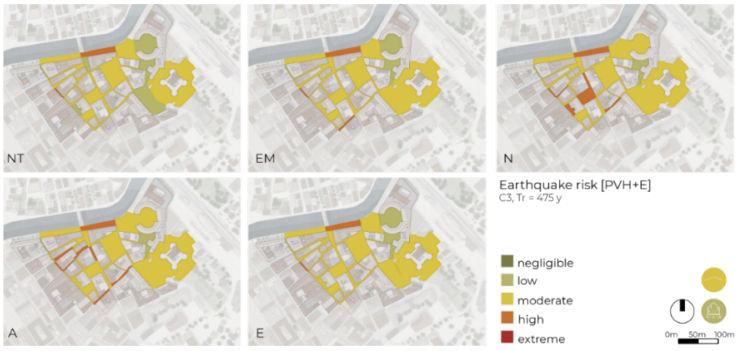

Figure 6 - Maps-over-time of earthquake risk in moderate H condition (H=475 years) and PV condition C3

The MOTs allow the identification of:

- POSs with recurrent high-risk values, mainly corresponding to wider POSs perpendicular to the river (see "Figure 4 – B, C") characterised by large pedestrian spaces, the presence of dehors, and their role as key nodes for daily activities and user flows;

- Time-sensitive high-risk values, emerging primarily in the earthquake scenario during peak occupancy hours.

Then, according to Section 2.4, hotspots are identified through the spatial overlay between the official flood and seismic emergency plans of Senigallia and the most critical daily single-risk configurations derived from the MOTs. Adopting a conservative approach, the reference time slots correspond to the highest *R* values within the recurring winter working-day scenario: A for floods and N for earthquake. Hotspots are defined as all POSs designated as main evacuation routes or gathering areas in the emergency plans that exhibit *R* ≥ Moderate in the selected scenario. The resulting overlay ("**Error! Reference source not found.**") highlights spatial mismatches between evacuation functions defined in the current Civil Protection emergency plans and actual risk conditions (Protezione Civile 2023).

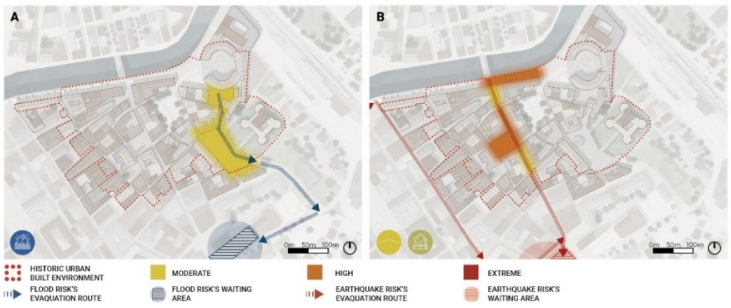

Figure 7 - Hotspots identified in the UBE of Senigallia. Panel (A) shows hotspots for flood in afternoon scenarios, while panel (B) shows hotspots for earthquake in noon scenarios

In the flood scenario, hotspots are mainly concentrated along the riverfront and near the Misa River. Although extreme values do not emerge under the selected moderate hazard level, all the evacuation segments fall within moderate risk classes, potentially affecting accessibility and walkability. In the earthquake scenario, criticalities are more pronounced. The main evacuation route within the study area intersects multiple Moderate and High-risk POSs. Elevated PVH_e values combined with peak indoor occupancy may hinder evacuation due to debris, façade failures, or falling elements. Moreover, several connecting streets show comparable risk levels, reducing the robustness of the evacuation network. Overall, the analysis reveals that: (i) the current evacuation network includes a limited number of main routes and few alternative safe paths, some of which may be exposed to potential risk-increasing conditions according to the assessed factors; (ii) routes are relatively long, particularly for users located near the riverfront.

Based on the identified hotspots, a design-oriented proposal is developed to revise and strengthen the existing emergency layouts. The approach is guided by principles of flexibility and adaptability, aiming to improve safety levels in emergency and evacuation conditions under both flood and earthquake events. The proposal is structured around three main actions, and is shown in "**Error! Reference source not found.**":

- *Identification of temporary safe waiting areas*. Selected central squares are designed as temporary safe areas, provided that they satisfy minimum safety requirements (Davis et al. 2023; Bernabei et al. 2021): (i) adequate capacity (maximum density < 3 persons/m^2, considering only unobstructed space); (ii) absence of significant exposure to falling elements in the seismic case; (iii) suitability under flood conditions, potentially supported by elevated or flood-adapted urban furniture; (iv) clear recognisability through dedicated emergency signage. Some areas are considered suitable for both hazards, while others are retained only for seismic scenarios due to their proximity to the river corridor.
- *Redefinition and integration of evacuation routes*. Alternative evacuation paths are proposed to bypass POSs identified as hotspots and to reduce dependence on a limited number of critical segments. In the seismic case, structurally compliant crossing points over the Misa River are considered as strategic alternatives, whereas in flood conditions river crossings are treated more

cautiously due to hydraulic risk. The revised layout aims to shorten evacuation distances, improve network redundancy, and enhance accessibility toward temporary safe areas.

- *Targeted building assessment along strategic segments*. For evacuation paths and temporary safe areas that remain essential within the revised layout, a more detailed seismic assessment of adjacent buildings is recommended to better characterise the expected damage patterns and their potential local impacts, particularly in terms of debris generation and possible obstructions along evacuation corridors caused by structural or non-structural failures. Priority may be assigned to public buildings, while structural improvement of private ones can be promoted through incentive-based strategies.

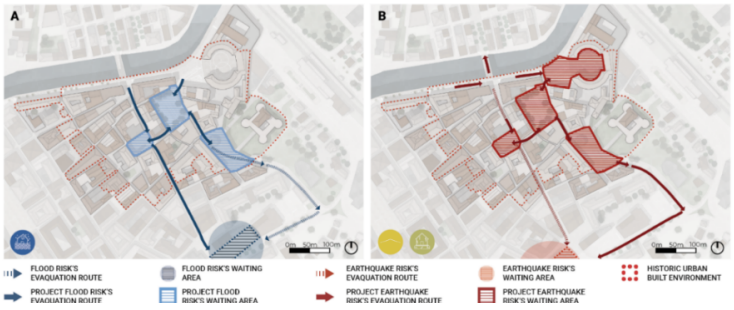

Figure 8 - Proposed implementations for the emergency plans for flood (A) and earthquake (B)

It should be noted that the present application refers to the most recurrent annual crowding condition and does not explicitly include mass-gathering scenarios. Under high-occupancy events, exposure levels would significantly increase, potentially altering the suitability of some temporary safe areas and evacuation paths. Therefore, the emergency plan should be further adapted and stress-tested for event-related overcrowding conditions, with specific attention to reversible uses of public spaces and compatibility between event layouts and emergency functions.

4. Conclusion

This study proposes a design-oriented framework that links single-risk assessment with emergency planning to support the identification of mitigation strategies in UBEs. By comparing risk maps with existing emergency plans, the approach enables the identification of evacuation routes and assembly areas whose risk conditions may compromise safe evacuation. Based on this evidence, the framework supports the definition of alternative evacuation layouts and temporary safe areas, contributing to more adaptable and hazard-consistent emergency strategies.

The methodology integrates hazard characteristics, physical vulnerability and dynamic user-related factors within a POS-centred approach. By aggregating building-scale information to the level of streets and squares, the framework captures spatio-temporal variations in exposure and vulnerability that are often neglected in conventional urban risk assessments. The application to the historical UBE of Senigallia highlights the importance of user dynamics for both flood and earthquake scenarios. Results show that risk distribution depends not only on hazard proximity or building vulnerability, but also on temporal variations in user exposure and vulnerability. Multi-layer single-risk MOTs identify recurrent and scenario-sensitive hotspots, providing a clear spatial and temporal understanding of critical areas. From a design-oriented perspective, the methodology allows authorities to evaluate emergency strategies under recurring use conditions. The scenario-based approach facilitates testing alternative “what-if” configurations, supporting prioritisation of interventions, optimisation of resources, and context-sensitive mitigation strategies.

Despite its contributions, the proposed approach presents some limitations. First, regarding the methodological approach, the assessment of the risk indicators through the AHP method should be extended to additional experts from different university research groups, with diverse backgrounds in flood

and earthquake risk, urban planning, and social vulnerability. Furthermore, the analysis should be complemented by a sensitivity analysis aimed at varying each weight and evaluating its impact on the POS classification. Second, the framework is conceived as a rapid and diagnostic tool to identify critical areas and support preliminary evacuation planning. For operational implementation, the proposed solutions should be complemented by more detailed analyses, including building-scale assessment of seismic and flood damage and evacuation simulations. Such analyses would allow the dynamic performance of evacuation routes to be evaluated under different crowding and behavioural conditions, providing more reliable estimates of potential obstructions, congestion points, and clearance times. Third, the proposed methodology should be applied to a wider range of case studies in order to further validate its feasibility. In particular, it should be tested on case studies for which information on past disaster events and the resulting damages is available, thereby enabling a more comprehensive characterization of impacts and supporting the integration of the proposed strategic framework.

Overall, the proposed methodology provides an operational and transferable tool to support design-oriented risk mitigation and emergency planning in multi-hazard urban contexts, offering decision-makers actionable evidence to prioritise interventions and enhance urban resilience.

Abstract: Flood Risk Assessment in Historic Urban Areas requires vulnerability models capable of capturing the intrinsic susceptibility of built heritage at the building scale. The present study focuses on the assessment of physical vulnerability, focusing on the impact of building characteristics. Physical vulnerability is defined as the susceptibility of historic buildings to floods, influenced by their construction typology, materials, structural characteristics and ground-floor configuration. A series of physical vulnerability indicators are derived from the existing literature and adapted to heritage-sensitive contexts, with particular attention to data availability and survey feasibility in historic urban fabrics. The indicators are aggregated through a weighted system based on expert judgement to obtain a synthetic physical vulnerability index intended to support building-scale screening and prioritisation. The methodology is applied to the historic centre of Bagnacavallo (Italy), a flood-prone urban area characterised by a dense and heterogeneous built heritage. Results reveal a significant spatial variability of physical vulnerability across the study area, reflecting differences in construction periods, architectural layouts and material properties. The building-scale analysis enables the identification of highly vulnerable heritage structures. The proposed approach offers insights into the intrinsic weaknesses of historic buildings by addressing physical vulnerability independently from hazard intensity and damage-probability modelling. The results support the heritage-oriented prioritisation of preventive conservation and retrofit interventions and demonstrate the value of physical vulnerability as a distinctive analytical dimension in flood risk studies for Historic Urban Areas.

Keywords: Flood Risk Assessment, Physical Vulnerability, Historic Urban Areas, Building-scale Analysis

1. Introduction

Historic Urban Areas are increasingly exposed to flood events driven by climatic changes, fluvial regulation, and progressive urban transformation (Chiara Arrighi et al. 2018; C Arrighi et al. 2023). In these contexts, flooding represents not only a hydrological hazard but also a critical threat to architectural heritage, where structural integrity, material authenticity and cultural value are interconnected. The compact morphology of historic fabrics, combined with ageing construction systems and conservation constraints, increases the potential for damage and complicates post-event resilience (Vojinovic et al. 2016).

The susceptibility of historic buildings to flood effects is influenced by their construction and architectural characteristics (Ferreira and Santos 2020; Vojinovic et al. 2016). Traditional buildings often exhibit increased sensitivity to water infiltration and prolonged water exposure. Ground-floor configurations, which are often aligned with street level and characterised by direct openings, facilitate water penetration and capillary rise. Furthermore, the coexistence of different construction phases and typological adaptations within historic urban fabrics contributes to differentiated structural behaviours under flood conditions. These factors underline the importance of considering vulnerability as an inherent characteristic of individual buildings, rather than a common feature of the overall urban fabric (Ferreira and Santos 2020).

Although flood risk is generally conceptualised as the interaction between hazard, exposure and vulnerability, operational assessments in historic environments often prioritise hydraulic modelling and scenario-based damage estimation (Chiara Arrighi et al. 2018; C Arrighi et al. 2023). Within these approaches, the structural dimension of building vulnerability is often simplified, aggregated at broad scales, or derived from standardised damage functions (Vojinovic et al. 2016). While these approaches provide valuable insights at the territorial or urban scale, they often fail to effectively characterise the inherent vulnerability of heritage structures.

Recent research has increasingly adopted indicator-based models to capture urban vulnerability patterns, integrating parameters related to structural typology, materials and conservation state (Agliata, Bortone, and Mollo 2021; Ferreira and Santos 2020). However, applications in historic contexts still face methodological challenges (Vojinovic et al. 2016). Indicators must be carefully calibrated to reflect heritage-specific characteristics while ensuring compatibility with available datasets and feasible survey procedures (Ferreira and Santos 2020; C Arrighi et al. 2023). Moreover, most existing indicator-based approaches focus on physical attributes of buildings, whereas parameters related to urban form and street-network configuration are less frequently incorporated into physical vulnerability assessments. Nevertheless, research on urban flood modelling highlights the role of street geometry, flow pathways, and local conditions in influencing flood propagation and exposure within cities (Mignot, Li, and Dewals 2019).

A focused assessment of intrinsic physical vulnerability provides a clearer interpretation of structural susceptibility within Historic Urban Areas (Ferreira and Santos 2020). By focusing on measurable architectural and structural attributes, it becomes possible to identify buildings' predisposition to flood damage, regardless of the hazard magnitude. This perspective is particularly relevant for heritage conservation plans, where mitigation/risk-reduction measures and retrofitting strategies can be prioritised according to structural fragility, also in view of their impacts on exposure factors, including population (Bernardini et al. 2025; Chiara Arrighi et al. 2018).

Within this framework, the present study proposes a methodology for assessing the physical vulnerability of historic buildings to flood at the building scale. A structured set of architectural and structural indicators is identified and refined for heritage contexts, ensuring consistency with existing spatial data and survey methods commonly used in Historic Urban Areas. These indicators are combined through a weighted aggregation procedure to determine a vulnerability index. This approach is then applied to the historic centre of Bagnacavallo (Italy), characterised by typological heterogeneity and flood-prone conditions. By focusing on the structural aspect of vulnerability, the present study aims to improve the understanding of the intrinsic fragility of buildings and to support preliminary prioritisation within heritage-oriented flood risk assessment in Historic Urban Areas.

2. Methodology

2.1 Case Study and Data Collection

The historic centre of Bagnacavallo, located in the province of Ravenna within the Emilia-Romagna region (Italy), represents a well-preserved medieval settlement in the Po Valley, the largest alluvial plain in Italy (Figure 1). The area is characterised by geomorphological conditions associated with flood susceptibility, as acknowledged by regional planning documents. According to the Emilia-Romagna Flood Risk Management Plan, the historic urban fabric is located within medium-hazard flood areas, thus confirming its relevance for vulnerability-oriented assessment (Piano di Gestione del Rischio da Alluvione - PGRA). Despite the historic centre not being directly affected by floods during the 2023 Emilia-Romagna event, flood extent maps show inundation in the surrounding areas (Perimetrazione aree allagate eventi 2023-2024). These findings emphasise the need for a structural susceptibility assessment aimed at mitigating potential future damage.

The analysis focuses on 468 buildings belonging to the pre-nineteenth-century core, which is representative of the consolidated historic fabric in terms of urban density, aggregation patterns and typological stratification. The individual building is adopted as the elementary spatial unit of analysis, enabling the direct evaluation of intrinsic architectural and structural characteristics influencing flood susceptibility. This micro-scale analytical perspective allows for differentiated structural configurations within a compact and historically stratified urban context. The built environment comprises a variety of structures, including

Figure 1 - Geographical location of the historic centre of Bagnacavallo and spatial distribution of the main building typologies within the analysed pre-nineteenth-century core.

traditional terraced houses, aggregated residential units, and larger palatial structures. This heterogeneity reflects the constructive and morphological characteristics typical of historic centres in the Po Valley, as shown in Figure 1 (Cantatore 2023).

Data acquisition is structured in order to ensure methodological transparency and reproducibility within a GIS environment (da Silva et al. 2020). Spatial datasets, including building footprints, road networks and urban blocks, are retrieved from regional and municipal geoportals. Building-level attributes relevant to physical vulnerability, including construction period, structural typology, primary materials, number of storeys, ground-floor configuration and conservation condition, were derived from the municipal Historic Centre Survey Plan and verified through targeted field inspections (Piano Particolareggiato del Centro Storico - PPCS 2023). The required attributes were compiled for all 468 buildings included in the analysis and harmonised within the GIS geodatabase. When inconsistencies between documentary sources, cartographic data and field observations were detected, the most recent field evidence was used to update the attribute record.

All spatial and descriptive information is integrated into a structured geodatabase. In the interest of ensuring internal consistency and enabling meaningful comparison across the building stock, the decision is taken

to standardise the attributes. This GIS-based database constitutes the analytical foundation for the subsequent definition and weighted aggregation of physical vulnerability indicators at the building scale.

2.2 Modelling intrinsic physical vulnerability

The intrinsic physical vulnerability of the built environment is assessed using three static indicators that describe building characteristics and stable morphological features at the building scale. The Flood Vulnerability Index (FVI) is derived from existing indicator-based approaches in the literature, while Flood Direction Exposure (FDE) and Road Width (RW) introduce morphology-related information based on street-network configuration, building orientation and spatial layout. These indicators are intended to capture relative differences in physical susceptibility within the historic fabric, rather than to reproduce event-specific hydraulic conditions.

The Flood Vulnerability Index (FVI), derived from the methodology proposed by (Davis et al. 2023; Miranda and Ferreira 2019), represents the central component of the proposed approach. This method is adopted due to its compatibility with detailed building survey data and its suitability for systematic GIS-based implementation at microscale. The FVI is defined as the product of Sensitivity Index (SI) and an Exposure Index (EI), normalised by the maximum theoretical value within the study area (Equation 1):

$$FVI = SI \times EI / FVI_{max} \quad (1)$$

SI captures intrinsic structural susceptibility to flood damage, and is calculated using seven parameters that describe material, structural and geometric characteristics. These include: (S1) state of conservation, evaluated according to the extent of deterioration and cracking; (S2) structural material, distinguishing among reinforced concrete or steel frames, masonry, timber and earthen constructions; (S3) facade finishing material, reflecting the resistance of envelope surfaces to water exposure; (S4) window/door frames' type and condition; (S5) number and configuration of ground-floor openings, representing potential water entry points; (S6) basement configuration, differentiating between absence of sub-grade spaces and direct-access basements; and (S7) entrance threshold height relative to street level. EI accounts for contextual characteristics that influence potential loss, including economic relevance, physical impact potential, and cultural value. It comprises three parameters: (E1) building use, reflecting functional and economic significance; (E2) surrounding surface morphology, describing configurations that may favour or limit water accumulation; and (E3) heritage designation level, representing increasing degrees of cultural value. Each parameter is classified into four vulnerability classes (A–D), associated with increasing weights: 10, 40, 70, and 100. The lowest class is intentionally assigned a non-zero weight to reflect the inherent baseline vulnerability of historic constructions due to ageing materials and traditional building systems. The SI and EI are obtained as weighted sums of their respective parameters prior to aggregation into the final FVI (Davis et al. 2023; Miranda and Ferreira 2019).

The Flood Direction Exposure (FDE) indicator describes the geometric exposure of building façades to potential flood flow directions using the street network as a morphological proxy. The street network is modelled as a parametric graph composed of nodes, defined at intersections, profile changes or width variations, and links, corresponding to road segments between nodes. Each building is associated with the corresponding street link within the GIS database. For each street link, two opposite directions are considered, representing a simplified approximation of possible flow alignment along the street axis. Building classification is determined by the angle between the façade orientation and each assumed direction, resulting in three exposure categories: parallel impact, oblique impact and perpendicular impact. The classifications obtained for the two opposite directions are combined using a 3 × 3 matrix, producing an FDE value ranging from 1 to 5. A value of 1 corresponds to parallel orientations in both directions, while a value of 5 corresponds to perpendicular orientations in both directions. Intermediate values reflect mixed alignments. The index is then normalised by dividing by the maximum possible value, resulting in a dimensionless indicator [-].

This formulation is not intended to represent hydraulic routing or simulated flood dynamics. It does not account for local flow concentration, obstruction effects, water depth, velocity, duration or return period. Its role is instead to introduce, within a preliminary vulnerability screening, a morphology-based descriptor of the potential directional exposure of façades.

The Road Width (RW) indicator represents a morphology-based proxy for the potential influence of road geometry on local flood propagation conditions (Balaian, Sanders, and Abdolhosseini Qomi 2024; Mignot, Li, and Dewals 2019). In compact historic fabrics, street width may affect flow confinement and the spatial distribution of water along the street network, although it cannot directly estimate hydraulic variables such as water depth, velocity or pressure. The index is calculated as the ratio between the width of each street and the maximum street width within the study area, ranging from 0 (excluded) to 1 (for the maximum road width in the considered Historic Urban Areas). This approach aims to identify the roads and buildings along them that are more susceptible to such effects than others.

It is important to note that FVI, FDE and RW are derived from intrinsic structural attributes and stable morphological characteristics of the historic fabric. Therefore, the parameters remain constant within the temporal limits of the analysis, and collectively provide a building-scale representation of intrinsic physical vulnerability within the Historic Urban Areas.

2.3 Index Construction and Weighting Approach

The Physical Vulnerability (PV) index is derived through the weighted aggregation of the three static indicators defined in the previous section. The relative importance of each parameter is determined using the Analytic Hierarchy Process (AHP), a multi-criteria decision-making method that ensures transparent and consistent integration of heterogeneous factors (Goepel 2018; Agliata, Bortone, and Mollo 2022).

Pairwise comparisons among the PV parameters are independently performed by six experts from university research groups, with different backgrounds in flood risk, urban planning, and built heritage conservation. Evaluations employed a linear integer scale from 1 (equal importance) to 9 (maximum importance) within the AHP Excel system (Goepel 2018). The final priorities are calculated through the row geometric mean method (RGMM) and normalised to ensure that their sum is equal to 1. The logical coherence of the pairwise judgments is verified through the Consistency Ratio (CR), with values below 10 % considered acceptable. For the PV index, the aggregated CR was 2.1 %, thereby confirming the reliability and the internal consistency of the comparisons.

The degree of agreement among experts was assessed using the AHP consensus indicator S*, a homogeneity index based on Shannon entropy (Goepel 2018). Six experts with different backgrounds in structural engineering, historic building conservation, and urban planning provided the pairwise comparisons, resulting in a high consensus levelof S* = 98 % for PV . This high level of consensus supports the internal coherence of the weighting scheme within the expert-based AHP procedure. Each parameter is then multiplied by its corresponding weight, and the weighted values are summed to produce the PV index. According to the derived AHP priorities, the PV index for each building is calculated as shown in Equation 2:

$$PV = 0.66 \cdot FVI + 0.235 \cdot FDE + 0.105 \cdot RW \quad (2)$$

This formulation results in a dimensionless measure ranging from 0 to 1, thereby ensuring comparability across the entire built environment.

The PV index is subsequently discretised into five ordered categories: negligible (0.0–0.2), low (0.2–0.4), moderate (0.4–0.6), high (0.6–0.8), and extreme (0.8–1.0). This classification facilitates interpretation, comparability, and GIS-based visualisation, enabling the spatial identification of vulnerable buildings and critical clusters within the historic fabric. The resulting maps support decision-making in flood risk management and heritage conservation by providing a spatially explicit representation of building-scale physical vulnerability (Evans et al. 2024; Taramelli et al. 2022).

3. Results

This section presents the spatial distribution of intrinsic physical vulnerability across the historic centre of Bagnacavallo, examining both the component indicators (FVI, FDE and RW) and the aggregated PV index (Figure 2). The class-based distribution confirms the predominance of low-to-moderate PV values, with 76% buildings classified as low and 17% as moderate. Negligible and high PV classes account for 4% and 3% of the building stock, respectively, while no buildings fall within the extreme class.

Figure 2 - Spatial distribution of the component indicators and PV, according to the general classification ranges adopted for the indicators in this work: (a) Flood Vulnerability Index (FVI), (b) Flood Direction Exposure (FDE), (c) Road Width (RW), (d) aggregated PV index derived from the weighted combination of the three indicators.

FVI map (Figure 2.a) highlights the intrinsic structural susceptibility of the built environment. A higher density of FVI values is observed along the primary roads within the historic core, suggesting a significant correlation between vulnerability and urban hierarchy. Buildings with a large ground-floor opening and complex structural configuration, particularly those located along main roads, show a higher level of vulnerability. Conversely, smaller terraced and row houses located along secondary and narrower streets tend to exhibit lower FVI values, reflecting simplified typologies and more compact façades. The buildings

surrounding the main square show high FVI values, due to the influence of heritage constraints and non-residential ground-floor uses. These uses may increase exposure and limit structural adaptability.

FDE map (Figure 2.b) provides a representation of exposure variations associated with building orientation concerning potential flood flow directions. The majority of buildings fall within parallel or oblique configuration with respect to the street layout, resulting in moderate exposure conditions. Conversely, buildings positioned perpendicularly at street intersections are more directly exposed to incoming water flow, increasing their susceptibility. The irregular and curvilinear layout of the historic street network locally modifies these geometric relationship, contributing to spatial variability in exposure across the urban fabric. Although slope plays a limited role in the present case study due to the flat morphology of the floodplain, the overall orientation of the urban layout remains a relevant factor in shaping potential impact conditions. It should be noted that FDE represents a morphological proxy derived from the geometric relationship between buildings and the street network, rather than from hydraulic flood simulations.

As shown in Figure 2.c, RW reflects the influence of road width on vulnerability. Buildings located along narrow streets generally exhibit higher RW-related vulnerability values, while those facing wider streets or open spaces, such as squares, show lower values. Within the analysed street network, narrow street sections represent a significant proportion of the historic core, reflecting the compact morphology typical of historic settlements in Po Valley. This distribution contributes to the higher RW values observed across the case study.

Finally, the aggregated PV index (Figure 2.d), derived from the weighted combination of FVI, FDE, and RW (Eq. 2), synthesises these spatial patterns. Consistently with the class-based distribution reported above, PV values are predominantly concentrated in the low-to-moderate range (0.2–0.6). This indicates that most buildings present limited to intermediate intrinsic physical susceptibility according to the adopted indicator-based classification. Nevertheless, there is a clear spatial correlation between areas of higher vulnerability and specific geographical locations, particularly along the main roads and primary squares. These areas correspond to buildings in which intrinsic structural susceptibility and adverse exposure conditions converge. The results demonstrate that physical vulnerability is not arbitrary but is closely associated with architectural typology, construction characteristics, and urban morphology. The strong correlation between the component indicators and the aggregated PV index confirms the robustness of the adopted weighting scheme and highlights the dominant influence of intrinsic structural features in shaping vulnerability patterns.

4. Discussion and Final Remarks

The application of the proposed methodology to the historic centre of Bagnacavallo highlights the analytical value of considering intrinsic physical vulnerability as a distinctive dimension within flood risk assessment for Historic Urban Areas. By focusing on structural and morphology-related characteristics at the building scale, the method supports the identification of spatially differentiated susceptibility profiles that may otherwise remain hidden in hazard-centred or macro-scale assessments. In this sense, the PV index should be interpreted as a screening and prioritisation tool, rather than as a direct predictor of flood damage.

The results demonstrate that physical vulnerability is strongly influenced by the interaction between architectural typology and urban morphology. Higher PV values are concentrated along the main roads and around the square, where larger buildings with wider ground-floor openings and more articulated structural configurations prevail. Conversely, smaller terraced and row houses located along secondary streets generally show lower vulnerability levels. These observations indicate that, even within a compact and historically homogeneous urban fabric, intrinsic structural variability significantly influences the spatial distribution of physical susceptibility to flooding.

The aggregated PV index shows broad spatial consistency with the distribution observed in the individual indicators, particularly with the FVI, which has the highest AHP-derived weight. This suggests that the

aggregation procedure preserves the main vulnerability patterns emerging from the component indicators, although the quantitative robustness of the adopted weights should be further examined through dedicated sensitivity analyses. As also observed in the results section, most buildings fall within low-to-moderate vulnerability ranges, while comparatively higher PV values identify spatial clusters where intrinsic structural susceptibility and adverse morphological conditions converge. In this context, the PV index operates as a screening and prioritisation instrument rather than a direct damage predictor, thereby facilitating preventive planning and targeted building-scale assessments.

The building-level resolution represents a key contribution of the study. By capturing the heterogeneity of the urban environment and enabling micro-spatial analysis, the approach provides a detailed understanding of vulnerability drivers and an operational basis for risk-informed decision-making. The translation of architectural and morphological attributes into spatially explicit metrics can also facilitate integration with planning instruments and conservation-oriented risk mitigation strategies.

Nevertheless, some methodological limitations should be acknowledged. The proposed PV index is based on intrinsic building attributes and stable morphological descriptors and therefore does not include event-specific hydraulic variables such as water depth, velocity, duration, flow concentration, obstruction effects or return period. Similarly, the FDE indicator is derived from the geometric relationship between façades and the street network and should be interpreted as a simplified morphological proxy rather than as an output of hydraulic flood modelling. The index has not been calibrated or validated against observed flood damage, measured inundation levels or independent expert classifications of damage susceptibility. These aspects do not undermine its use as a preliminary screening tool, but they limit its interpretation as a predictive damage model. Future research should combine the proposed building-scale vulnerability assessment with hydrodynamic simulations, post-event damage observations and sensitivity analyses on weights and class thresholds.

In conclusion, the study demonstrates that the systematic assessment of intrinsic physical vulnerability at the building scale provides a robust and transferable methodological framework for flood risk analysis in Historic Urban Areas. By revealing spatially structured patterns of susceptibility, the approach supports evidence-based prioritisation and contributes to advancing heritage-sensitive risk mitigation strategies.

Abstract: Water serves as a primary integrating resource and, since hydrological processes are influenced by the physical urban form, it should be used as the backbone of territorial planning. This work proposes the operationalization of the watershed as a land unit in assessing the sensitivity of urban built heritage to flood events from the perspective of climate change. To determine the area of study, the ottocoded watershed database updated in 2026 was employed. Then, the landscape layers relevant to the characterization of the land unit were selected. Morphological, socioeconomic, and environmental analyses were performed using the open-source software QGIS and the Hand Model application. The results were reclassified and overlaid to identify the most vulnerable elements in flood occurrence. The watershed lens enabled the observation that infrastructure and occupation patterns remodeled the site's characteristics, influencing the vulnerability of the heritage landscape and its asset ensemble to water-related events. This uncovers its potential as an interface between climate risk assessment, urban planning, and historic urban landscape management. In this sense, adopting the watershed drainage area as a land unit allowed interpreting the section as a complex system of interconnected elements within its larger context, enabling a deeper understanding of the landscape and encouraging a truly holistic approach.

Keywords: Built heritage, Watershed, Vulnerability Assessment, Historic Urban Landscape, Climate change.

1. Introduction

Urban heritage, understood as the set of tangible and intangible elements within a city, is an important factor of identity and social cohesion, representing a valuable resource for maintaining well-being in urban areas (Taylor 2023; Y. Wang et al. 2024; UNESCO 2011). From the HUL perspective, cities are the product of a continuous and historical overlapping of layers that manifest both natural and cultural attributes (Ji, Shao, and Du 2020). One of the main drivers of this constant state of transformation is urbanization processes that, when poorly planned, can weaken urban centers and their inhabitants, making them particularly vulnerable to the negative impacts of climate change and other anthropogenic phenomena (United Nations 2017)—a condition that becomes especially critical when it involves built heritage (Adetunji and Daly 2024).

Climate change undermines the sustainable development of communities, posing multiple risks to cultural heritage (Graus et al. 2024; Lankester and Knight 2024; Gallina et al. 2016). It continuously challenges conservation efforts, with severe impacts on the social and economic spheres, highlighting the need to integrate heritage management into the development of adaptation and mitigation actions (Quesada-Ganuza et al. 2021). This integration aligns with the Historic Urban Landscape (HUL) approach, which includes, among other fundamental steps, the assessment of heritage vulnerability to the effects of climate change for consideration in urban planning (World Heritage Training and Research Institute for the Asia and the Pacific Region et al. 2016). Vulnerability assessments are increasingly used to identify critical

points and to provide informational support for the development of solutions across different scales (Fritzsche et al. 2017). According to the IPCC (2022), assessing vulnerability means assessing “The propensity or predisposition to be adversely affected. Vulnerability encompasses a variety of concepts and elements, including sensitivity or susceptibility to harm and lack of capacity to cope and adapt”.

Recognized as the main driver of material degradation of heritage, much of the research combining climate change and preservation focuses on water-related events (Sesana et al. 2021; Salazar, Figueiredo, and Romão 2024; Quesada-Ganuza et al. 2021; Figueiredo, Romão, and Paupério 2020). Most of these studies address the impact of floods on specific elements (Figueiredo, Romão, and Paupério 2020), using object-related indices. This pattern reinforces a gap in the literature, emphasized by Quesada-Ganuza et al. (2021), related to the use of holistic approaches capable of considering the complexity of the context in which the heritage object is embedded. From this perspective, landscape characteristics represented through spatial data form a new dimension of importance for vulnerability assessments, since land use and occupation patterns influence the dynamics and impact of the event (S. Wang, Chen, and Gao 2022; Hassan Rashid, Manzoor, and Mukhtar 2018; Mendonça and Medeiros Leitão 2009; Ferreira, Walsh, and Ferreira 2018).

As a topographic area that collects precipitation toward a common drainage axis, the watershed is a territorial unit that interacts directly with climatic vectors and with land use and occupation (Arshed et al. 2023; Fox 2009, chap. 06). Therefore, this work proposes the operationalization of the watershed as a working scale for a flood vulnerability analysis capable of being reflected in heritage, enabling the guidance of integrated management and planning actions. This proposal's feasibility was tested in a watershed of the city of Fortaleza (Ceará, Brazil) significant for containing the greatest portion of the built heritage portfolio. The vulnerability calculation employed a set of GIS tools to conduct map algebra, based on georeferenced data collected from different governmental repositories. The approach can guide the distribution of conservation efforts through the identification of buildings in more critical situations, proving to be a valuable tool for heritage management.

2. Case Study

Fortaleza, capital of Ceará state (Figure 1, presents a current estimated population of 2.5 million inhabitants, the city has its origins in the 17th century around Forte Schoonenborch, later named Forte Nossa Senhora da Assunção. From the 20th century onward, Fortaleza experienced rapid urban and population growth based on investment in infrastructure and the strengthening of tourism, without, however, having planning policies. This resulted in occupation driven by economic and real estate agents that radically transformed the territory, erasing part of the local memory through heritage demolitions under the “demolish to build” discourse (Raimundo Freitas Aragão, Marcos da Silva Rocha, and Helania Martins de Souza 2019).

Fortaleza's vegetation is typically coastal, with mangrove and restinga areas, a pluviometric index of 1,378 mm/year, and a heterogeneous rainfall regime concentrated in the first quarter of the year. Climate is classified as tropical semi-humid, with an average annual temperature ranging from 26°C to 28°C. The main hydrography of the municipality recognizes four major watersheds: the Cocó River, Maranguapinho River, Pacoti River, and the coastal watershed (IPECE 2026; Prefeitura Municipal de Fortaleza, Secretaria Municipal de Urbanismo e Meio Ambiente, and ICLEI 2020; SEUMA 2015).

Urban occupation patterns associated with climate change have exposed the city to 4 major risks: increase in temperature, extreme rains, prolonged droughts, and sea level rise. According to the Digital Atlas of Disasters in Brazil, between 2001 and 2023, 6 hydrological events were recorded that resulted in 11 deaths, 70,31 million people left homeless, and 116.11 million people directly affected. This meant R$ 189,03 million in material damages and R$ 23,03 million in public losses. (Ministério da Integração e do Desenvolvimento Regional, n.d.; Prefeitura Municipal de Fortaleza, Secretaria Municipal de Urbanismo e Meio Ambiente, and ICLEI 2020).

The analysis scope adopts an Ottocoded level 6 watershed, which represents the smallest drainage area delimited for the region (Figure 1). The Ottocoded hydrographic base is a representation form proposed by Otto Pfafstetter that depicts river flow, connected sections, and water displacement direction. Originating from the Brazilian Systematic Mapping, version 6 follows the hydrographic delimitation proposed by the HydroSHEDS project, a global database containing publicly accessible hydroecological information, associating the water resource management efforts by the National Water Agency with a broader scale (Ana Paula Fiorezi, Alexandre de Amorim Teixeira, and Diana Leite Cavalcanti 2024). The study area, of 21,4 km², on the north coast of the municipality, encompasses 76 (72%) of the 106 listed heritage assets, highlighting the importance of the area for local historical development.

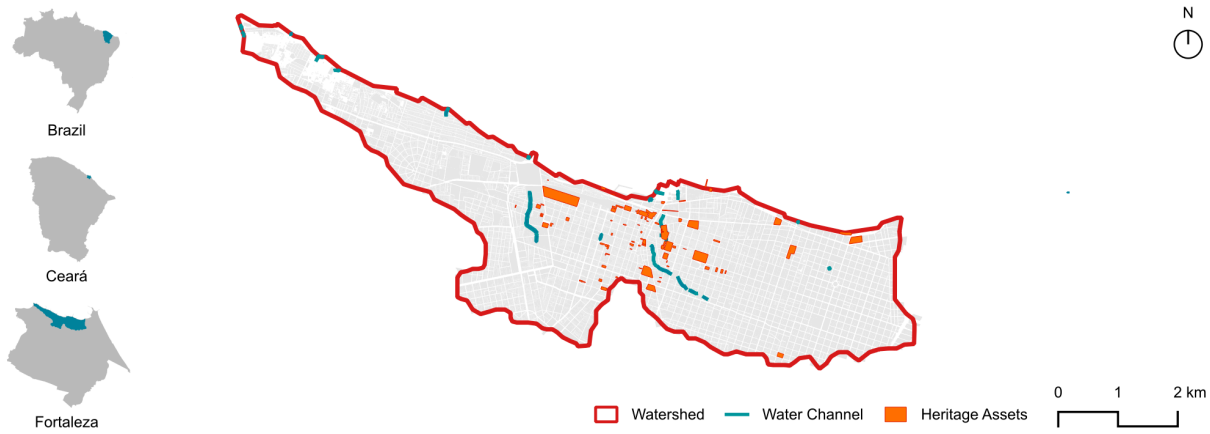

Figure 1 – Location of the study area and delineation of the basin containing the heritage resources of interest.

3. Methodology

For the selection of layers relevant to the vulnerability analysis, this study examined peer-reviewed publications on multi-criteria flood analyses. The authors consulted ScienceDirect, Scopus, and Web of Science databases to select Open Access works published between 2020 and 2025, using the combination of keywords ("flood vulnerability" OR "flood risk") AND ("multi-criteria analysis" OR "multi-criteria evaluation" OR "multi-criteria decision analysis") AND "climate change". A refinement of the initial set, comprising 368 articles, excluded duplicates and removed publications that did not mention, in the title, abstract, or keywords, all topics of interest: "flood risk" or "flood vulnerability"; "multi-criteria" or "multicriteria"; and "climate change". After screening 33 filtered items, 21 publications reported the layers used and formed the basis for the informational selection in this study (Table 1). The primary factor for including layers in the list of interest was their occurrence. A substantial portion of publications utilized common physical and socioeconomic layers, yet many singular occurrences were also noted. This suggests a lack of consistency in how vulnerability is characterized. The authors added new layers during the process to bridge informational gaps in vulnerability characterization.

Table 1 – Amount of layers (by type) incorporated into the reference publications.

Zahid et al. (2025)	5	3	1	2

The vulnerability assessment of the study area was carried out through map algebra. The application of the method involved the operationalization of selected geo-referenced spatial layers, provided by sources at different governance scales, resulting in a physical and social characterization of the area (Table 2). To produce analyses tailored to the study area, the layers were clipped to the boundaries of the selected watershed using the free software QGIS (version 3.40.15 - Bratislava) (QGIS Development Team 2024). The HAND Model software (version 1.0) (Antonio Donato Nobre et al. 2016) was used for obtaining the HAND, drainage, and Flow Accumulation layers, enhancing the identification of local hydrological characteristics. All geographic layers were converted to raster format to ensure faster operations.

To perform the map algebra operation, the values of each rasterized attribute were classified according to their influence on the vulnerability to flooding within the study extent, always recognizing five value classes to standardize the investigations; subsequently, these classes were reclassified through a normalization from 1 to 5, from least to most influential. The definition of the threshold values for these classes was carried out in three ways: (i) when the layer data were continuous and not uniformly distributed, the natural breaks (Jenks) classification was used; (ii) when the data had a large range and were predominantly concentrated in low values, a logarithmic scale classification was applied; and (iii) when the data were categorical, a correspondence was established with the values already in use. Thus, 19 layers were reclassified (Table 2), and their average was computed to represent the overall flooding vulnerability of the analyzed territory.

Table 2 – Description of the layers employed by the authors to support the vulnerability analysis.

Feature	Layer	Interpretation	Source
Physical	Elevation	Low elevation areas receive run off from higher regions	SEFIN (2020)
Physical	Slope	Low-slope areas drain water poorly, creating potential for accumulation.	SEFIN (2020)

Physical	Terrain Ruggedness Index (TRI)	Flat areas drain water poorly, creating potential for water accumulation.	SEFIN (2020)
Physical	Flow accumulation (ACC)	Higher values indicate higher water accumulation.	SEFIN (2020)
Physical	HAND	Low HAND shows the closest vertical distance from the nearest river, indicating lower altitude areas more susceptible to flooding.	SEFIN (2020)
Physical	NDVI	Low NDVI indicates urbanized areas.	INPE (2025)
Physical	Soil type	High porosity indicates fast absorption.	SGB/CPRM (2026)
Climatic	Mean annual precipitation	High precipitation values are related to flooding, increasing the likelihood of inundations.	Funceme (2017)
Climatic	Annual frequency of precipitation > = 50 mm	Intense rainfall (>50 mm) corresponds to large water volumes, associated with flooding and inundations.	Funceme (2017)
Climatic	Average maximum precipitation	Areas with a higher number of rainy days exceeding 50 mm are less favorable.	Funceme (2017)
Infrastructure	Drainage density	Areas with a higher density are less favorable.	SEFIN (2020)
Infrastructure	Road density	High road density indicates soil sealing, creating artificial channels that direct urban runoff.	SEFIN (2020)
Infrastructure	Construction sites, foundations, and ruins	Areas near buildings under development, in ruins, or in poor condition are more sensitive.	SEFIN (2020)
Socioeconomic	Population density	A greater number of people are exposed to flooding.	IBGE (2017)
Socioeconomic	Age < 4 years old	Children up to 4 years old have reduced mobility, associated with high dependence due to cognitive limitations.	IBGE (2017)
Socioeconomic	Age > 60 years old	Elder people may face mobility issues, reduced fitness to handle extreme situations, and reluctance to abandon their homes.	IBGE (2017)
Socioeconomic	Female demographics	Sociocultural norms prevent women from engaging in some activities, exposing them more to the effects of adverse events.	IBGE (2017)
Socioeconomic	Total nominal monthly household income	People with lower incomes face difficulty to recover from flooding events.	IBGE (2017)
Socioeconomic	Household density	A greater number of homes are exposed to flooding.	IBGE (2017)

4. Results and Discussion

4.1 Landscape characterization

The reclassification of the layers enabled the spatial interpretation of data through maps (Figure 2) and quantitative analyses (Figure 3) capable of supporting the characterization of the territory and interpreting cultural heritage sensitivity within the scope. The assessment of physical characteristics showed that, despite having high porosity throughout the extent of the scope, there is a predominance of high-sensitivity physical factors (Figure 3). The combination of large areas with high Slope indices (57,4% class 5), TRI (58,5% class 5), HAND (54,8% class 5), in a region mostly with low Flow Accumulation (62,4% class 1), defines the watershed with high water accumulation potential, low drainage capacity, and isolated from adjacent drainage areas. Considering these characteristics, floods are mainly related to rainfall accumulation, reinforcing the need to incorporate information about the distribution of climatic events in the territory—areas with higher maximum averages, annual averages, and amounts of days with rainfall above 50 mm were interpreted as more sensitive.

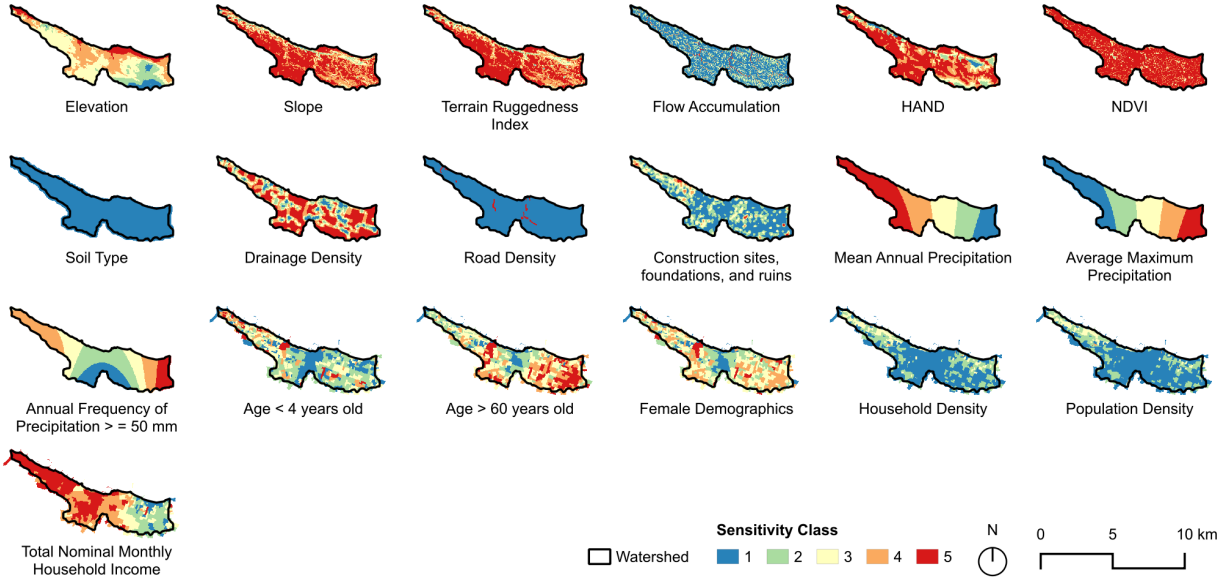

Figure 2 – Layers reclassification. Classes vary from the least influential (class 1) to most influential (class 5) according to their respective interpretations of the sensitivity/ability to cope represented by the layer.

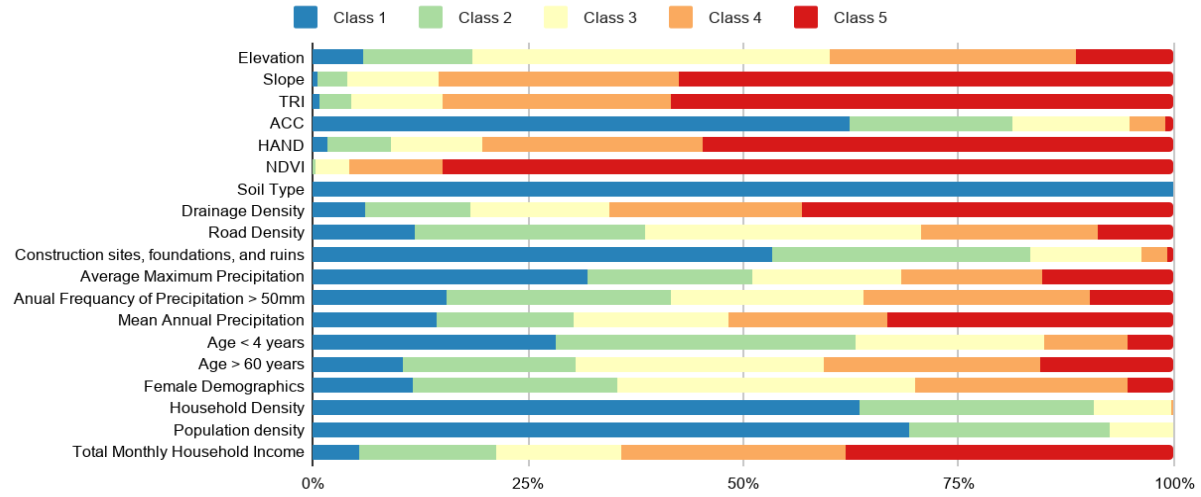

Figure 3 – Area distribution of reclassified layers by class. Classes vary from the least (class 1) to most influential (class 5) according to their respective interpretations of the sensitivity/ability to cope represented by the layer.

The high predominance of non-vegetated areas (84,9% class 5) shown on the NDVI map contributes significantly to the territory's sensitivity and reinforces the need to include analyses of infrastructure and urban morphology layers. Association of low gray drainage densities (43% in class 5 and 22% in class 4) and road density (check other index) evidences high infrastructural sensitivity. The presence of constructions, foundations, and ruins in a few points of the scope (53% in class 1) revealed low structural sensitivity of the surroundings. The dataset confirmed a developed urbanized area, marked by soil imperviousness and inefficient gray infrastructure to deal with the repercussions caused by water-related events.

The population and housing densities found (class 1 in 70% and 63% of the area, respectively) demonstrated a lower number of people and households affected, with it being possible to note low concentration in the central portion of the scope. To incorporate the diversity of impacts on the population, sensitivity associated with differential vulnerability (Zebisch et al. 2023) was assessed through income and demography layers, whose distribution preserved the observed low centrality. Lower income was the greatest sensitivity factor found, with 38% in class 5 and 26% in class 4, exposing that a significant portion of families have lower income. The distribution of the number of elderly people (over 60 years) is balanced, with it being possible to note concentrations in levels 3 and 4 that require attention. Women and children (from 0 to 4 years) classification predominate in levels 2 and 3. Despite the observed urbanization, the data showed the concentration of socioeconomic aspects in regions neighbouring the central portion of the scope. The economic condition of the population is not homogeneous and can affect recovery and adaptation capacity. In this scenario, the older population is the demographic group most prone to sensitizing the scope, demanding more specific and targeted recovery and adaptation actions.

4.2 Land and heritage sensitivity

Results calculated from the average of the reclassified maps (equation 1) comprise a short interval, from 2.05 to 3.95, showing that the combination of the multiple sensitivities and the abilities to cope resulted in a moderate vulnerable territory, with the absence of totally safe or critically vulnerable areas. Despite the homogeneity, the spatial distribution of these values allowed observing that the western zone of the watershed is the most vulnerable area to flooding (Figure 4). This result is mainly influenced by the socioeconomic and infrastructure layers with more critical classifications, which could be the focus of planning actions. The central portion proved less vulnerable because of lower demographic classes and population, and housing density. This may delineate an urban void in the region, reinforcing the need for informational enrichment to characterize territorial dynamics related to aspects such as land use and occupation. This landscape composition affects the heritage under analysis, which is mostly concentrated in the region, reducing connection with the cultural asset and weakening local identity and social memory.

$$\frac{\sum \text{class layers}}{n \text{ layers}} \quad (1)$$

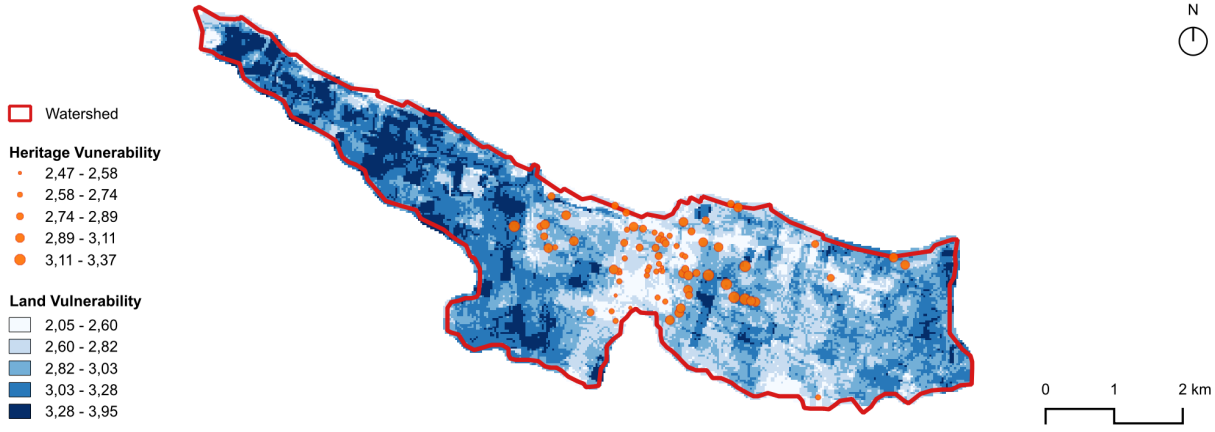

Figure 4 – Landscape and urban heritage vulnerability, assessed using map algebra.

The layer containing the lot boundaries geometries that encompass the heritage buildings assets was overlaid on the landscape vulnerability map, and the index calculated for the territory was transposed to heritage buildings through the QGIS zonal statistics tool, further reducing the found interval (2.47 - 3.37). Taken together, this scenario shows that contextual factors—physical, infrastructural, and socioeconomic—influence the vulnerability of real estate assets, suggesting that this assessment cannot be limited to structural attributes. The quantitative approach used made it possible to establish a hierarchy based on the calculated level of vulnerability, objectively identifying not only the location but also the criticality of the assets. This approach focuses necessary efforts on developing more effective conservation measures, tailored not only to the physical characteristics of the object but also to the environment in which it is situated.

5. Conclusions

Built heritage faces threats related to increasingly frequent extreme climate events. Preservation actions that integrate climate risks require an understanding of both the conservation state of the built heritage and the characteristics of its location. The present work proposes the operationalization of the watershed as the unit of analysis for assessing the vulnerability of built heritage to flooding from the landscape perspective. Adopting the watershed defined an analytical unit with predominantly homogeneous physical characteristics, reinforcing the need to include attributes related to other systems, such as the social, economic, and urban infrastructure systems.

The adoption of a working scale operating at the ecological dimension—the same as that of the natural phenomenon under study—enabled the selection of a concise and efficient territorial subset for the assessment of potential climate impacts. As a working scale, the watershed can allow investigations related to other hazards relevant to the context—particularly when they interact with the occurrence of flooding. It can also enable the proposal of mitigation, adaptation, and response actions for the administrative regions contained within it, engaging with traditional planning and management strategies.

This approach considered 19 layers collected from governmental databases for the characterization of the territory. The reclassification process created dimensionless values across layers with different metrics and enabled the map algebra operation. Interpreting the results operationalized maps and statistics, revealing a territory that, despite being heterogeneous, exhibited moderate vulnerability. The need to visualize the data spatially shaped the reclassification of the layers: classification strategies, such as Jenks natural breaks or the logarithmic scale, were chosen to facilitate the perception of the layers on the GIS map, producing clear representations. This methodological choice may imply a loss of informational detail, since the tool automates the distribution of data into classes, and the process can mask nuances. Therefore, future investigations may adopt a more analytical and mathematical approach, better equipped to handle the mathematical particularities involved in data processing for the definition of vulnerability classes. The multiple datasets used in the literature to characterize the territory and to ground the authors' analyses reinforce that knowledge of the territory is essential for more accurate assessments. This condition highlights the need to incorporate information-enrichment strategies through community participation, combining technical and local knowledge, in order to better support methodological developments like the attribution of weights that represent the relevance of the landscape layers.

The projection of vulnerability relative to the territory onto the dimension of heritage assets revealed the need for more careful consideration. The vulnerability assessment showed that the adverse effects of climate hazards are not limited to the constructed dimension of built heritage, which is influenced by the physical, climatic, urban infrastructure, and socioeconomic dimensions that contextualize them and are shared across distinct assets. Therefore, incorporating this holistic, landscape-centred view can inform and raise awareness among stakeholders involved in heritage conservation, guide decision-making, and support a more integrated and strategic management of portfolios.

A structured methodology for post-fire structural assessment and rehabilitation of unreinforced masonry housing in seismic regions

Rodrigo CHIPOCO.[1], Denisse GONZALEZ [2]

[1] AEI Smart Build Solutions Ltda., Viña del Mar, Chile, rodrigo@aeismart.cl
[2] AEI Smart Build Solutions Ltda., Viña del Mar, Chile, denisse@aeismart.cl

Abstract: Structural fires in unreinforced masonry housing represent a critical challenge in seismic regions, particularly when thermal exposure does not cause immediate collapse but induces cumulative damage that may compromise future structural performance. In such scenarios, decision-making between total demolition and structural rehabilitation often lacks clear and reproducible technical criteria adapted to local construction practices.

This paper proposes a structured methodology for post-fire structural assessment and rehabilitation of unreinforced masonry housing, oriented toward supporting technical decision-making between demolition and rehabilitation. The methodological framework integrates specialized visual inspection, qualitative classification of thermal damage based on recognized post-fire indicators, consideration of expected structural behavior under seismic demand, and the definition of intervention criteria grounded on material compatibility, minimal intervention, and improvement of shear structural behavior. The proposed approach is consistent with the general principles of formal post-fire inspection protocols, while being adapted to the specific characteristics of masonry structures and post-disaster contexts.

The methodology is applied through the comparative analysis of two real post-fire reconstruction cases in Chile, corresponding to single-story unreinforced masonry dwellings exposed to estimated temperatures below 400 °C. The assessment allowed severe thermal damage scenarios to be ruled out and localized reductions in structural continuity and stiffness to be identified, which were addressed through compatible strengthening strategies, including reinforcement meshes, structural mortars, and upper confinement elements.

The results indicate that, under conditions of moderate thermal damage, structural rehabilitation of post-fire unreinforced masonry housing is technically feasible, avoiding unnecessary demolitions and promoting resilient reconstruction solutions. The proposed methodology may be applicable to similar post-fire scenarios involving unreinforced masonry housing in seismic regions and provides a preliminary basis for future standardization of assessment and intervention criteria in post-disaster contexts.

Keywords: *structural fire; unreinforced masonry; post-fire structural assessment; post-disaster rehabilitation; seismic regions.*

1. Introduction

Large-scale urban fires generate complex scenarios for the structural assessment of existing buildings. Unlike other extreme events, fire does not necessarily cause immediate collapse but induces progressive material degradation that may compromise future structural performance (Ingham 2009; ACI 2021). This condition is particularly critical in unreinforced masonry (URM) housing located in seismic regions, where the assessment must consider not only the post-fire condition but also the expected structural response under seismic demand.

In buildings constructed under standards preceding modern seismic design codes, thermal exposure may affect both the integrity of structural elements and the global continuity of the load-resisting system. Masonry degradation, deterioration of mortars and concrete, and loss of upper confinement generate a

condition of technical uncertainty, especially in the absence of instrumental testing capable of quantifying the reduction in mechanical properties (RILEM 2000; ACI 2021).

In practice, these scenarios are often addressed through conservative decisions, frequently oriented toward total demolition. However, this approach does not always reflect a rigorous structural assessment and may be inefficient from a technical, economic, and social perspective, particularly in attached or continuous housing, where partial demolition may adversely affect the overall structural behavior (fib 2017).

In this context, a structured methodology is required to link observed damage with explicit technical criteria for decision-making and intervention. This study proposes a methodology for the post-fire structural assessment and rehabilitation of unreinforced masonry housing in seismic regions, organized into three levels: damage assessment, structural decision-making, and intervention definition. Its application to real reconstruction cases in the Valparaíso region not only validates its technical relevance but also establishes a systematic, replicable, and traceable process for decision-making in post-fire scenarios within seismic contexts.

2. Context and Case Studies

The analyzed cases correspond to residential buildings affected by the February 2024 wildfire in the Valparaíso Region, Chile, within the framework of an ongoing post-disaster reconstruction process. The dwellings were constructed in the 1970s and correspond to low-rise unreinforced masonry (URM) typologies, including attached, semi-detached, and continuous row configurations, located in the Canal Beagle and Canal Chacao sectors, in the municipalities of Viña del Mar and Quilpué, respectively. This condition is particularly relevant, as the interaction between adjacent units influences both the structural assessment and the feasibility of partial demolition.

During the initial assessment process, a portion of the dwellings were classified for demolition. However, subsequent technical evaluations identified that many of them did not present a risk of collapse, although they required structural repair and strengthening to meet current safety and regulatory requirements. This situation highlighted the need for more precise criteria to distinguish between repairable and non-repairable damage.

The dwellings consist of load-bearing solid clay brick masonry walls, continuous concrete strip footings, and the absence of upper confinement elements prior to the fire. The compressive strength of the base material was estimated at approximately 5 MPa. At the time of inspection, the roof structures were completely destroyed; therefore, the assessment focused on the remaining visible load-resisting elements. **Figure 1** presents the geometric configuration of the dwellings, while **Figure 2** illustrates their grouping within the Canal Beagle sector.

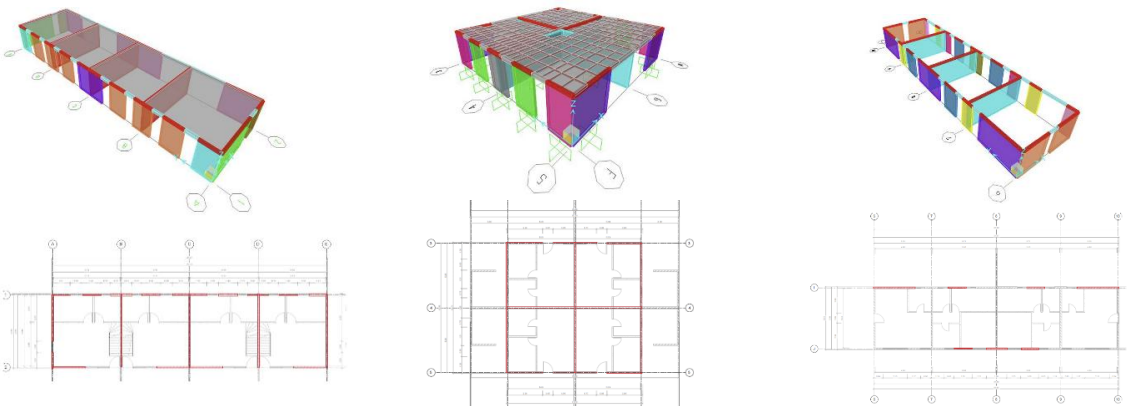

Figure 1 - General typological characteristics of the analyzed dwellings

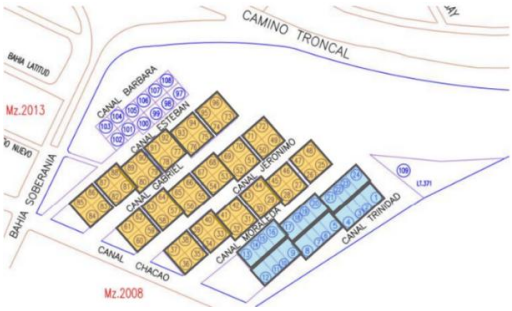

Figure 2 - Spatial configuration of housing units in the study area (MZ 2007 cadastral plan, Municipal Works Department, Viña del Mar)

2.1. Thermal Exposure Conditions and Inspection Timeline

In both cases, the post-fire assessment suggested thermal exposure below 400 °C, based on widely recognized damage indicators, such as the absence of brick vitrification, partial preservation of mortar joints, lack of widespread spalling, and the absence of critical deformations in steel elements.

Although the estimated thermal exposure remained below 400 °C based on observable indicators, this estimation involves uncertainty due to the absence of direct measurements. Nevertheless, the adopted qualitative–rational approach is consistent with post-fire assessment methodologies reported in the literature (RILEM 2000; Ingham 2009; ACI 2019).

The post-fire structural inspection was conducted after complete thermal stabilization of the structures. In the Canal Beagle sector, the detailed inspection was carried out approximately 20 days after the fire, while in Canal Chacao it was conducted after 14 days. These timeframes helped avoid premature diagnoses associated with transient thermal conditions and ensured a reliable assessment of residual structural damage.

3. Structured Methodology for Post-Fire Structural Assessment

The proposed methodology is conceived as a structured decision-making framework, consistent with the general principles of formal post-fire inspection protocols, yet specifically adapted to unreinforced masonry (URM) typologies and to the constraints inherent to post-disaster reconstruction contexts.

The methodology is organized into three sequential and interrelated levels:

- Level I: damage assessment,
- Level II: structural decision-making,
- Level III: structural intervention definition.

This approach transforms conventional inspection and design practices into a structured procedure with explicit criteria, defined outputs, and full traceability, enabling a consistent and reproducible decision-making process.

3.1. Level I: damage assessment

3.1.1. Field Survey

The first stage consisted of a systematic and specialized visual inspection, applied to each dwelling using a post-fire inspection record sheet, as shown in **Figure 3**. This instrument enabled the structured

documentation of both general building characteristics and observed structural conditions, including the spatial localization of damage.

The inspection covered all visible structural elements, including load-bearing walls, wall intersections, openings, upper wall elements (bond beam level), remaining steel structural components, visible damage in reinforced concrete elements, and the overall condition of the structural system after the loss of the roof.

Foundations were not included in the direct visual survey, as they were generally not exposed.

The collected information was documented through; an individual inspection record for each dwelling, damage sketches indicating the spatial distribution of cracks and affected areas, and a photographic record used for subsequent validation, as illustrated in **Figure 4**.

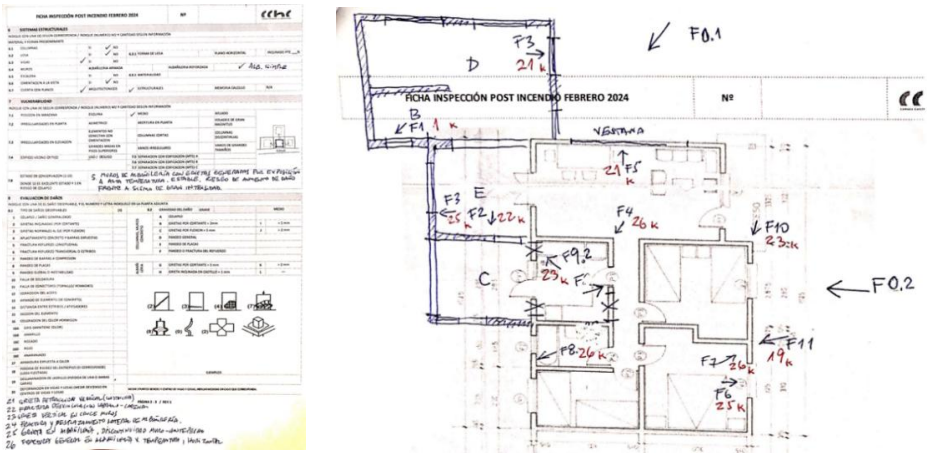

Figure 3 - Field inspection sheet and damage recording diagram

This procedure not only enabled the recording of field observations but also allowed the development of a traceable documentation framework, supporting the verification of on-site data against subsequent structural analysis, design development, and municipal submission processes.

3.1.2. Thermal Damage Indicators

Figure 4 - Representative photographic record of observed damage

Thermal damage assessment was conducted based on observable field indicators, considering visual criteria commonly recognized in post-fire evaluation practice (Ingham 2009; ACI 562-19). The indicators considered included masonry cracking, color changes in concrete and masonry elements, loss of material cohesion, surface disintegration, spalling in concrete elements, mortar deterioration, deformation of residual steel elements, and the presence of combustion-related residues in specific areas associated with prolonged fire exposure due to localized combustible loads, such as furniture or other interior contents.

The interpretation of these indicators enabled the development of a qualitative assessment of thermal damage levels, not based on direct temperature measurements but on observable pathological evidence

consistent with post-fire behavior reported in the literature (ACI 2021; fib 2017; RILEM 2000). The damage evaluation considered crack orientation, continuity, width, and spatial distribution, as well as their relationship with structurally critical zones such as corners, wall intersections, and upper wall regions.

3.1.3. Damage Classification

Based on the field survey, damage was systematically classified into three levels, as defined in Table 1.

Table 1 - Damage Classification

Damage Level	Description	Structural Condition	Recommended Decision
Minor	Superficial cracking, mainly affecting finishes. Structural walls without significant damage.	Structural performance not compromised	Direct rehabilitation
Moderate	Presence of cracks and fissures in walls, with localized material deterioration and evidence of higher thermal exposure.	Possible reduction in structural capacity	Rehabilitation with strengthening
Severe	Wall displacement, loss of masonry unit integrity, large cracks, and extensive damage.	Loss of structural stability	Demolition

In the cases analyzed using this methodology, all evaluated dwellings were classified within the minor and moderate damage categories. No severe damage conditions were identified that would imply a loss of global structural stability or an imminent risk of collapse.

3.1.4. Level I Outputs

The outputs of this stage were not limited to a narrative description of the observed damage but consisted of specific evaluation products, as summarized in Table 2.

Table 2 - Outputs of Level I: Field Assessment and Damage Documentation

Output	Description	Objective
Inspection technical sheet	Structured record of housing characteristics and observed damage	Systematize field data
Photographic record	Visual evidence of observed damage	Validation and traceability
Damage sketch	Spatial identification of cracks, fissures, and affected areas	Relate damage to structural geometry
Damage classification	Determination of damage level: minor, moderate, or severe	Basis for decision-making
Technical observations	Qualitative comments from the evaluator	Complement structural analysis

3.2. Level II: Structural Decision-Making Methodology

3.2.1. Decision Criteria

Structural decision-making was based on determining the feasibility of rehabilitation versus the need for demolition of the affected dwellings. Given the practical constraints associated with post-emergency reconstruction, where destructive testing or advanced instrumental assessments are not feasible, a qualitative–rational approach was adopted for thermal damage classification. This approach was based on the correlation between observed visual indicators and temperature ranges reported in the specialized literature (Ingham 2009; ACI 2021; fib 2017).

The decision process relied on an integrated structural interpretation of the observed damage, considering the continuity of load-bearing walls, the integrity of wall intersections, the global stability of the system, and

the extent of damage affecting structural elements. A dwelling was considered rehabilitable if it maintained structural continuity, showed no evidence of out-of-plane failure or wall displacement, and presented non-predominant damage, even in the presence of localized deterioration or damage to upper confinement elements that could be repaired.

In contrast, demolition was considered when there was loss of structural continuity, global instability, or predominant damage affecting the load-resisting system. These criteria were applied using a technical–rational approach rather than a strictly numerical threshold.

The criteria considered are summarized in **Table 3.**

Table 3 - Decision Criteria

Primary Criterion	Evaluated Condition	Recommended Decision
Structural continuity	Walls and connections maintain integrity	Rehabilitation
Global stability	No out-of-plane failures or wall tilting observed	Rehabilitation
Damage extent	Damage is not predominant in the structural system	Rehabilitation
Recoverability of elements	Bond beams and damaged areas are repairable	Rehabilitation
Loss of continuity	Disconnection of walls or failure at wall intersections	Demolition
Structural instability	Presence of wall tilting or risk of collapse	Demolition
Predominant damage	Significant damage affecting the structural system	Demolition

Note: Criteria are applied through integrated structural interpretation rather than fixed numerical thresholds.

3.2.2. Regulatory and Administrative Criteria

In addition to the residual structural condition, rehabilitation had to be compatible with the applicable regulatory framework. For this purpose, the following aspects were considered: the feasibility of developing a formal architectural and structural design project, compliance with minimum habitability requirements, submission of the project to the local Municipal Works Department (Dirección de Obras Municipales, DOM), the existence of prior municipal approval of the original dwelling, and structural validation through a calculation report and external review.

In this context, the decision to rehabilitate was not based solely on a visual or qualitative assessment, but on the actual feasibility of formalizing a reconstruction permit and obtaining subsequent municipal approval in accordance with current regulations.

Additionally, the proposed rehabilitation strategies were developed and verified through formal structural design projects in accordance with current Chilean regulations, considering criteria related to strength, stability, and expected structural behavior under seismic demand. These verifications supported the technical feasibility of the adopted solutions. However, the objective of this study is not to develop a detailed quantitative seismic analysis, but rather to propose a structured methodology for assessment and decision-making in post-fire scenarios.

3.2.3. Level II Outputs

The output of this stage corresponds to a technical determination of structural feasibility, classifying each dwelling as: rehabilitable, requiring demolition, or rehabilitable subject to a specific strengthening strategy.

In the cases studied, the field survey and subsequent analysis allowed the initially proposed total demolition to be ruled out and replaced with a structural rehabilitation and/or strengthening strategy.

3.3. Level III: Structural Intervention Methodology

The third stage consisted of linking the observed damage and the rehabilitation decision with a specific structural intervention strategy.

A key aspect of this methodology is that the intervention is not defined based on observed in-service failure, but rather on the expected structural behavior under seismic demand.

3.3.1. Identification of Structural Deficits

Based on the field survey and structural analysis, three main structural deficits associated with thermal damage were identified, as summarized in Table 4:

a) Mechanical degradation of masonry: evidenced by cracking, color changes, loss of material cohesion, and surface disintegration. This condition results in a reduction of load-bearing capacity and increased uncertainty in structural behavior under seismic loading (Ramirez et al. 2023).

b) Loss of structural continuity in upper bond beams: associated with concrete degradation, cracking, and spalling, compromising load transfer and wall confinement (Ramirez et al. 2023; Hernández-Montes et al. 2023).

c) Reduction in system ductility: thermal exposure induces more brittle behavior in masonry, reducing its energy dissipation capacity and increasing vulnerability to lateral actions (Li and Purkiss 2005).

Table 4 - Correlation between Observed Damage, Structural Deficits, and Intervention Strategies

Observed Damage	Structural Interpretation	Identified Deficit	Intervention Strategy
Cracking in masonry walls	Mechanical degradation due to thermal effects	Reduction in load-bearing capacity	Strengthening with welded wire mesh and shotcrete
Superficial material disintegration	Loss of material cohesion	Local reduction in strength	Application of bonded structural coating
Discoloration of concrete	Moderate thermal exposure	Possible reduction in mechanical properties	Evaluation and complementary strengthening
Spalling in concrete elements	Loss of cover and cross-section	Reduction in load-bearing capacity	Repair or replacement of the affected element
Damage in upper bond beams	Loss of structural continuity	Deficient load transfer	Rehabilitation or reconstruction of bond beams
Absence or deterioration of upper confinement	Lack of confinement	Reduced global stability of the system	Incorporation of upper confinement elements
General system degradation	Increased brittle behavior	Reduction in ductility	Global strengthening using a composite system

3.3.2. Structural Performance Objectives of the Intervention

The intervention was defined based on structural performance objectives, as summarized in Table 5.

Table 5 - Structural Performance Objectives of the Intervention

Objective	Description
Restore structural continuity	Ensure effective connection between load-bearing elements
Improve shear resistance	Increase resistance to expected seismic demand
Enhance ductility	Promote controlled inelastic behavior
Improve confinement	Improve integrity and stability of load-bearing walls
Ensure load transfer	Guarantee structural load path from roof to walls
Material compatibility	Integrate strengthening elements without construction incompatibilities

3.3.3. Intervention Strategies

The intervention strategies were defined based on the identified structural deficits, aiming not only to repair the observed damage but also to improve expected structural behavior under seismic demand.

Wall strengthening: the adopted solution consisted of applying a structural shotcrete layer reinforced with welded wire mesh, mechanically anchored to the existing substrate to ensure composite action between the remaining masonry, existing concrete elements, and the strengthening layer, as illustrated in Figure 5. This strategy aimed to restore or replace deteriorated areas, increase the load-bearing capacity of the system, improve its expected seismic behavior, and reduce the risk of brittle failure.

Rehabilitation or replacement of upper bond beams: in areas where damage to upper tie beams was identified, their rehabilitation or full replacement was defined, with the aim of restoring the load-bearing capacity of the element, recovering the perimeter confinement, and ensuring proper load transfer from the roof to the load-bearing walls. The strengthening solution is illustrated in Figure 6.

Global ductility enhancement: the incorporation of continuous reinforcement using welded wire mesh and shotcrete was also conceived as a strategy to enhance the overall ductility of the structural system, improving its capacity for stress redistribution and promoting a more stable structural response under seismic demand.

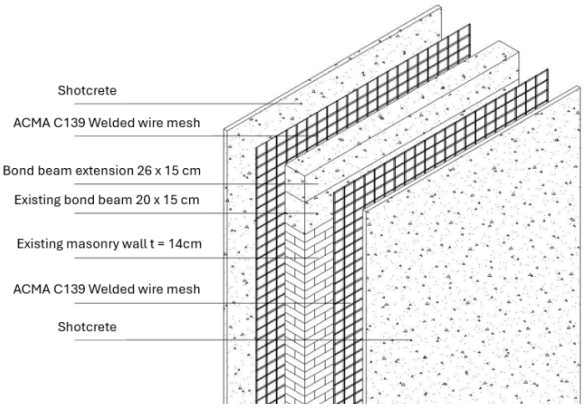

Figure 6 - Wall reinforcement scheme with welded wire mesh and shotcrete

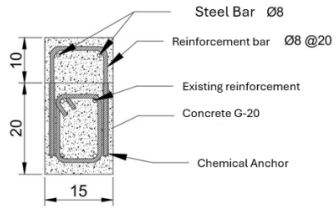

Figure 5 - Schematic detail of upper bond beam rehabilitation

3.3.4. Methodology Synthesis

The overall methodology is summarized in Table 6.

Table 6 - Summary of the Proposed Post-Fire Assessment Methodology

Methodological Level	Input	Process	Output
Level I: Assessment	Field inspection	Data collection using inspection sheets, damage sketches, and photographic records	Damage classification
Level II: Decision	Damage classification and structural assessment	Application of criteria based on structural continuity and damage extent	Definition: rehabilitation or demolition
Level III: Intervention	Rehabilitation decision	Identification of structural deficits and strengthening design	Structural intervention strategy

4. Implemented Structural Rehabilitation Strategies

Based on the identification of structural deficits associated with thermal damage and considering the expected structural behavior under seismic demand, structural rehabilitation strategies were defined and implemented to restore load-bearing capacity, improve structural continuity, and enhance the global ductility of the evaluated dwellings.

The adopted solutions were consistently applied across the analyzed cases, responding to criteria of constructability, feasibility under post-emergency conditions, and coherence with the structural performance objectives defined in the proposed methodology.

4.1 Shear Strengthening of Masonry Walls

The strengthening of masonry walls was aimed at increasing their load-bearing capacity under lateral actions, considering the potential degradation of mechanical properties due to thermal exposure.

The adopted solution consisted of installing welded wire mesh (ACMA C139 type), mechanically anchored to the existing substrate, followed by the application of a structural mortar layer approximately 3 cm thick on the interior face of the walls. This system improved shear resistance, controlled crack propagation, and promoted a more stable structural response.

Additionally, a fiberglass mesh embedded in a compatible mortar was applied on the exterior face, primarily intended for crack control and durability, without a primary structural function.

Overall, the intervention transformed the original system into a composite structural system with improved expected behavior under seismic demand.

4.2 Incorporation of Upper Bond Beam

To restore the structural continuity of the system, a continuous reinforced concrete bond beam was incorporated at the top of the load-bearing walls.

This element, approximately 30 cm in height, acts as an upper confinement system, integrating the walls structurally, improving the redistribution of horizontal forces, and providing an effective connection with the roof.

Its incorporation increased the global stability of the system, reduced vulnerability to out-of-plane failure, and ensured proper load transfer from the roof to the load-bearing walls.

5. Results

The application of the proposed methodology enabled a systematic and structured assessment of fire-damaged unreinforced masonry dwellings, ensuring traceability between field data collection, structural decision-making, and the definition of intervention strategies.

5.1 Characterization of Observed Damage

Field inspections revealed that, despite the scale of the fire, the dwellings did not exhibit collapse conditions or global structural instability. The observed damage was primarily characterized by cracking masonry walls, discoloration of concrete elements associated with thermal exposure, superficial material degradation, and damage to upper bond elements.

In addition, the total loss of the roof was observed in most cases, resulting in direct thermal exposure of load-bearing walls. No indicators of severe thermal damage were identified, such as brick vitrification, massive material loss, or critical deformation of structural elements.

Based on these observations, the damage was classified as either minor or moderate, with no cases identified as severe in terms of global structural stability.

5.2 Technical Validation of Structural Condition

The qualitative damage assessment, based on observable indicators, provided a consistent basis for interpreting the residual structural condition of the dwellings.

Available technical data included compressive strength testing of concrete core samples extracted from existing slabs in representative dwellings, with the purpose of verifying whether the existing structural elements could be retained and incorporated into the proposed rehabilitation strategy. Six valid test results yielded equivalent cylindrical compressive strengths ranging from 20.6 MPa to 25.9 MPa, while two additional core samples could not be tested due to damage sustained during the extraction process. These results provided quantitative information regarding the residual condition of the existing concrete elements and supported the technical decision to retain and incorporate the existing structural components within the proposed rehabilitation strategy.

These findings allowed severe damage scenarios to be ruled out and supported the technical feasibility of structural rehabilitation.

5.3 Adopted Structural Decision

Based on the application of the defined methodological criteria—particularly those related to structural continuity, global stability, and damage extent, the viability of rehabilitation was confirmed for all analyzed cases (100%), and total demolition initially considered during the preliminary assessment was discarded.

Accordingly, a structural rehabilitation strategy was adopted, compatible with the development of formal architectural and structural design projects, their submission to the local municipal authority, and subsequent approval in compliance with current regulations.

This result represents a significant finding, demonstrating that initial demolition decisions can be revised and reversed through a structured technical evaluation process based on explicit and traceable criteria.

5.4 Implementation of Rehabilitation Strategies

The structural intervention strategies defined in Level III were implemented consistently with the identified structural deficits, as illustrated in Figure 7. In particular, the incorporation of shear strengthening in

masonry walls and the construction of upper bond beams restored structural continuity, improved load-bearing capacity, and enhanced expected global stability under seismic demand.

5.5 Comparative Analysis of Case Studies

The comparative analysis of the Canal Beagle and Canal Chacao cases showed that, although both typologies presented similar structural conditions and levels of thermal exposure, differences were observed in the spatial distribution of damage.

In Canal Beagle, damage was more localized, whereas in Canal Chacao a more distributed cracking pattern was identified, associated with the combined effects of thermal damage and prior seismic actions.

These differences did not affect the overall structural decision; however, they required localized adjustments in the extent and configuration of the strengthening strategies, while maintaining a consistent methodological approach in both cases.

Figure 7 - Example of implemented structural strengthening solution in the field

6. Discussion

The results demonstrate that, under conditions of moderate thermal damage, total demolition of unreinforced masonry dwellings is not necessarily a technically justified solution.

The main contribution of this study lies in the application of a structured methodology that translates damage observation into explicit criteria for assessment, decision-making, and intervention, reducing reliance on non-systematic conservative judgments. In this context, the adopted qualitative–rational approach proves appropriate for post-emergency scenarios, where advanced testing is not feasible (fib 2017; ACI 2021), enabling a consistent technical basis derived from observable indicators.

The comparative analysis suggests that the methodology can be adapted to different damage configurations while maintaining consistency in decision-making. Variations between localized and distributed damage are reflected in adjustments to strengthening strategies without altering the overall structural logic (fib 2017; Ingham 2009).

Additionally, the results highlight the importance of considering system-level behavior in attached or continuous housing, where the demolition of a single unit may compromise the global stability of the structure.

From a practical perspective, the validation of the proposed solutions through their development as formal design projects, submission to municipal authorities, and subsequent approval represents a relevant verification of their technical and regulatory feasibility.

A key limitation of the study is the absence of instrumental testing to quantify material degradation, which introduces a degree of uncertainty associated with expert judgment. However, this condition reflects the constraints of real post-fire reconstruction contexts. Therefore, the proposed methodology should be understood as a decision-support framework integrated with subsequent structural verification processes, rather than as a standalone quantitative seismic performance assessment methodology.

These findings are consistent with previous studies indicating that, under moderate thermal exposure, masonry structures may retain sufficient residual load-bearing capacity, provided that appropriate strengthening strategies are implemented.

7. Conclusions

This study demonstrates that the structural rehabilitation of unreinforced masonry dwellings affected by low to moderate thermal severity fires is technically feasible when a structured post-fire assessment methodology is applied.

The proposed methodology integrates field data collection, damage interpretation, and intervention design into a coherent, traceable, and reproducible process, supporting technically sound decision-making.

A key finding is the ability to revise and reverse initial demolition decisions through the application of explicit technical criteria based on structural continuity, global stability, and damage extent. Furthermore, defining interventions based on identified structural deficits and expected structural behavior under seismic demand —rather than solely on observable damage— enhances the expected structural behavior of rehabilitated dwellings under future seismic demand and incorporates resilience criteria into the reconstruction process.

The methodology may be applicable to post-fire reconstruction scenarios involving similar unreinforced masonry typologies and comparable levels of thermal damage. Although additional validation under different building configurations and fire exposure conditions is required, the proposed framework provides a preliminary basis for future standardization of assessment and intervention criteria in post-fire scenarios in seismic regions, as well as a practical tool for decision-making in post-disaster reconstruction processes.

Assessment of the impact of mining activities with particular focus on mining tremors affecting masonry structures

Leszek SŁOWIK[1], Janusz RUSEK[2], **Leszek CHOMACKI**[1], Piotr KNYZIAK[3]

[1] Building Research Institute, Warsaw, Poland, l.slowik@itb.pl, l.chomacki@itb.pl

Abstract: The dynamic and static effects associated with underground mining cause damage to buildings within the affected area. Underground mining induces continuous and discontinuous deformations in the mining area, as well as mining-induced tremors, which pose a serious threat to building structures. Underground mining operations can also cause changes in the groundwater level, leading to the flooding. This article concerns the assessment of the impact of mining tremors on masonry buildings. The paper presents an example of structural protections during the construction phase. The strengthening counteracts the negative effects of mining tremors. The main part of the paper consists of an example of the reinforcement of a church attic under mining tremors excitation. The article presents the stability analysis of the church attic structure, which was ultimately reinforced due to the effects of mining. The example highlights the importance of the technique of reinforcing masonry structures using carbon fibre meshes, used to reduces damages caused by mining underground exploitation. The example cited in the article serves as inspiration for the effective use of this type of solution in tensile stress zones within masonry structures. This has been verified in practice following the reinforcement of the structure. The article emphasises the need to apply solutions designed to specific local conditions in order to ensure structural integrity in regions affected by mining operations and to maintain the safety of their structures. The example described may serve as inspiration for an individual and modern approach to the subject of building reinforcement and modernisation.

Keywords: mining tremors, building structures, masonry, structural reinforcement.

Seismic Vulnerability Assessment of a Heritage Unreinforced Masonry Building: Pushover Analysis

Helena Arias Lara LEITE[1,2,3], Gustavo Henrique SIQUEIRA[4]

[1] Universidade Estadual de Campinas, Campinas, SP, Brazil, h081593@dac.unicamp.br

Abstract: Cultural heritage buildings are structures that hold historical, artistic, or cultural significance and are often recognized and protected due to their value to a particular society or culture. Many of these buildings are built with unreinforced masonry (URM). For this type of structure, lateral loads — particularly seismic forces — pose the greatest risk. In this context, this paper conducted a pushover analysis (using the N2 method) of a URM heritage building in northeast Brazil to derive its fragility and capacity curves. The façade of the building was idealized with the equivalent frame (EF) method, and modelled with the OpenSees opensource software framework, using 'Concrete02' material to simulate the flexural behavior of the panel and 'pinching4' to account for shear. Several load patterns were considered in this analysis, among which the most representative ones should have been the modal and the triangular if the building studied vibrated primarily in the fundamental mode. The modal analysis, however, showed that the former affirmation is untrue, and a Modal Pushover Analysis should have been conducted instead. This is a limitation of the present work. The capacity and fragility curves were generated and, according to them, the building studied will most likely reach the first damage level (DL1 - slight damage), and has a 20% likelihood of reaching the second one (DL2 - moderate damage).

Keywords: N2 Method, Equivalent Frame Method, Seismic Vulnerability, Unreinforced Masonry Building, Pushover Analysis

1. Introduction

Despite being located in the center of the South American Plate, Brazil is not completely free from earthquakes. According to Associação Brasileira de Normas Técnicas (2023), its territory can be divided into 5 zones, ranging from 0 to 4. The less hazardous zone, which contemplates most of the country, is zone 0, and the most hazardous one is zone 4.

Hazard, however, is not the only aspect that should be taken into account when assessing seismic risk, as reminded by Liu et al. (2024): "accurate prediction of seismic risk mandates comprehensive data encompassing ground shaking intensity, demographic and socio-economic indicators, as well as the vulnerability of exposed buildings and infrastructure".

Since the colonization of Brazil took part from the Atlantic Ocean inward, coastal states hold many buildings that date back to the late 16th century, whereas western states, such as those that are home to the Amazon rainforest or the Pantanal wetland, do not. When looking at the seismic acceleration map that divides the country into 5 zones, one can notice that zones 2, 3 and 4 coincide with the Amazon rainforest and/or the Pantanal wetland; whereas three coastal states located in the northeast of Brazil - Paraíba, Rio Grande do Norte and Ceará - are classified into zone 1.

Most of these early settlements' buildings were built with unreinforced masonry (URM), a type of construction especially vulnerable to lateral loads, such as seismic loads, according to Como (2013). Several of such buildings are registered as heritage buildings, defined by UNESCO (2013 apud Leite et al., 2025) as "buildings ... that have a diversity of values including symbolic, historic, artistic, aesthetic, ethnological or anthropological scientific and social significance". Therefore, the preservation of these buildings is in our collective interest.

One way of assessing the vulnerability of a building is via its fragility curve: "a graphical representation that shows the probability of a structure experiencing different levels of damage or performance deterioration at varying intensities of ground shaking" (Camayang et al., 2024).

In this context, this paper focuses on the seismic performance assessment of the oldest church in the city of Natal (the capital city of the state of Rio Grande do Norte), an URM building registered as heritage, using nonlinear static methods. The main façade of the building was modeled using the Equivalent Frame (EF) approach (Lagomarsino et al., 2013) with distributed plasticity (DP) through OpenSees (McKenna, 2011), and its seismic performance was evaluated through the N2 Method (Fajfar, 2000).

2. Literature Review

2.1 Pushover-based Analysis

When affected by strong earthquakes, most buildings experience significant inelastic deformations. "A truly realistic assessment of structural behavior in the inelastic range can be made only through nonlinear analysis." There are different types of nonlinear analyses, among which are pushover-based methods, such as the N2 method, which are less demanding and require less data. "Pushover-based methods combine nonlinear static (i.e., pushover) analysis with the response spectrum approach". A multi-degree-of-freedom (MDOF) system is transformed into an equivalent single-degree-of-freedom (SDOF) one, and seismic demand can be obtained from this equivalent SDOF system. This transformation, however, represents the main limitation of the pushover-based methods, because it is an approximation. Despite the aforementioned limitation, if compared to traditional elastic analyses, a pushover-based analysis provides important additional information about the expected structural response, such as data on the strength and ductility of structures and design weaknesses. (Fajfar, 2021)

According to European Committee for Standardization (2004), in order to perform a pushover analysis, "at least two vertical distributions of the lateral load should be applied": a uniform one, proportional to mass; and a modal one, with forces proportional to the lateral force distribution from elastic analysis, i.e., proportional to the first mode shape. For regular buildings, this is well approximated by the triangular pattern.

2.2 The N2 Method

The N2 method was proposed by Fajfar and Gašperšič (1996) as a way of connecting pushover analysis with the response spectrum approach and "for structures that vibrate primarily in the fundamental mode", it will likely "provide reasonably reliable estimates of global seismic demand" (Fajfar and Gašperšič, 1996).

This method can be divided in several steps, according to Fajfar (2000). The first step consists on gathering the data from the structure and the elastic acceleration spectrum, from which it is possible to determine the inelastic spectra in acceleration-displacement (AD) format. After that, a pushover analysis is performed on the MDOF model, under increasing lateral load, and considering different load patterns. The subsequent step consists on the transformation of the MDOF quantities (Q) to equivalent SDOF quantities ($Q*$), as represented on eq. 1, where Γ is the transformation factor, determined by the mass of the equivalent SDOF system ($m*$) and the mass of the MDOF system (m_i) and the displacement shape (ϕ_i), as represented on eq. 2. Then, it is possible to determine the seismic demand for the equivalent SDOF system, from which it is

possible to obtain the global and local seismic demands for the MDOF model. Finally, a performance evaluation can be made, and damage can be analyzed.

$$Q^* = \frac{Q}{\Gamma} \tag{1}$$

$$\Gamma = \frac{m^*}{\sum m_i \phi_i^2} \tag{2}$$

2.3 The Equivalent Frame (EF) Method

In the EF method, the masonry building is represented by an equivalent nonlinear frame structure. “Each resistant masonry wall is subdivided into a set of deformable masonry panels, in which the deformation and the nonlinear response are concentrated, and rigid portions, which connect the deformable ones”. Whereas piers are the main vertical resistant elements (and they carry both vertical and lateral loads), spandrels are the lintels, i.e., the parts of the wall above openings, and they are “secondary horizontal elements (for what concerns vertical loads), which couple the response of adjacent piers in the case of lateral loads”. Lagomarsino et al., 2013).

The definition of the macro-elements geometry is extremely influential on the result of the analysis. A special attention must be paid to the piers, because they represent the main resisting elements of the EF scheme (Siano et al., 2018). After the definition of the macro-elements’ geometry, they must be modeled so that their behavior can be assessed. According to Siano et al. (2018), the non-linearity of the material can be taken into account by two different approaches: lumped plasticity (LP) and distributed plasticity (DP) models. According to Requena-Garcia-Cruz et al. (2023), masonry pears can have flexural or shear failure. The first “can be captured by simulating the axial load-bending moment (N-M) response”, whereas the second “is linked to the diagonal cracking failure and it can be simulated through shear force - deformation / displacement (V-γ) or (V-d) laws”.

3. Methodology

The church that is the object of study in this paper was initially built in 1601, demolished and rebuilt twice. The construction that still stands these days dates back to 1694, according to Araújo (2018). It is made of stone masonry. Its main façade is represented at Figure 1a. It was registered as a heritage building in 1992 (Fundação José Augusto, 2025). This church is located in the city of Natal, which is situated into the seismic zone 1, as highlighted in Figure 1b.

The dimensions of the frontal façade are: width = 12 meters, height of the bell tower = 13 meters, height of the cross’ support = 10 meters, height of the left part = 6 meters. The only information regarding the wall thickness that could be found is that, when the bell tower was rebuilt, it was done so as a load bearing wall with a thickness of 2 meters (Araújo, 2018). Since this information is only pertinent to the bell tower (right part of the façade), a decision was made to consider an overall thickness of 1.30 meters, which is also considerable, albeit a bit more conservative than the bell tower thickness.

In order to apply the EF Method on the church, the spandrels, piers and rigid nodes must be defined before the EF idealization, which is represented on Figure 2. The geometry of the cross section of the pier and spandrel elements was taken as an average for all elements, i.e., since the height of each element should be taken as its in plane dimension, instead of each pier and spandrel having a different height, an average was made and, for piers, the height considered was 0.60 meters, whereas for spandrels the height considered was 1.00 meter. The base considered was the out of plane dimension, i.e., the aforementioned overall thickness of 1.30 meters.

Figure 1 – a) Façade of the church studied: Igreja Matriz de Nossa Senhora da Apresentação (Arquidiocese de Natal, 2025) and b) Location of the city where the church is built according to the brazilian seismic zoning map (Associação Brasileira de Normas Técnicas, 2023; Dlubal Software GmbH, 2024)

In a similar manner as Rodrigues et al. (2024) and inspired by Requena-Garcia-Cruz et al. (2023), OpenSees was used. The materials considered were 'Concrete02' to simulate the flexural behavior of the URM panel and 'pinching4' to simulate shear. Regarding the adoption of 'Concrete02' for simulating URM, Rodrigues et al. (2024) used 'Concrete02' to simulate the flexural behavior of a URM panel of a similar church as the one studied in this paper, whereas Requena-Garcia-Cruz et al. (2023) used 'Concrete06'. Although the latter material "was originally proposed for concrete, it has been proved to satisfactorily capture the masonry behavior" (Sepe et al., 2014, apud Requena-Garcia-Cruz et al., 2023). The same justification was made by Rodrigues et al. (2024) regarding the former material.

The piers and spandrels were also implemented as a displacement-based element with fiber cross-section. Distributed plasticity was adopted for all pier and spandrel elements, modelled as displacement-based beam-column elements ('dispBeamColumn') with 5-point Gauss-Lobatto integration and fiber cross-sections. This formulation, known as DP-DI, allows inelastic deformations to spread along the element length as the analysis progresses, capturing the gradual degradation of stiffness and strength characteristic of unreinforced masonry. The nodal intersection regions were modelled as linear elastic rigid zones, consistent with the equivalent frame idealization. The nonlinear behavior of the masonry is captured by the constitutive laws assigned to the fibers for the axial-flexural response ('Concrete02' material), while the nonlinear shear response is modelled by a separate uniaxial material ('pinching4') coupled to the fiber section through an aggregated section formulation. (Rodrigues et al., 2024).

Several parameters are needed for the correct description of the shear force-deformation curve. As specified by Rodrigues et al. (2024), the ultimate shear strength follows the Turnšek and Čačovič failure criteria; the initial deformation $\gamma 1$ was taken as V3/Ke, with the initial elastic shear stiffness $K_e = GA_s$, where G is the shear modulus and A_s the cross section of the wall (and therefore different for piers and spandrels). The ultimate deformation γ_3 was specified as 0.4%, according to the recommendations of Ministero delle Infrastrutture e dei Trasporti (2019), and γ_4 was specified as 1%, according to Federal Emergency Management Agency (2000).

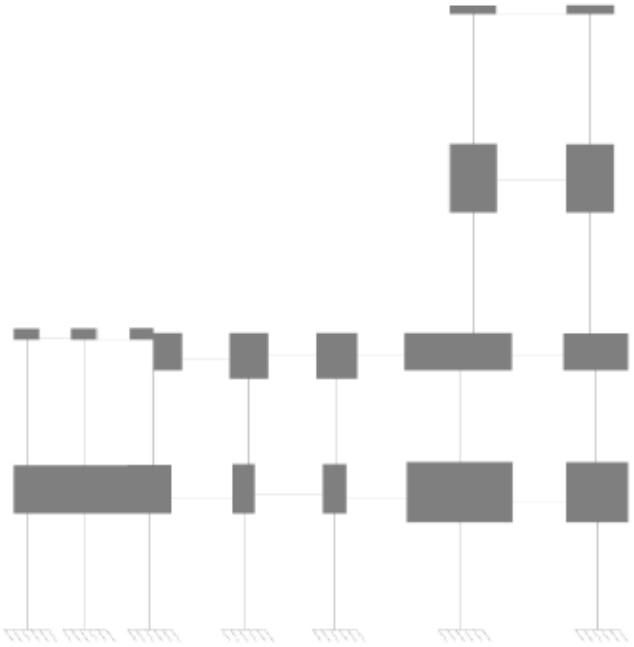

Figure 2 – Equivalent frame idealization

The parameter γ_2 was taken as the average of γ_1 and γ_3. The shear strength of the unreinforced masonry walls is given by eq. 3, where σ_0 is the average compression stress (taken as 0.10 MPa), τ_{0d} is the diagonal cracking strength (taken as 0.20 MPa), l and t are the width and the thickness of the wall section, respectively, and β is a coefficient dependent of the slenderness of the pier and spandrel elements. The residual shear strength V_4 was taken as 20% of the ultimate shear strength V_3, and V_1, V_2 and V_3 were all taken as equal to V_t.

$$V_t = 1.5\tau_{0d} lt\beta \sqrt{1 + \frac{\sigma_0}{1.5\tau_{0d}}} \tag{3}$$

The other material properties considered are shown on Table 1, where γ is the specific weight of the masonry, E is the modulus of elasticity, G is the shear modulus, f_{pc} is the compressive strength, f_t the tensile strength, ε_{c0} is the strain at peak and ε_u is the ultimate strain.

Table 1 – Mechanical properties considered for the constitutive law (Ministero delle Infrastrutture e dei Trasporti, 2019; Requena-Garcia-Cruz et al., 2023; Rodrigues et al., 2024)

γ (kN/m³)	E (MPa)	G (MPa)	f_{pc} (MPA)	f_t (MPa)	ε_{c0}	ε_u
18	1490	490	-6.2	0.18	-0.00832	-0.025

The N2 method was used, and several load patterns were considered. The patterns considered in this study are uniform (UN), mass-proportional (MASS), modal (MODAL) and triangular (TR). Roof displacement was controlled in all patterns.

Lagomarsino and Giovinazzi (2006) established a damage threshold criteria using a κ fraction of peak base shear on the ascending and descending branches of the pushover curve. The damage levels are DL1 (slight damage), DL2 (moderate damage), DL3 (extensive damage) and DL4 (collapse). κ is the total base shear divided by the maximum base shear of the pushover curve. After deriving the capacity curves for a structure and the damage thresholds for all patterns considered, the following step of this analysis is to generate the fragility curves, which represent the answer to the question "given that the seismic demand is $S_{d,pp}$, what is

the probability that the displacement exceeds each damage threshold"? According to the approach of Lagomarsino and Giovinazzi (2006), the fragility curves can be generated by, at first, identifying the displacement thresholds (MDOF) and converting them to SDOF, according to eq. 1. Then, for each damage state, the probability of exceedance given a spectral displacement S_d is calculated using a standard normal cumulative distribution function and a total dispersion $\beta = 0.50$, which accounts for both demand uncertainty (β_D) and capacity uncertainty (β_C).

3.1 An important limitation of the present study

As mentioned on the first paragraph of section 2.2, this analysis will provide reliable results "for structures that vibrate primarily in the fundamental mode" (Fajfar and Gašperšič, 1996). As the analysis progressed, the authors noticed that this structure does not have a clear dominant mode and, therefore, the results achieved have more limitations than initially predicted and a different analysis should have been conducted. A decision was made, however, to proceed with the present study, which represents an initial investigation intended to evaluate the limitations and applicability of the adopted approach, and a suggestion was given on section 5.1 for an improved analysis in order to obtain more reliable results.

4. Results and discussion

4.1 Pushover analysis and performance points

The elastic response spectrum was obtained from the brazilian standard (Associação Brasileira de Normas Técnicas, 2023) for a return period (TR) of 475 years and a soil type E with SPT N ≤ 15 in the first 30 meters. It is represented on Figure 3a. According to Associação Brasileira de Normas Técnicas (2023), Rio Grande do Norte (the state in which the heritage building is located) can be considered at zone 1, with a maximum horizontal seismic acceleration of 0.05g (g being the acceleration due to gravity), for soil type B (rocky).

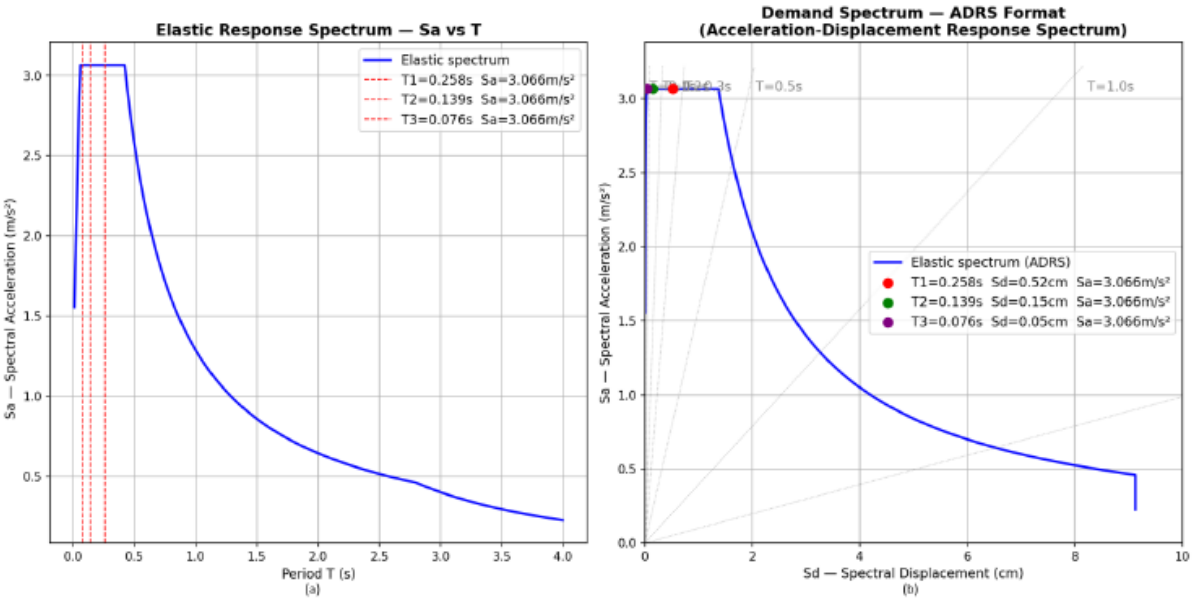

Figure 3 – (a) Response Spectrum (Sa vs T) and (b) Demand spectrum (ADRS format)

In order to convert the elastic response spectrum to the Acceleration-Displacement Response Spectrum (ADRS) format, one must calculate the spectral displacement (Sd) according to eq. 4. The ADRS is represented on Figure 3b. T1, T2 and T3 represent the modal periods of the structure, obtained from the

eigenvalue analysis of the MDOF model. In this same eigenvalue analysis, aside from the modal periods, the fraction of the total mass participating in the horizontal (direction of loading) direction for each mode (U_1), the fraction of the total mass participating in the vertical direction for each mode (U_2) and the cumulative sum ($\sum U_1$) after 3 modes were also computed, and they are shown on Table 2. It is shown that the modes are almost purely X-direction modes, which is consistent for a planar masonry wall pushed horizontally. The cumulative $\sum U_1$ = 98.2% after 3 modes means that the analysis captures almost all the seismically relevant mass in X. However, the limitation mentioned on section 3.1 can also be seen, because it is clear that modes 1 and 2 are equally dominant in this structure.

$$S_d(T) = S_a(T) \times \left(\frac{T}{2\pi}\right)^2 \tag{4}$$

Table 2 – Modal properties - First 3 modes

Mode	T (s)	U_1 (%)	U_2 (%)	$\sum U_1$ (%)
1	0.2580	49.89	0.01	49.89
2	0.1391	47.30	0.01	97.19
3	0.0763	1.00	0.00	98.20

For each load pattern, the pushover analysis is made and the N2 method is run with the objective of computing the performance point (the target displacement, i.e., the expected roof displacement under the design earthquake), the base shear at the performance point (V_t) and the spectral displacement at the performance point ($S_{d,pp}$), which is simply the SDOF target displacement. These results are all plotted on Figure 4.

4.2 Capacity and Fragility curves

The capacity curve was generated for each load pattern. The performance point and the 4 damage threshold markers were added to each curve, and they were all plotted together, as shown of Figure 4.

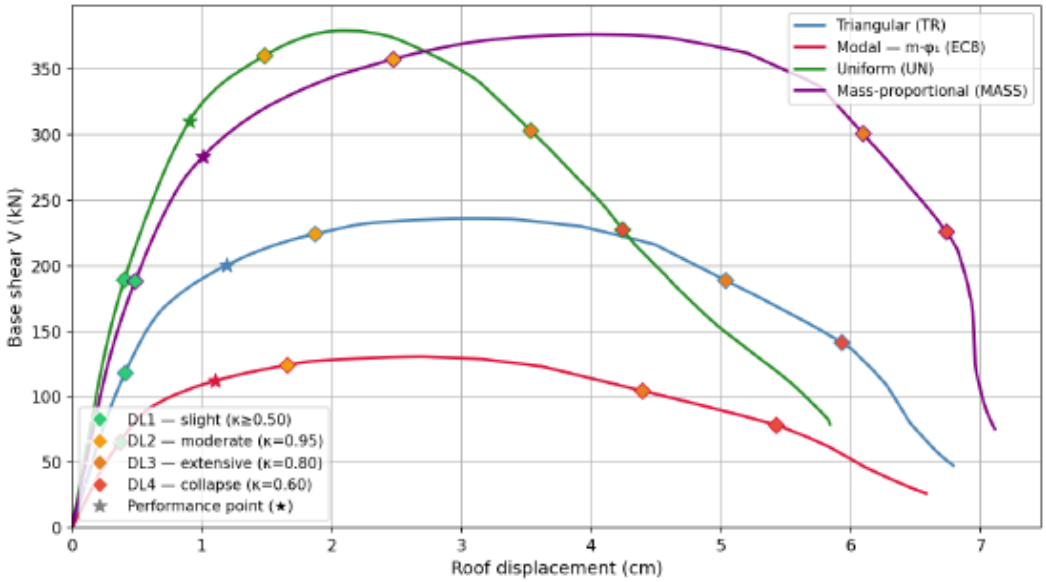

Figure 4 – Capacity curves for each load pattern, with damage threshold markers

Figure 4 shows that the uniform and mass-proportional load patterns have the highest peak base shears (379.4 kN and 376.6 kN, respectively). Additionally, the mass-proportional pattern has also the largest displacement at peak, at around 4 cm and the uniform one is the most different shape-wise. These two patterns, however, are generally considered less representative because they apply more force to lower storeys compared to triangular pattern and they tend to overestimate capacity by not capturing the whipping (or whiplash) effect of upper storeys. In the structure that is the object of this study, this effect is somewhat limited because it is a low-rise structure, therefore the height amplification is not as dramatic as it would be in a tall building.

The lowest peak base shear occurs with the modal pattern, a pattern that should be the most representative one for structures that have the first mode as a clear dominant one. Since the object of this study does not have this clear domination of one mode, as previously pointed, this is also not very representative. The triangular pattern, that should not differ much from the modal one (for regular structures), shows the second lowest peak base shear. This pattern resulted in a pushover curve similar in shape with the pushover curves generated by the modal and the mass-proportional patterns. However, European Committee for Standardization (2004) recommends it as the primary load pattern for structures where the first mode is dominant, which is not true for the structure studied in this paper, as seen on Table 2.

The fragility function was calculated for each pattern and each damage level, as shown on Table 3, and the fragility curves were generated, as shown on Figure 5.

According to these fragility curves, and considering all load patterns studied, for the response spectrum given by Associação Brasileira de Normas Técnicas (2023), the heritage building studied will most likely exceed DL1, will have a fair chance of exceeding DL2 and will most likely not exceed DL3 and DL4. From a preservation point of view, this can be viewed as positive, because the likelihood of the occurrence of moderate damaging is less than 25 %, and, therefore, no big intervention will be needed as a retrofitting strategy.

Table 3 – Fragility - Exceedance Probabilities at Performance Point (logonormal, β = 0.50)

Pattern	$S_{d,pp}$ (cm)	P(DL1) (%)	P(DL2) (%)	P(DL3) (%)	P(DL4) (%)
TR	0.665	98.4	18.2	0.2	0.1
MODAL	0.596	98.6	20.9	0.3	0.1
UN	0.905	94.6	16.1	0.3	0.1
MASS	0.847	92.8	3.7	0.0	0.0

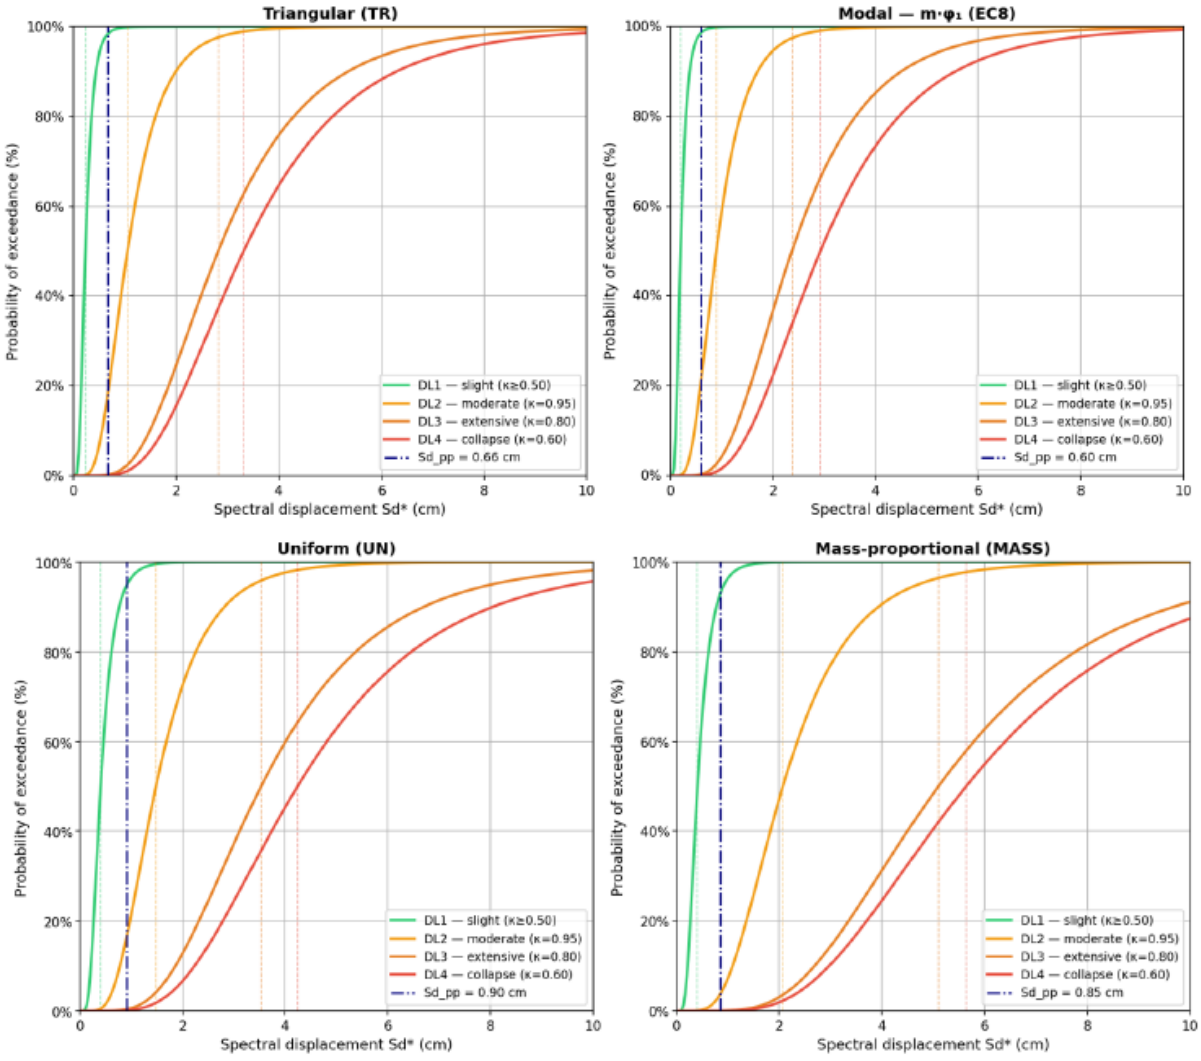

Figure 5 – Fragility curves

5. Conclusions

Despite not being on the most hazardous earthquake zone in Brazil, heritage buildings located on zone 1, such as the church 'Matriz de Nossa Senhora da Apresentação' (object of the present study) are particularly vulnerable to these types of loading. This is due to the fact that colonial or heritage buildings were built with unreinforced masonry, which can be especially susceptible to horizontal loads.

A pushover analysis is a relatively simple method that can provide reliable estimates of the seismic response of buildings. The present study derived the in-plane capacity and fragility curves of the oldest church in the Brazilian city of Natal using pushover analysis to assess its seismic vulnerability. As previously noted, although the uniform and mass proportional load patterns resulted on the highest peak base shear and the lowest probabilities of damage level exceedance, they are the least representative load patterns, because they apply more force to lower storeys compared to triangular pattern and they tend to overestimate capacity by not capturing the whipping (or whiplash) effect of upper storeys.

The patterns that resulted in the highest vulnerability and the lowest peak base shears were the triangular and the modal ones. The latter should have been the pattern that best represented the church studied, and

the former should have been the second best one; however, since the first mode is not clearly dominant, this entire analysis has more limitations than expected, and a different analysis, such as a Modal Pushover Analysis, should be conducted in order to obtain more reliable results.

After deriving the fragility curves, it was possible to ascertain that the building study will likely achieve the threshold for DL2, which results in moderate damage, but will most likely not exceed DL3 and DL4. From a preservation point of view, this can be viewed as positive, because, due to the level of damage achieved, no big intervention will be needed as a retrofitting strategy.

5.1 Suggestion for an improved study

This study was conducted with the objective of assessing the structural vulnerability of a heritage building in Brazil by deriving its capacity and fragility curves. The concept of this pushover analysis was based on the assumption that either the triangular or the modal load patterns would be a good representation of the dynamic inertia force distribution for this structure. This would be true for structures that have a clear dominant mode. In this case, the nearly equal participation of the first two modes is likely a consequence of the structural irregularity. A single pushover analysis with any fixed load pattern is questionable when two modes have nearly equal participation, because no single static load distribution can adequately represent the dynamic response, and, therefore, further studies about this particular structure, in order to improve the quality of the representation of the resulting pushover curve, are necessary. A more rigorous approach would be a Modal Pushover Analysis (MPA), as suggested by Chopra and Goel (2002), which runs separate pushovers for each significant modes and combines the results.

Resumo:

Os eventos climáticos extremos ocorridos no Rio Grande do Sul em 2024 produziram danos extensivos à infraestrutura pública e comprometeram, de modo particularmente severo, a rede de educação básica. Em resposta, o Governo Federal estruturou, no âmbito do Fundo Nacional de Desenvolvimento da Educação (FNDE) e do Ministério da Educação (MEC), um programa emergencial destinado à recomposição integral de escolas e creches atingidas, com base em critérios técnicos, normativos e orçamentários. O presente artigo analisa o processo de seleção de 28 propostas de reconstrução, com apoio em laudos técnicos padronizados de engenharia, nos projetos referenciais do FNDE e na sistematização dos dados constantes de base de dados estruturada, com ênfase nos aspectos técnico-patológicos, locacionais e financeiros. Os resultados, na análise da infraestrutura, evidenciam predominância de grau de risco crítico, recorrência de patologias associadas à ação da água, comprometimento estrutural e funcional de diversos sistemas construtivos e recomendação majoritária de mudança de local para implantação de novas unidades em localidades mais seguras. No plano financeiro, verificou-se investimento total de R$ 191.167.583,92, distribuído entre creches e escolas padronizadas, com destaque para o Município de Estrela/RS, que concentrou seis propostas e adotou solução construtiva industrializada. Conclui-se que o Programa Emergencial se configura como instrumento essencial para a recomposição plena da rede física educacional, reforçando a diretriz de reconstrução total — e não de reformas paliativas — como resposta adequada aos danos decorrentes dos desastres climáticos.

Palavras-chave: Reconstrução escolar; Patologia das construções; Desastres climáticos; Infraestrutura educacional; FNDE.

1. Introdução

A intensificação dos eventos climáticos extremos tem imposto desafios crescentes à infraestrutura pública brasileira, especialmente nos territórios sujeitos a enchentes, enxurradas, alagamentos recorrentes e instabilidades geomorfológicas. No Rio Grande do Sul, os eventos de 2024 produziram efeitos devastadores sobre a rede pública de ensino, comprometendo edifícios escolares, equipamentos, instalações, acessos e condições mínimas de segurança para o funcionamento das atividades educacionais.

No âmbito da resposta federal, o Programa Reconstrução Emergencial do RS foi estruturado a partir de um desenho técnico-administrativo que condicionou o repasse de recursos à apresentação de laudos de engenharia capazes de demonstrar, com evidências objetivas, a extensão dos danos, a criticidade dos sistemas construtivos e a inviabilidade de recuperação da infraestrutura existente. Tal desenho permitiu qualificar a seleção das propostas com base em parâmetros uniformes de avaliação, ancorados em modelo padronizado de laudo disponibilizado aos proponentes.

Este artigo tem por objetivo examinar, em perspectiva técnico-acadêmica, o processo de seleção das propostas, a função dos laudos técnicos padronizados, os critérios de enquadramento em reconstrução, os principais achados patológicos identificados e a distribuição financeira dos investimentos realizados nas 28 propostas aprovadas. Para robustecer a análise, são tomados como casos ilustrativos os laudos da EMEI Amiguinhos da Natureza, no Município de Relvado/RS, e da EMEI Criança Feliz, no Município de Estrela/RS, ambos emblemáticos quanto à relação entre dano construtivo, vulnerabilidade locacional e decisão pela reconstrução integral em novo local.

2. Metodologia

A pesquisa caracteriza-se como documental, descritiva e analítica, com base em documentação técnica oficial produzida no âmbito do Programa Emergencial de Reconstrução da infraestrutura educacional do Rio Grande do Sul. O corpus documental foi composto por quatro eixos de evidência: (i) o Modelo de Laudo Técnico Comprobatório de Comprometimento da Infraestrutura Escolar, disponibilizado pelo FNDE aos entes proponentes; (ii) os laudos técnicos individuais elaborados pelos municípios; (iii) Base de dados consolidados dos laudos e das propostas, com ênfase na caracterização e sistematização dos danos evidenciados; e (iv) as consolidações financeiras por município e por tipologia de projeto padronizado.

O modelo de laudo foi concebido para padronizar o levantamento dos danos e organizar a análise por sistemas construtivos — cobertura, vedações, instalações hidrossanitárias, instalações elétricas, pisos, estrutura e paisagismo — classificando-os segundo graus de risco e impacto de recuperabilidade, em conformidade com a terminologia da inspeção predial adotada pelo documento.

No tratamento dos dados, procedeu-se à leitura técnica dos laudos e à extração sistemática das variáveis constantes da planilha consolidada: localização anterior e atual, recomendação de novo local, vulnerabilidade da área, recorrência de sinistros, classificação dos subsistemas, grau de risco, impacto, proposta indicada, valor de investimento, valor pago e estágio de execução. O cruzamento desses dados permitiu analisar conjuntamente os aspectos patológicos, locacionais, institucionais e financeiros do processo.

Como estudos de caso ilustrativos, foram mobilizados dois laudos. O primeiro, referente à EMEI Amiguinhos da Natureza, registra que a unidade foi atingida pela enxurrada, situa-se em área vulnerável, possui arroio nas proximidades e teve expressa recomendação de mudança de local, culminando com conclusão pela reconstrução total da escola em outro espaço fora da área de risco. O segundo, referente à EMEI Criança Feliz, registra exposição de 87 horas à enchente, implantação em área alagável, recorrência de agravos ambientais, comprometimento de múltiplos sistemas e conclusão pela reconstrução total em outro local, com demolição do imóvel atual e limpeza final do lote.

3. Desenvolvimento do tema

3.1. Procedimentos para seleção das propostas do Programa Reconstrução Emergencial do RS.

O processo de seleção das propostas foi estruturado com base na Medida Provisória nº 1.248/2024 e na Resolução FNDE nº 12/2024, que estabeleceram critérios técnicos e administrativos para o repasse de recursos federais destinados à reconstrução de unidades escolares.

Foram selecionadas 28 propostas, abrangendo escolas de ensino fundamental e creches, cujos imóveis apresentaram danos classificados como severos ou irrecuperáveis. Entre os principais critérios adotados destacam-se: a comprovação de comprometimento estrutural, a exposição recorrente a riscos ambientais e a inviabilidade técnica ou econômica de recuperação das edificações existentes. Recursos disponibilizados aos municípios nas ações de reforma

A seleção das propostas de reconstrução foi estruturada a partir de um fluxo técnico-administrativo orientado por comprovação documental, laudo técnico mais ART, do comprometimento da unidade escolar atingida. O ingresso no programa exigiu laudo técnico formal subscrito por profissional habilitado, contendo caracterização do imóvel, identificação dos danos, classificação dos sistemas construtivos, análise do grau de risco e conclusão objetiva quanto à necessidade de reconstrução.

No conjunto examinado, foram contemplados 16 municípios, consolidadas 28 propostas de reconstrução, distribuídas entre as tipologias Creche Tipo 1 (7 propostas), Creche Tipo 2 (9 propostas), Escola 13 Salas (1 proposta), Escola 5 Salas (8 propostas) e Escola 9 Salas (3 propostas), totalizando R$ 191.167.583,92 em valor de investimento previsto.

A seleção evidenciou que o programa federal foi concebido para recompor integralmente a capacidade física da rede de ensino afetada, e não para financiar intervenções pontuais de reparo. A base de dados consolidada registra, para as 28 propostas, indicação de solução correspondente à reconstrução, inclusive nos casos em que o impacto foi classificado como “recuperável”, uma vez que a exposição recorrente ao risco e o custo técnico-social de permanência no local justificaram a substituição integral da infraestrutura. As Figuras 1 e 2 ilustram, de forma sucinta, os danos registrados nos 16 municípios mais afetados, os quais foram contemplados com novas infraestruturas de ensino.

Figura 1 – Imagens dos danos causados nas enchentes do Rio Grande do Sul (A).

Figura 2– Imagens dos danos causados nas enchentes do Rio Grande do Sul (B).

3.2. O modelo de laudo técnico como instrumento de padronização e decisão

O Modelo de Laudo Técnico Comprobatório de Comprometimento da Infraestrutura Escolar disponibilizado pelo FNDE cumpriu função estruturante no processo de seleção, ao padronizar os níveis de inspeção, os subsistemas a serem observados, a classificação do grau de risco e a formulação da conclusão final. O documento orienta a vistoria por métodos não destrutivos e inspeção visual, além de exigir registro fotográfico e análise segmentada dos sistemas prediais, em consonância com a lógica da inspeção predial e da patologia das construções.

O modelo organiza a avaliação segundo três níveis de resposta: grau de risco crítico, associado a impacto irrecuperável ou a custo excessivo de recuperação; grau de risco regular, associado a perda parcial de desempenho; e grau de risco satisfatório, quando não há anomalias significativas. Tal arquitetura metodológica permitiu que os dados dos laudos fossem transpostos para a planilha de sistematização, formando uma base comparável entre municípios e unidades escolares distintas.

A relevância desse instrumento pode ser observada tanto no laudo da EMEI Amiguinhos da Natureza quanto no da EMEI Criança Feliz, que reproduzem a lógica do modelo: caracterização da unidade, definição do nível de inspeção, classificação por sistemas, discussão dos danos, análise do risco e conclusão pela reconstrução. Em ambos os casos, a decisão final não decorre apenas de avarias localizadas, mas da combinação entre dano físico, recorrência de agravos ambientais e risco futuro de reocupação do mesmo sítio.

3.3. Projetos padronizados do FNDE e sistemas construtivos industrializados

As propostas aprovadas tomaram por referência os projetos padronizados do FNDE, abrangendo creches Tipo 1 e Tipo 2, figura 3, bem como escolas de 5, 9 e 13 salas, figura 4. A base de dados consolidada demonstra que a recomposição da rede foi estruturada por meio dessas tipologias, o que assegurou padronização orçamentária, compatibilidade entre demandas e projetos e maior racionalidade na instrução das propostas.

Figura 3 – Detalhes dos projetos padronizados – Creches Tipo 1 e Tipo 2

Figura 4 – Detalhes dos projetos padronizados – Escolas 5, 9 e 13 Salas

Do ponto de vista estratégico, a adoção de projetos padronizados facilita não apenas a seleção das propostas, mas também a análise técnica posterior, a contratação, o acompanhamento e a fiscalização. No contexto emergencial, tal opção reduz incertezas de escopo, encurta o tempo de maturação dos empreendimentos e favorece a previsibilidade do custo público necessário para recomposição da oferta educacional.

Além disso, estudo indica a adoção de solução industrializada em propostas do Município de Estrela/RS, aspecto que se associa à estratégia de imprimir maior celeridade à execução das obras. Esse recorte é particularmente relevante porque o município de Estrela concentrou seis propostas, todas registradas com a indicação para solução industrializada, evidenciando o uso do mecanismo como instrumento de resposta mais rápida à emergência.

3.4. Sistematização dos dados e metodologia de análise dos laudos

O procedimento metodológico envolveu: (i) leitura individualizada dos laudos técnicos; (ii) extração padronizada das informações relativas aos sistemas construtivos; (iii) classificação das manifestações patológicas e do grau de risco; (iv) análise cruzada entre recorrência de sinistros, localização e conclusão técnica; e (v) a sistematização dos dados para avaliação do enquadramento das propostas no Programa Emergencial.

A análise foi orientada por referências do campo da patologia das construções, normas técnicas brasileiras e diretrizes institucionais do FNDE.

A base de dados sistematizada, em formato matricial, sintetiza os dados extraídos dos laudos e organiza a análise por eixos: características do terreno e da localização, vulnerabilidade ambiental, recorrência de sinistros, estado dos sistemas construtivos, correlações patológicas, grau de risco, impacto, proposta de solução, indicação de novo local, valores de investimento e estágio de execução. Essa estrutura viabiliza uma leitura sistêmica do conjunto das 28 propostas.

A sistematização demonstra que a avaliação não se limitou a uma percepção impressionista do dano, mas foi composta por uma cadeia lógica: identificação dos agravos; classificação de cada sistema; consolidação do risco global; verificação da possibilidade de permanência ou realocação; e definição da resposta pública adequada. Tal metodologia é especialmente relevante em cenários de desastre, nos quais a pressão por rapidez pode comprometer a qualidade da decisão se não houver um protocolo técnico claro.

No caso da EMEI Amiguinhos da Natureza, por exemplo, o laudo registrou danos severos em esquadrias, cercamentos, instalações elétricas e componentes diversos, além da localização em área alagável próxima ao arroio, concluindo pela reconstrução total em novo local. Já no caso da EMEI Criança Feliz, o laudo documentou que a escola, edificada em concreto armado e com dois pavimentos, permaneceu exposta por 87 horas à enchente, encontrava-se em área vulnerável e alagável, e teve cobertura, forro, instalações, vedações e partes estruturais severamente comprometidos, culminando com recomendação de reconstrução em outro local e demolição do imóvel existente.

3.5. Recursos disponibilizados aos municípios nas ações de Reconstrução

No plano financeiro, a política de reconstrução foi estruturada a partir de valores de referência vinculados às tipologias padronizadas do FNDE. A consolidação da planilha demonstra que, entre as 28 propostas, os investimentos variaram de R$ 3.461.389,15, correspondente ao menor valor registrado para Creche Tipo 2, até R$ 13.413.560,69, referente à proposta de Escola 13 Salas contemplada no Município de Estrela/RS, totalizando R$ 191.167.583,92 em investimentos previstos para recomposição da rede escolar.

A distribuição por tipologia revela concentração em unidades de educação infantil e escolas de porte intermediário: 9 Creches Tipo 2, somando R$ 38.678.824,66; 8 Escolas 5 Salas, somando R$ 67.133.356,88; 7 Creches Tipo 1, com R$ 41.926.925,66; 3 Escolas 9 Salas, com R$ 30.014.916,03; e 1 Escola 13 Salas, com R$ 13.413.560,69. Esse perfil mostra que a recomposição se concentrou na educação infantil e na oferta de escolas padronizadas de menor e médio porte, compatíveis com a distribuição territorial dos danos.

Sob a ótica territorial, os maiores volumes financeiros se concentraram em Estrela/RS (R$ 35.944.701,09), Cruzeiro do Sul/RS (R$ 30.921.748,24), Rio Grande/RS (R$ 16.783.339,22), Lajeado/RS (R$ 15.751.711,42), Marques de Souza/RS (R$ 13.466.361,16) e Relvado/RS (R$ 11.853.058,76). Em Estrela, o montante representa aproximadamente 18,8% de todo o volume previsto para as 28 propostas, o que reforça a centralidade do município no recorte empírico do estudo.

A base de dados também registra R$ 18.964.477,70 como valor pago até o estágio de consolidação apresentado, o que corresponde a cerca de 9,9% do investimento total previsto, revelando que o programa se encontrava em fase inicial ou intermediária de implementação no momento do registro. Esse dado é compatível com a presença, na base, de empreendimentos “em licitação” e “em execução”, com percentuais físicos ainda reduzidos em várias propostas.

Do ponto de vista do desenho da política pública, é importante enfatizar que esses recursos não se destinam à simples reforma da infraestrutura atingida, mas à reconstrução integral da unidade escolar, com base em um novo projeto, nova implantação ou redefinição segura do local, assegurando apoio financeiro suficiente para recompor plenamente a capacidade instalada da rede educacional. A coerência entre a lógica financeira e a lógica técnica aparece no estudo com o indicativo de solução “RECONSTRUÇÃO” para todas as propostas analisadas.

3.6. Descrição dos dados nos municípios mais atingidos (estrela/RS)

Para aprofundar o estudo, elegeu-se o Município de Estrela/RS como recorte analítico específico, por duas razões principais: (i) trata-se do município com maior volume financeiro entre as propostas analisadas, totalizando **R$ 35.944.701,09**; e (ii) foi o município que, no conjunto observado, aparece associado à adoção de solução construtiva industrializada em todas as suas seis propostas.

Em Estrela, as seis propostas distribuíram-se da seguinte forma: 1 Escola 13 Salas (EMEF Leo Joas) no valor de **R$ 13.413.560,69**; 4 Creches Tipo 2 — EMEI Arroio do Ouro, EMEI Cantinho do Lar, EMEI Criança Feliz e EMEI Pingo de Gente — cada uma com valor de **R$ 3.980.597,52**; e 1 Creche Tipo 1 (EMEI Raio de Sol) no valor de **R$ 6.608.750,32**. O conjunto revela um desenho de recomposição que combina grande unidade escolar com forte presença de equipamentos de educação infantil.

A base consolidada registra, para as propostas de Estrela, predominância de área vulnerável, recorrência de sinistros e recomendação de novo local, com exceção de algumas especificidades de classificação de impacto e estado dos sistemas. Também registra, de maneira expressa, a opção por solução industrializada, associada à necessidade de maior rapidez na execução das obras diante da magnitude do desastre e da urgência da retomada do atendimento educacional.

O laudo da EMEI Criança Feliz oferece importante densidade qualitativa para interpretar esse conjunto. A escola foi descrita como edificação de concreto armado, dois pavimentos, com 547,58 m² de área construída, implantada em terreno plano, porém localizada em área vulnerável, com recorrência de agravos ambientais, em área alagável, e com recomendação de mudança de local. O documento registra ainda que a escola permaneceu 87 horas exposta à enchente e que a cota do terreno era de 24,00 m, abaixo da condição considerada adequada para novas construções no município.

Do ponto de vista dos sistemas construtivos, o laudo da Criança Feliz é particularmente elucidativo: classificou como críticos os subsistemas de cobertura (estrutura de suporte, calhas e telhas), as vedações (pintura, alvenaria, esquadrias, revestimentos e forro), as instalações hidrossanitárias, as instalações elétricas, o piso interno e os elementos de paisagismo; na estrutura, registrou vigas em condição crítica e lajes e pilares em condição regular, com observação de percolação excessiva e danos decorrentes do impacto de objetos arrastados pela enchente, inclusive árvores e silos oriundos de indústria vizinha.

O laudo também consignou perda de seção em vigas, armaduras expostas, trechos de alvenaria em ruínas, destruição quase integral das telhas e da estrutura do telhado, comprometimento total da entrada de energia e previsão de obstrução generalizada das instalações hidrossanitárias. Ao final, concluiu pela reconstrução total em outro local, acompanhada de demolição do imóvel atual e limpeza final do lote, por considerar excessivo o custo de recuperação e inadequada a permanência da escola em área sujeita a novas enchentes.

Esse quadro aproxima-se, em essência, da situação registrada no laudo da EMEI Amiguinhos da Natureza, figura 5, também classificada em área vulnerável, com proximidade de curso d'água, danos severos e recomendação de mudança de local. Em ambos os casos, o programa federal opera não como mecanismo de restauração pontual, mas como instrumento de recomposição definitiva da rede, ancorado na retirada das unidades de contextos territoriais reiteradamente inseguros.

Figura 5 – Detalhes dos danos evidenciados nos laudos da EMEI Criança Feliz, no município de Estrela, RS

3.7. Principais achados técnicos e visão sistêmica dos dados

A leitura sistêmica das 28 propostas evidencia uma predominância de diagnósticos associados à umidade excessiva, fissuração, arrancamento, obstrução, oxidação, desplacamento, instabilidade estrutural, entulhamento e, em alguns casos, ataque biológico. Esses descritores aparecem consolidados na planilha

como correlações patológicas dos diversos sistemas construtivos, demonstrando que os danos não se restringiram a acabamentos, mas afetaram o desempenho global das edificações.

No campo locacional, a base de dados consolidada aponta que 25 das 28 propostas apresentam recomendação de novo local, enquanto apenas 3 permanecem associadas à não recomendação de mudança. Esse dado reforça a centralidade da variável territorial na decisão administrativa: o problema não era apenas o dano construtivo pretérito, mas a forte probabilidade de sua recorrência caso a unidade permanecesse implantada no mesmo sítio de risco.

Os dois laudos de caso são ilustrativos desse raciocínio. Na EMEI Amiguinhos da Natureza, o laudo conclui pela reconstrução total em outro espaço fora da área de risco de alagamentos, sublinhando a vulnerabilidade locacional da unidade. Na EMEI Criança Feliz, figura 6, embora alguns elementos estruturais ainda apresentassem classificações intermediárias, o laudo é categórico ao apontar que o custo excessivo de recuperação, aliado à permanência em área alagável e abaixo da cota considerada adequada, inviabiliza a recuperação e justifica a reconstrução em novo local.

Figura 6 – Detalhes dos danos evidenciados nos laudos da EMEI Criança Feliz, no município de Estrela, RS

Esses achados demonstram que, no âmbito do Programa Emergencial, a noção de "reconstrução" deve ser compreendida em sentido amplo: trata-se da recomposição total e segura da capacidade física da unidade escolar, inclusive com redefinição de implantação territorial, e não de mera reposição de componentes danificados.

3.1. Gargalos institucionais na fase licitatória dos empreendimentos

No debate brasileiro sobre implementação de políticas públicas, a noção de capacidade estatal remete ao conjunto de recursos burocrático-institucionais, organizacionais e políticos que permitem ao Estado formular, coordenar e executar políticas de forma efetiva; mais do que um estoque abstrato de recursos, tais capacidades precisam ser ativadas por arranjos de implementação capazes de articular atores, instrumentos e processos em contextos concretos de ação governamental. No campo das contratações públicas, essa discussão ganha densidade específica porque a Lei nº 14.133/2021 elevou o planejamento à condição de princípio e estruturou o processo licitatório como um fluxo que abrange fase preparatória, análise de riscos, definição do modelo de gestão contratual, critérios de medição e pagamento, controle jurídico e posterior acompanhamento da execução.

À luz desse referencial, os dados das 28 propostas indicam que o principal gargalo da fase licitatória não está mais na ausência de projetos, uma vez que todos os empreendimentos constam com estudo ou projeto finalizado, mas na incapacidade de converter essa maturidade técnica em contratação efetiva. Metade da carteira permanece em licitação e, nesse subconjunto, predominam pendências relacionadas à revisão da

documentação técnico-financeira, à liberação de etapas formais para início da obra e ao não encaminhamento de documentos para análise, o que revela fragilidades no arranjo de implementação que conecta município, mandatária e instâncias de validação. Em termos analíticos, isso sugere que a existência de suporte procedimental da Caixa Econômica não elimina, por si só, os custos de coordenação, saneamento técnico e gestão de riscos que a literatura e o TCU reconhecem como centrais na fase preparatória das contratações.

3.2. Gargalos institucionais na fase de execução dos empreendimentos

Na etapa de execução, o problema assume outra feição. A literatura técnico-institucional brasileira sobre obras públicas enfatiza que o êxito do empreendimento depende de um ciclo que começa antes da licitação e prossegue com contratação, fiscalização, medição, pagamento e prestação de contas; por isso, a simples formalização contratual não assegura a entrega do objeto. Esse padrão aparece de forma nítida na carteira analisada: embora 14 propostas estejam classificadas como “em execução”, o montante efetivamente pago corresponde a apenas 9,92% do total empenhado, e parcela expressiva dos casos ainda depende da primeira medição, do desbloqueio de conta ou da regularização do fluxo de repasses para avançar fisicamente. À luz da Lei nº 14.133/2021 e das orientações do TCU, isso indica um deslocamento do gargalo da licitação para a gestão contratual, isto é, para o acompanhamento da execução, a atualização dos riscos, a fiscalização do objeto e a liberação tempestiva dos pagamentos. Observa-se que a escassez de equipes técnicas em municípios de pequeno porte, muitas vezes carentes de especialistas em arquitetura e engenharia, compromete a celeridade dos processos administrativos.

Desse modo, o caso analisado reforça uma hipótese recorrente na literatura brasileira: em políticas intensivas em coordenação federativa e contratação de obras, a efetividade não depende apenas de autorização formal para contratar, mas da capacidade de sustentar, ao longo do ciclo, mecanismos de planejamento, controle, fiscalização e articulação entre os atores envolvidos. No plano empírico, isso significa que os atrasos observados decorrem menos de um déficit isolado de projeto e mais de uma combinação entre fragilidade de planejamento operacional, morosidade no saneamento das pendências licitatórias e baixa conversão da execução contratual em avanço físico-financeiro, com impacto direto sobre o prazo de entrega das unidades. Na figura 7 mostra-se a obra mais avançada do programa de reconstrução, localizada no município de Encantado/RS.

Figura 7 – Detalhes da Construção da Creche – EMEI Lago Azul, Encantado/RS.

3.3. Análise crítica do processo: da seleção das propostas à implementação dos empreendimentos

A análise do processo de reconstrução da infraestrutura escolar do Rio Grande do Sul revela um desenho institucional consistente na identificação do problema e na seleção das intervenções, mas com limitações relevantes na capacidade de implementação. O programa demonstrou elevada robustez na fase de

diagnóstico técnico, ancorada em laudos padronizados e critérios homogêneos de classificação do dano, mas encontrou maiores dificuldades na transição entre aprovação, licitação, execução e entrega das unidades. Essa assimetria entre qualidade do diagnóstico e morosidade da implementação é compatível com a literatura brasileira sobre capacidades estatais, que aponta que instrumentos e normas, por si sós, não asseguram efetividade sem arranjos operacionais capazes de ativá-los ao longo de todo o ciclo da política pública.

Entre os pontos fortes, destaca-se a forma de seleção das propostas, baseada em laudos técnicos padronizados, que conferiram objetividade à tomada de decisão e reduziram a discricionariedade. A análise não se restringiu ao dano construtivo imediato, mas incorporou de maneira sistemática a variável territorial, especialmente a recorrência de alagamentos e a permanência das unidades em áreas vulneráveis. O fato de 25 das 28 propostas apresentarem recomendação de novo local evidencia que a política foi orientada por uma lógica de reconstrução segura, voltada à mitigação do risco futuro e não apenas à reposição física da edificação perdida.

Outro aspecto positivo foi a adoção dos projetos padronizados do FNDE, que assegurou coerência técnica, previsibilidade orçamentária e maior racionalidade à carteira de investimentos. Essa estratégia reduziu incertezas de escopo, facilitou a análise das propostas e favoreceu a compatibilização entre demandas municipais e soluções previamente consolidadas. No caso de Estrela/RS, a adoção de sistemas construtivos industrializados sinaliza tentativa de acelerar a resposta pública em contexto emergencial, sem abdicar de parâmetros mínimos de padronização e controle. O programa, portanto, acertou ao combinar padronização técnica, financiamento integral e diretriz de reconstrução total, afastando soluções paliativas.

Não obstante, os dados evidenciam gargalos relevantes na fase licitatória. Embora todos os empreendimentos possuíssem projetos finalizados, metade da carteira permanecia em licitação, com pendências concentradas na revisão técnico-documental, na liberação de etapas formais e, em alguns casos, na ausência de documentos enviados para análise. Esse quadro indica que o problema deixa de ser técnico-construtivo e passa a ser técnico-administrativo, revelando fragilidades na coordenação entre municípios, mandatária e instâncias de validação. A atuação da Caixa Econômica reforça controles e regularidade procedimental, mas não elimina as assimetrias de capacidade administrativa entre os entes subnacionais, o que contribui para a lentidão do fluxo.

Em síntese, o programa apresenta força seletiva e fragilidade implementacional. Sua robustez reside no diagnóstico técnico, na incorporação do risco territorial e na padronização das soluções; sua limitação está na conversão dessas decisões em execução físico-financeira tempestiva. O caso evidencia que políticas de reconstrução pós-desastre exigem não apenas projetos e orçamento, mas capacidade estatal continuada para articular seleção, licitação, gestão contratual e execução de forma integrada e célere.

Na figura 8 mostra-se o itinerário ao longo do tempo das principais fases da reconstrução das escolas no Rio Grande do Sul.

Figura 8 – Etapas Técnico-Administrativa da Reconstrução de Escolas e Creches no Rio Grande do Sul.

3.4. Plano de ação estruturado p/ ser atendido às recorrentes catástrofes

A experiência do Rio Grande do Sul evidencia que a resposta pública à destruição da infraestrutura escolar não pode depender, a cada evento extremo, da criação de medidas casuísticas e de novos atos normativos, pois esse modelo tende a ampliar o intervalo entre o desastre e a implementação das soluções educacionais. Nesse contexto, mostra-se necessária a instituição de um plano de ação estruturado e permanente, capaz de ser acionado automaticamente quando houver reconhecimento federal de situação de emergência ou estado de calamidade pública.

Essa formulação encontra respaldo em proposta institucional recente voltada ao aperfeiçoamento dos instrumentos de resposta do FNDE em contextos de emergência e calamidade pública, a qual defende a criação de mecanismo normativo prévio capaz de acionar automaticamente procedimentos excepcionais sempre que houver reconhecimento federal da situação de crise, sem necessidade de edição de novos atos a cada ocorrência. Em termos operacionais, esse protocolo deve prever a habilitação imediata dos entes federativos atingidos, a simplificação dos fluxos de adesão e análise técnica, a priorização administrativa das demandas emergenciais e a utilização de modelos e parâmetros previamente aprovados para a reconstrução da infraestrutura escolar.

Os achados do estudo reforçam a pertinência dessa proposta, uma vez que o principal entrave observado não esteve na ausência de solução técnica, mas na dificuldade de converter, com rapidez, propostas já estruturadas em contratação e execução efetiva. Assim, um plano de ação estruturado permitiria reduzir etapas redundantes, conferir maior celeridade à resposta institucional e aproximar o tempo da política pública da urgência imposta pelos desastres climáticos, preservando os mecanismos de controle e prestação de contas.

Desse modo, a institucionalização de um protocolo permanente de resposta educacional a calamidades públicas representa avanço na capacidade estatal de garantir continuidade ao serviço público de educação em contextos de crise. Mais do que medida administrativa, trata-se de converter a experiência acumulada no caso gaúcho em referência para futuros programas emergenciais, tornando a reconstrução da infraestrutura escolar menos contingente e mais célere, previsível e coordenada.

4. Conclusões

O presente artigo analisou o processo de reconstrução da infraestrutura escolar do Rio Grande do Sul após o desastre climático de 2024, com foco na seleção de 28 propostas, no papel dos laudos técnicos padronizados, na adoção de projetos referenciais do FNDE e nos desafios institucionais observados nas fases licitatória e executiva. Os resultados demonstram que o Programa Emergencial foi eficaz na identificação do dano, na qualificação técnica das decisões e na orientação pela reconstrução integral e segura das unidades escolares, especialmente ao incorporar a variável territorial e a recorrência do risco como elementos centrais da tomada de decisão.

Entretanto, a análise crítica evidencia que a robustez do diagnóstico e da seleção não se converteu, com a mesma intensidade, em capacidade de implementação. A permanência de parcela significativa da carteira em licitação, a baixa conversão do valor empenhado em execução física e a dependência de medições iniciais para liberação de recursos revelam limites estruturais na travessia entre aprovação e entrega das obras. Esse descompasso confirma que, em políticas públicas intensivas em coordenação federativa e contratação de obras, a efetividade depende menos da autorização formal e mais da capacidade de sustentar, ao longo do ciclo, mecanismos integrados de planejamento, gestão contratual, fiscalização e pagamento.

À luz desse diagnóstico, a conclusão central do artigo é que a reconstrução pós-desastre demanda a institucionalização de instrumentos permanentes de resposta emergencial, capazes de serem

automaticamente acionados a partir do reconhecimento federal de situação de emergência ou calamidade pública. A proposta de um Protocolo FNDE de Resposta Educacional a Calamidades Públicas, com habilitação automática dos entes afetados, simplificação dos fluxos de adesão e análise, priorização administrativa e uso de parâmetros e modelos previamente aprovados, emerge como desdobramento lógico das evidências analisadas. Tal mecanismo permitiria reduzir etapas administrativas, conferir maior celeridade à atuação institucional e alinhar o tempo da política pública à urgência imposta pelos desastres climáticos, sem prejuízo do controle, da transparência e da prestação de contas.

Conclui-se, portanto, que o principal legado do programa analisado não se restringe à recomposição física das 28 unidades escolares, mas à demonstração de que a resposta pública a eventos climáticos extremos exige arranjos institucionais mais ágeis, previamente regulamentados e orientados à continuidade do serviço educacional. Ao evidenciar simultaneamente os acertos do modelo de seleção e as limitações da implementação, o estudo contribui para o aperfeiçoamento de futuras políticas emergenciais, apontando que a reconstrução segura da infraestrutura educacional deve ser acompanhada de uma governança excepcional de implementação, capaz de transformar diagnóstico qualificado em entrega efetiva no tempo exigido pela emergência.

É fundamental otimizar o fluxo administrativo para viabilizar as contratações por dispensa de licitação em casos emergenciais. Como a legislação impõe prazos rigorosos para essa modalidade, a elaboração dos projetos e a instrução processual devem ser céleres, garantindo que o município aproveite a prerrogativa legal dentro do tempo permitido.

Agradecimentos

Ao corpo técnico do FNDE e Secretarias Municipais de Educação do RS.

Abstract: The increasing frequency and intensity of natural hazards associated with climate change and environmental degradation have progressively challenged traditional approaches to building pathology and construction repair, traditionally focused on resistance and post-damage intervention. In this context, the resilience concept has progressively evolved from a predominantly structural and resistance-based paradigm to a multidimensional framework encompassing robustness, redundancy, adaptability, rapid recovery, and learning capacity of the built environment. This work reviews the resilience concept through history as well as the main natural hazards relevant to the built environment, highlighting their impacts on critical assets. Emphasis is placed on infrastructures and building stocks exhibiting heightened vulnerability, including aging residential and industrial buildings, transport and utility networks, cultural heritage assets, and urban areas characterized by high exposure and interdependency among systems. Despite progress in resilience science, major gaps persist in multi-hazard modelling and GEOAI-enabled diagnostics for the built environment. Existing assessments remain largely static and hazard-specific, failing to represent dynamic, interacting risks across different hazards and interlinked infrastructure networks. Although GEOAI has accelerated hazard detection, its broader application is constrained by data inequity, limited ground truth, computational demands, and model drift, which hinder its integration into operational resilience frameworks. A further gap persists between engineering-focused hazard modelling and socio-technical resilience planning, limiting the representation of cascading events and systemic vulnerabilities within decision-support tools. The paper discusses the assessment of infrastructure response under hazard scenarios through the integration of resilience principles supported by the growing capabilities of GeoArtificial Intelligence (GEOAI). By combining engineering assessment with data-driven intelligence and strategic planning, the proposed approach frames resilience as a measurable, actionable, and governance-relevant objective. This contribution highlights the role of GEOAI as a key enabler for advancing resilient construction practices and for supporting policy frameworks aimed at safeguarding critical assets and infrastructures against natural hazards.

Keywords: Extreme events, Urban resilience, Multi-hazard resilience assessment, GEOAI

1. Introduction

Climate change and environmental degradation are increasing both the frequency and intensity of natural hazards, placing growing pressure on the built environment. Floods, storms, and heatwaves are occurring within increasingly complex multi-hazard scenarios, threatening the performance, durability, and continuity of buildings and infrastructure. Projections indicate that, by 2050, average annual losses to infrastructure from riverine flooding could rise by 5% under low-emission scenarios (RCP 2.6) and up to 13% under high-emission scenarios (RCP 8.5), reaching approximately €375–405 billion globally (Ando et al., 2022).

In addition to climate-related hazards, seismic events and other geophysical risks, such as volcanic activity, landslides, and tsunamis, remain significant sources of concern, particularly as nearly half of the world's population lives in areas exposed to these hazards. In Europe, seismic risk is unevenly distributed, with the highest levels concentrated in the Euro-Mediterranean region, especially in countries such as Italy, Greece, and Romania, where high hazard coincides with dense and often vulnerable building stocks. Moderate-risk regions, including the Iberian Peninsula and parts of Central Europe, are characterised by lower seismicity but may still experience significant impacts due to exposure, while Northern Europe exhibits comparatively low hazard levels (UNDRR, 2025; Silva et al, 2023).

Traditionally, engineering has emphasized the capacity of structures to resist predefined loads and hazard levels through deterministic safety factors and hazard-specific design rules. Although these methods have improved structural safety, they often fail to capture the dynamic, systemic, and interdependent character of risk in urban environments. Increasing evidence of cascading failures, infrastructure interdependencies, and prolonged disruptions has therefore shifted attention toward resilience-based frameworks (Rezvani et. al, 2022).

Resilience has progressively shifted from a narrow engineering paradigm centred on rapid recovery towards a more comprehensive and systemic framework encompassing robustness, redundancy, adaptability, recovery, and learning. This perspective recognizes that infrastructure must not only withstand and absorb shocks but also adjust to changing conditions and restore functionality efficiently. Such an approach (Figure 1) is particularly critical for systems and assets characterized by high exposure and vulnerability, including aging buildings, transport and utility networks, cultural heritage, and densely populated urban areas, , where disruptions can propagate across interconnected systems and amplify cascading impacts (Rezvani et. al, 2022; Rezvani et. al, 2023).

Figure 1 – Conceptual diagram of the Need for resilience + GEOAI

Despite recent advances, significant gaps remain. Many resilience assessment methods are still static and hazard-specific, limiting their ability to capture temporal risk dynamics, multi-hazard interactions, cascading

effects, and systemic vulnerabilities. For instance, conventional flood risk assessments often treat hazard and vulnerability as independent components, overlooking how changes in flood frequency or magnitude may inadvertently increase exposure and vulnerability over time (Di Baldassarre, 2014). A well-known example of cascading effects is the 2011 Fukushima Daiichi nuclear disaster, where an earthquake-induced tsunami triggered failures in multiple interconnected systems (Batikh et al., 2025).

A further limitation is the disconnection between engineering models and socio-technical resilience planning, reflecting the inadequate integration of human and technical dimensions (Thomas et al., 2019). GEOAI offers promising tools for hazard detection, monitoring, and analysis through remote sensing, geospatial processing, and machine learning (Figure 1). For example, recent GEOAI-based approaches integrating Geographical Information System (GIS), probabilistic seismic hazard analysis, and spatial modelling tools have been used to identify high-risk areas and assess the resilience of lifeline infrastructure networks under earthquake scenarios, supporting more targeted risk mitigation and planning strategies (Tehrani et al., 2025).

This paper contributes by synthesising resilience concepts, hazard impacts, and GEOAI capabilities into an integrated perspective for assessing and improving resilience in the built environment under multi-hazard conditions.

2. Evolution of the resilience concept

“Building resilience is increasingly recognized not just as a humanitarian or environmental imperative, but as a fundamental pillar of sustainable economic development.” (UNDRR, 2025).

The concept of resilience has evolved significantly across disciplines, expanding in meaning and application. It originated in the physical sciences and engineering, where it described the ability of a material or system to absorb disturbance and quickly return to its original state (Figure 2). This engineering resilience emphasizes stability, resistance, and rapid recovery after disruption. In the built environment, it traditionally guided design practices focused on strength, safety factors, and the capacity of structures to withstand predefined loads and hazard intensities (Castaño-Rosa et. al, 2022; Rezvani et. al, 2023b).

In the 1970s, ecology broadened the concept by defining resilience as the capacity of ecosystems to absorb disturbance while maintaining essential functions, structures, and feedback. This ecological perspective introduced the idea of multiple equilibrium states and highlighted adaptation and reorganization as equally important as resistance. Unlike engineering resilience, it recognizes uncertainty, nonlinearity, and the risk of irreversible change when critical thresholds are crossed (Holling, 1973; Sánchez-Pinillos, 2024).

Resilience later expanded into socio-technical systems, incorporating perspectives from social sciences, economics, and urban studies. In this view, resilience includes not only the physical robustness of infrastructure but also the adaptive capacity of communities, institutions, and governance systems. It reflects the understanding that the built environment is shaped by interactions between physical structures, human behaviour, organizational processes, and policy frameworks (Sharifi, 2023; Rezvani et. al, 2023).

Figure 2 – Timeline for the evolution of resilience concept

This evolution has led to multidimensional resilience frameworks for the built environment, including robustness, redundancy, adaptability, recovery, and learning. These dimensions provide a more comprehensive basis for evaluating how buildings and infrastructure perform under hazard conditions (Al-Humaiqani and Al-Ghamdi, 2022).

Overall, resilience marks a shift from static, deterministic design toward dynamic, systems-based thinking. Instead of only preventing failure, resilience-based approaches seek to maintain essential functions during and after disruption. Although applying resilience in practice remains challenging due to differing definitions, metrics, and data limitations, it remains a key framework for addressing the interconnected challenges of natural hazards, climate change, and urbanization, and for supporting more adaptive, robust, and sustainable infrastructure systems (Tanguay and Amor. 2024).

3. Natural hazards and impacts on the built environment

Natural hazards are a major source of risk for the built environment, and their frequency, intensity, and distribution are increasingly shaped by climate change and environmental degradation (Table 1). They include both climate-related and geophysical events, each with different mechanisms and consequences for buildings and infrastructure. Understanding these impacts is essential for assessing vulnerability and improving the resilience of critical assets (Tanguay and Amor. 2024).

Climate-related hazards include floods, storms, heatwaves, droughts, and wildfires. Many of these events are becoming more frequent, intense, and prolonged in several regions, with growing spatial extent, as evidenced by recent assessments. At the same time, an additional 2.5 billion people are projected to live in urban areas by 2050, further increasing exposure to these hazards (Dodman et. al., 2022). Floods can cause structural damage through hydrostatic and hydrodynamic forces, erosion, and foundation instability, while also damaging non-structural elements and contents. Heatwaves can degrade materials, reduce cooling efficiency, and increase thermal stress, especially in dense urban areas affected by the heat island effect. Storms and strong winds can damage roofs and façades and disrupt power and communication systems, often producing cascading effects (Cheval et. al, 2024; Mendes et. al., 2024).

Geophysical hazards such as earthquakes, landslides, and volcanic activity are generally less frequent but can be highly destructive. Earthquakes threaten structural integrity through dynamic loading and may lead to collapse, especially in buildings not designed to seismic standards. Landslides can damage foundations, transport routes, and access corridors, particularly where unstable slopes, poor drainage, or weak construction practices already exist (Harle et. al, 2024).

Hazard impacts go beyond direct physical damage. Disruptions to transport, water, energy, and telecommunications can impair essential services and trigger cascading failures across interconnected systems (Figure 3). Long-term effects may include accelerated material deterioration, shortened asset lifespan, and rising maintenance and repair costs. Cultural heritage structures are especially vulnerable because of their fragility and historical value (Brunner et. al, 2024)

Figure 3 – Hazard-impact chain

An additional challenge is the rise of multi-hazard and compound events, where hazards occur together or in sequence and intensify one another. These dynamics expose the limits of single-hazard assessments and reinforce the need for integrated approaches that consider physical damage, system interdependencies, functionality, and long-term resilience (Trogrlić et al., 2024).

4. Vulnerability of infrastructure, and gaps in resilience assessment

Within ISO 14091 (2021), climate risk assessment follows a structured framework aligned with the IPCC, with a stronger operational focus, where risk is defined by the interaction between hazard, exposure, and vulnerability. Hazards comprise climate-related events or trends (e.g., floods, heatwaves, sea-level rise) characterised by their intensity, frequency, duration, and spatial extent, while exposure refers to the presence of people, infrastructure, and assets in areas at risk. Vulnerability captures the susceptibility of these systems, typically expressed through sensitivity and limited coping capacity, while adaptive capacity is treated as a distinct but related component reflecting the ability of systems to adjust and reduce potential impacts (Figure 4). These components are interdependent and context-specific, requiring assessment under current and future conditions while accounting for temporal dynamics and uncertainty. Within this framework, resilience is not explicitly defined but can be understood as the ability of a system to anticipate, absorb, and recover from climate-related impacts through risk-informed adaptation strategies. In applied approaches, such as the Resilient Built Environment – Central Europe (RBE-CE) system, these components are operationalised through normalised indicators and combined to quantify climate risk across building and neighbourhood scales (Moro et. al., 2025).

In the built environment, vulnerability is shaped by a combination of physical, functional, and systemic characteristics, including structural condition, design standards, material properties, maintenance levels, and hazard exposure. In many regions, a significant proportion of the building stock consists of aging structures not designed to withstand current hazard intensities or meet modern performance-based standards, making them particularly susceptible to physical damage and functional disruption during hazard events (Tanguay and Amor, 2024).

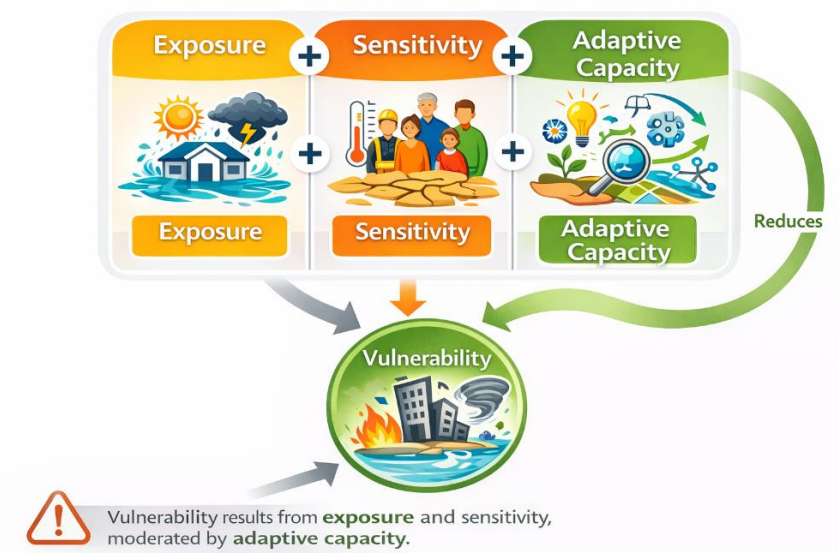

Figure 4 – Vulnerability framework diagram

Aging residential and industrial buildings are especially vulnerable. Many suffer from material deterioration, outdated construction methods, and inadequate maintenance, which reduce their ability to resist or adapt to hazards. Informal and non-engineered buildings, common in rapidly urbanizing areas, further increase vulnerability because they often lack regulatory oversight, technical design, and quality control (Rezvani et. al, 2022).

Critical infrastructure systems, such as transport networks, energy grids, water supply, and telecommunications, also face substantial risk. Their vulnerability is heightened by strong interdependence: failure in one system can trigger disruptions in others. For example, a power outage may affect water distribution, transport operations, and emergency response, amplifying overall hazard impacts. In addition, the spatially distributed and linear nature of infrastructure networks makes them highly exposed, since damage at key nodes or links can reduce the functionality of entire systems (Brunner et. al, 2024).

Cultural heritage assets form another highly vulnerable category. These structures often combine physical fragility with significant historical, architectural, and social value. Their preservation is particularly challenging because interventions must strengthen the asset while maintaining its authenticity. Many heritage buildings also rely on traditional materials and construction techniques that may perform poorly under extreme hazard conditions (Rezvani et. al, 2022).

Dense urban areas are especially exposed to multi-hazard impacts. The concentration of people, buildings, and infrastructure, together with strong interdependence, increases the likelihood of systemic failure. Vulnerability is further influenced by land-use patterns, inadequate drainage, limited open space, and socio-economic inequalities, which affect both exposure and recovery capacity. Therefore, vulnerability is not only a property of individual assets but also of the wider system in which they operate, highlighting the need for integrated assessments that address both component fragility and system interactions (Sharifi, 2023).

Despite progress in resilience research, current assessment methods still have major limitations. Many remain static, relying on predefined scenarios and fixed system conditions, and therefore fail to capture the changing nature of hazards, infrastructure performance, and recovery over time. Another weakness is the continued reliance on single-hazard approaches, which overlook interactions between hazards and the potential for compound and cascading events, leading to underestimation of real risk (Trogrlić et al., 2024).

A further challenge is the gap between engineering-based models and broader socio-technical resilience frameworks. Engineering approaches focus on structural performance, reliability, and failure probability, while socio-technical perspectives include governance, institutional capacity, community preparedness, and economic resilience. Limited integration between these views weakens holistic decision-making (Sharifi, 2023). Data limitations also constrain resilience assessments, especially where reliable, high-resolution information is scarce. Uncertainties in climate projections, hazard models, and infrastructure response add further complexity.

5. Integrating Resilience Principles with GEOAI

The rapid development of GEOAI has created important new opportunities for improving resilience assessment in the built environment (Figure 6). By combining geospatial technologies, remote sensing, and machine learning, GEOAI makes it possible to process large and diverse datasets and to support more dynamic evaluations of hazard exposure, infrastructure condition, and system performance (Rezvani et. al, 2023b)

A key strength of GEOAI lies in hazard detection and monitoring. Satellite imagery, unmanned aerial systems, and ground sensors can be integrated with machine learning models to detect and track hazards such as floods, wildfires, landslides, and storm damage in near real time. These capabilities improve situational awareness and support rapid response, especially in inaccessible or data-scarce regions. Time-series analysis of geospatial information also helps identify long-term trends and patterns, contributing to a better understanding of hazard evolution and changing risk conditions (Padgett et. al., 2024).

GEOAI is also valuable for vulnerability and damage assessment. Advanced image analysis can extract information on building characteristics, structural condition, and land use, enabling large-scale mapping of exposed assets. After hazard events, machine-learning algorithms (MLA) can support damage classification and loss estimation, helping decision-makers prioritize recovery actions. These approaches complement

conventional engineering assessments, which are often slower and limited in spatial scope (Rezvani et. al, 2023b).

Another important contribution is predictive and scenario-based modelling. By integrating climatic, environmental, infrastructural, and socio-economic datasets, GEOAI enables the representation of complex system interactions and supports the analysis of multi-hazard scenarios, including cascading effects and infrastructure interdependencies. Compared with static, single-hazard approaches, this provides a more realistic understanding of temporal variability and system interdependencies (Brunner et. al, 2024).

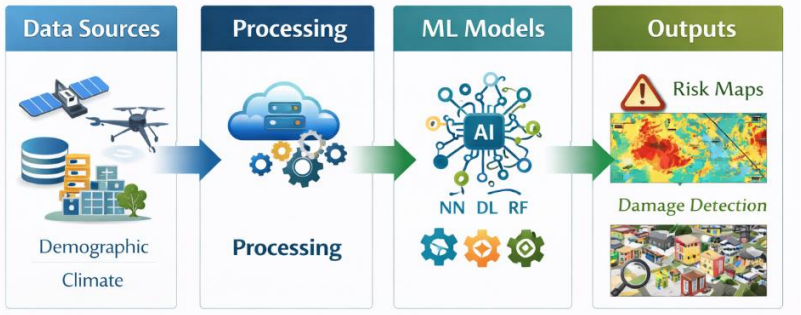

Figure 6 – GEOAI workflow

However, the effective application of GEOAI depends on overcoming key technical and organisational challenges. The integration of heterogeneous geospatial data remains a major barrier, as datasets often differ in structure, scale, and format. Frameworks such as AtlasHDF, which leverages HDF5 for efficient data integration, and PlaniSphere, which aggregates geospatial data through Web Map Service (WMS) protocols, illustrate emerging solutions for managing complex data environments. Nevertheless, the lack of standardised data models continues to hinder interoperability. Efforts such as Geographic Markup Language (GML), fuzzy spatial data models, and emerging Open Geospatial Consortium (OGC) standards, including Training Data Markup Language for AI (TrainingDML-AI), aim to address these limitations by improving data consistency, uncertainty representation, and interoperability.

Cyberinfrastructure (CI) and Geospatial Cyberinfrastructure (GCI) frameworks further support GEOAI applications by integrating data resources, computational tools, and network protocols, enabling scalable and interoperable geospatial analysis (Di and Deng, 2010).

Despite these advances, GEOAI faces persistent limitations. Data availability and quality remain critical challenges, particularly in regions with sparse or inconsistent geospatial information. The lack of reliable ground-truth data constrains model training and validation, affecting accuracy and generalisability. High computational demands and model drift further limit scalability and long-term performance. In addition, GEOAI models often show limited transferability across geographic contexts, requiring continuous recalibration (Padgett et al., 2024; Rezvani et. al., 2023b).

Finally, translating GEOAI outputs into actionable policies remains a significant challenge. Addressing this requires improved interoperability, standardisation, transparency, and governance, as well as stronger coordination among data sources, models, institutions, and stakeholders.

The integration of GEOAI with engineering-based models offers a promising pathway toward hybrid resilience frameworks. While engineering models provide detailed insights into structural behaviour, GEOAI contributes dynamic, data-driven understanding of hazards and system interactions. Together, these approaches enable more realistic multi-hazard modelling, improved assessment of infrastructure interdependencies, and more effective decision-support tools, such as interactive risk maps and scenario-based planning platforms (Figure 7).

Overall, the convergence of resilience theory and GEOAI supports a transition toward dynamic, data-informed, and system-oriented approaches, enabling more proactive and adaptive resilience planning in the built environment.

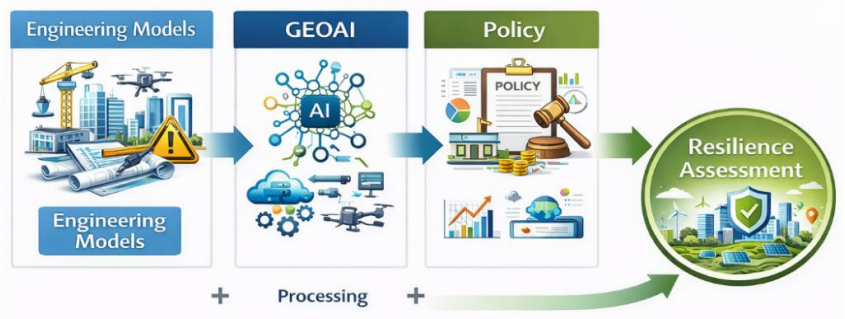

Figure 7 – Integrated framework

6. Implications for Policy and Construction Practice

The growing importance of resilience in the built environment has major implications for both policy and construction practice. As natural hazards become more frequent, severe, and interconnected, conventional risk reduction strategies are no longer enough. Instead, resilience must be embedded across the full lifecycle of buildings and infrastructure, from planning and design to operation, maintenance, and recovery (Rezvani et. al, 2024)

From a policy perspective, a central challenge is turning resilience into a measurable and enforceable objective. This requires standardized metrics, indicators, and assessment methods that can be applied consistently across sectors and scales. Existing regulations are largely based on prescriptive codes that focus on safety and minimum performance under specific hazard scenarios. Although these remain necessary, they do not fully address broader issues such as system functionality, recovery time, and adaptability. Integrating resilience into codes and standards therefore requires a shift toward performance-based and risk-informed approaches, where acceptable levels of service continuity, downtime, and recovery are clearly defined (Al-Humaiqani and Al-Ghamdi, 2022).

Policy frameworks must also reflect the multi-hazard and systemic nature of risk. This means improving coordination across sectors and governance levels, while promoting integrated planning that considers infrastructure interdependencies. Urban planning is especially important, as land-use regulation, zoning, and the protection of critical assets can reduce exposure and vulnerability and help avoid concentrating risk in highly exposed areas. (Trogrlić et. al, 2024).

GEOAI further strengthens evidence-based policymaking by enabling real-time monitoring, dynamic risk assessment, and scenario analysis. These tools can improve early warning systems, emergency response, and investment prioritization. However, their use depends on strong data governance, including data quality, standardization, sharing protocols, and privacy protection (Padgett et. al, 2024).

In the construction sector, resilience requires more holistic design, construction, and maintenance practices. Engineers must consider not only structural safety, but also functionality, adaptability, and lifecycle performance. This includes resilient design measures such as redundancy in critical systems, modular construction for easier repair, and materials suited to changing environmental conditions. Digital tools such as GEOAI, BIM, and digital twins can support simulation, monitoring, predictive maintenance, and resource efficiency (Al-Humaiqani and Al-Ghamdi, 2022).

Figure 9 – Decision-making flowchart

Successful implementation also depends on training, interdisciplinary collaboration, and knowledge transfer. Although resilience may involve higher initial costs, it can reduce long-term damage and recovery expenses. With supportive incentives and lifecycle-based investment thinking, resilience can become a practical foundation for safer, more adaptable, and more sustainable built environments (Tanguay, and Amor, 2024).

7. Conclusions

This study highlights the growing complexity of assessing and managing risks in the built environment under changing natural hazard conditions. The shift from traditional resistance-based approaches toward multidimensional resilience frameworks represents an essential change in both theory and practice, yet remains incomplete due to persistent conceptual, methodological, and operational challenges. Current assessment methods often fail to capture the dynamic, interconnected nature of infrastructure systems, particularly under multi-hazard and cascading scenarios, underscoring the need for integrated, system-level approaches.

In this context, GEOAI offers significant potential by enabling large-scale, data-driven, and near real-time analysis. When combined with engineering models, it supports hybrid approaches that can better represent both physical processes and system interactions. However, its effectiveness depends on data quality, validation, and integration within decision-making frameworks.

A persistent gap remains between technical assessments and policy implementation, driven by the lack of standardised metrics, difficulties in communicating complex results, and institutional fragmentation. Addressing this requires stronger alignment between scientific research, policy, and practice.

Resilience must be understood as a systemic property emerging from the interaction between infrastructure, institutions, users, and environmental conditions. Accordingly, assessment approaches should integrate engineering, environmental, and socio-technical dimensions.

Advancing resilience requires dynamic, data-informed, and system-oriented frameworks that move beyond traditional resistance-based models. Embedding these approaches into policy and practice will depend on technological innovation, institutional coordination, and the development of standardised, user-oriented tools.

Acknowledgments

Abstract: Climate change is increasing the vulnerability of cultural heritage buildings through rising temperatures, more frequent and intense heatwaves, changing precipitation patterns, flooding, storms and other extreme weather events. These hazards affect the performance, durability and long-term preservation of heritage assets, requiring conservation strategies that integrate climate adaptation and resilience objectives. While significant progress has been made in understanding climate-related risks to cultural heritage, less attention has been paid to the skills and competencies required of professionals responsible for its conservation, rehabilitation, and management. The ECOHERITAGE Erasmus+ project aims to identify skills gaps, develop a European training programme, and create digital learning resources to support higher education institutions and professionals working in heritage conservation and sustainable construction. It presents the project's rationale, methodology, and expected outcomes, and discusses how educational innovation can contribute to climate adaptation and resilience in the built heritage sector.

Keywords: Cultural Heritage Buildings; Climate Change; Resilience; Higher Education; Skills Development; Sustainable Retrofitting.

1. Introduction

Cultural heritage buildings constitute a significant component of Europe's built environment and play a fundamental role in preserving historical, architectural, cultural and social values. They contribute to the identity of cities and regions, support tourism and local economies, and provide tangible links between past and present generations. Beyond their cultural significance, heritage buildings are increasingly recognised as important assets within sustainable development strategies, contributing to social cohesion, place-making and urban regeneration. However, cultural heritage buildings are becoming increasingly vulnerable to the impacts of climate change (UNESCO, 2007).

Higher air temperatures, more frequent and intense heatwaves, changing precipitation patterns, flooding, storms and other extreme weather events are accelerating the deterioration of historic materials and affecting the performance, durability, and resilience of heritage assets. Climate-related hazards may also compromise the safety, functionality and long-term preservation of buildings with historical and cultural significance. Consequently, heritage conservation can no longer be addressed independently from climate adaptation and resilience strategies.

Over the last decade, several European research and innovation projects have significantly advanced knowledge on climate change impacts on cultural heritage. Projects such as Climate for Culture (FP7), STORM (H2020) and ARCH (H2020) have developed climate-risk assessment methodologies, monitoring systems, resilience frameworks, decision-support tools and adaptation strategies for heritage buildings and historic urban areas. Their results have demonstrated that climate change is increasing the vulnerability of cultural heritage through rising temperatures, heatwaves, flooding, coastal hazards and extreme weather events, while also highlighting the need for preventive conservation and long-term resilience planning. However, despite these advances, relatively limited attention has been given to the development of educational frameworks and professional competencies required to implement climate adaptation measures in practice. This gap between scientific knowledge and professional capacity-building provides the rationale for the ECOHERITAGE project, which focuses on education, skills development and training for climate-resilient cultural heritage buildings.

At the same time, European policies such as the European Green Deal, the Renovation Wave Strategy and the EU Adaptation Strategy encourage the transformation of the built environment towards greater sustainability, energy efficiency and climate resilience (EC, 2019; 2020; EPRS, 2024). While these objectives are widely promoted in the building sector, their implementation in cultural heritage buildings remains particularly challenging. Interventions must balance the need to improve environmental performance with the obligation to preserve authenticity, historical value and architectural integrity. This requires specialised knowledge and multidisciplinary approaches that integrate conservation principles, engineering solutions, sustainability assessment and climate adaptation measures.

Despite growing awareness of these challenges, there remains a significant gap in education and training opportunities specifically addressing climate resilience in cultural heritage buildings. Existing programmes in architecture, engineering, heritage conservation and construction management often address these themes separately, providing limited opportunities for interdisciplinary learning. Furthermore, professionals currently involved in the conservation, rehabilitation and management of heritage assets frequently lack access to continuing education programmes focused on climate risk assessment, sustainable retrofitting strategies, nature-based solutions and resilience planning. Addressing this skills gap is essential to ensure that future professionals are equipped to respond to the complex challenges posed by climate change. Capacity building, knowledge transfer and educational innovation are increasingly recognised as key enablers for the sustainable preservation of cultural heritage. In this context, higher education institutions play a critical role in developing new curricula, training methodologies and learning resources that reflect emerging societal and environmental needs.

The ECOHERITAGE project (Resilient and Bioclimatical Advancement of Cultural Heritage Buildings), funded under the Erasmus+ Programme, was conceived to address these challenges. Bringing together universities and specialised organisations from Portugal, Germany, Spain, Greece and North Macedonia, the project aims to identify educational and professional needs, develop an innovative training framework and create digital learning resources focused on climate-resilient retrofitting of cultural heritage buildings.

This paper presents the rationale, objectives and methodological framework of the ECOHERITAGE project. It discusses the need for new educational approaches in the field of climate resilience and heritage conservation and introduces the training framework that will be developed (during the period 2025-2027) to support students, academics and professionals working with cultural heritage buildings. By linking

climate adaptation, sustainability and educational innovation, the project seeks to contribute to the development of a new generation of professionals capable of preserving Europe's cultural heritage while responding effectively to future environmental challenges.

2. Climate Change and Cultural Heritage Buildings: Current Challenges and Educational Gaps

2.1 Main Climate Threats

Cultural heritage buildings are increasingly exposed to the impacts of climate change, which may accelerate deterioration processes and compromise their long-term conservation. These buildings often include historic materials, traditional construction techniques and architectural features that were not designed to respond to current or future climatic scenarios. As a result, their vulnerability may be higher than that of contemporary buildings (Sesana et al. 2021; Fatorić & Seekamp 2017; EPRS 2024; UNESCO/IPCC/ICOMOS 2021). Among the main climate-related threats, heatwaves and rising temperatures can contribute to thermal stress, material expansion and contraction, changes in indoor environmental conditions and increased cooling demand. These effects may be particularly relevant in historic buildings where passive environmental control strategies are limited or where interventions must respect conservation principles (Pereira et al. 2024). Flooding and heavy precipitation represent another major risk. Increased rainfall intensity and more frequent extreme weather events can affect foundations, walls, façades, roofs and drainage systems. Water infiltration may lead to moisture accumulation, salt crystallisation, biological growth, surface decay and structural deterioration. In heritage buildings, such damage can result not only in technical and functional problems but also in the loss of cultural and historical value.

Moisture-related deterioration is especially relevant in cultural heritage buildings, as many historic materials are highly sensitive to changes in humidity and water movement. The combination of moisture, temperature variation and pollutants may accelerate decay mechanisms in stone, mortar, timber, metals and decorative elements (Liberato & Trigo 2014). Freeze-thaw cycles may also affect heritage materials, particularly in regions where temperature fluctuations around 0 °C are frequent. Water absorbed into porous materials can freeze and expand, causing cracking, scaling and progressive material loss. Although this process is not new, changing climatic conditions may alter its frequency, intensity and geographical relevance (Romero-Gómez et al. 2025).

Extreme events, including storms, droughts, heatwaves and intense rainfall, increase uncertainty in conservation planning. These events may produce sudden damage, overload existing maintenance systems and expose the need for preventive risk assessment and adaptation strategies. Therefore, climate change should be understood not only as an environmental issue but also as a conservation, management and educational challenge for the cultural heritage sector (Mendes & Flores-Colen 2024).

2.2 Challenges for Heritage Conservation

The adaptation of cultural heritage buildings to climate change involves a complex balance between preservation and transformation. On the one hand, heritage buildings must be protected against climate-related risks. On the other hand, any intervention must respect their authenticity, integrity, historical significance and cultural value. This creates a tension between the need for adaptation and the principles of conservation.

Energy efficiency interventions are a particularly relevant example of this challenge. Improving the energy performance of buildings is central to European sustainability objectives, but interventions in heritage buildings cannot follow standard retrofitting approaches. Measures such as insulation, window replacement, ventilation systems or renewable energy integration must be carefully assessed to avoid damaging historic materials, altering architectural character or compromising heritage values.

Material compatibility is another key concern. Retrofitting solutions must be technically effective but also compatible with existing materials and construction systems. The use of inappropriate materials or techniques can accelerate degradation, create moisture imbalances or reduce the reversibility of interventions. This is particularly important when introducing innovative solutions, nature-based strategies, waste-based materials or eco-design approaches in heritage contexts.

Risk management is therefore essential. Cultural heritage buildings require integrated assessment methods that consider climate hazards, material vulnerability, building use, conservation status, social value and long-term maintenance capacity. Risk assessment should support decision-making by helping professionals identify priorities, select suitable adaptation strategies, and plan interventions that are both technically sound and heritage-sensitive.

The ECOHERITAGE project addresses these challenges by promoting an interdisciplinary approach that combines climate adaptation, sustainable retrofitting, conservation principles, energy efficiency and risk assessment. This reflects the need to prepare future professionals to work across disciplinary boundaries and to respond to complex problems in the cultural heritage building sector.

2.3 Current Knowledge Gaps

Although climate change and sustainability are increasingly prominent in debates on the built environment, significant knowledge gaps remain regarding cultural heritage buildings. These gaps can be grouped into technical, professional and educational dimensions.

Over the past decade, several European research and innovation projects have generated valuable knowledge on climate risks and adaptation strategies for cultural heritage. For example, the Climate for Culture project produced extensive climate-risk mapping, climate simulations and impact assessments for historic buildings across Europe, highlighting the vulnerability of heritage assets under future climatic scenarios (Leissner et al., 2015; Climate for Culture, 2014). Similarly, the ARCH project developed resilience frameworks, governance approaches and decision-support methodologies to enhance the capacity of historic urban areas to respond to climate-related and other hazards (ARCH, 2023). The STORM project further contributed by developing monitoring technologies, risk management methodologies and decision-support tools aimed at safeguarding cultural heritage from natural and climate-related threats (STORM, 2021).

Despite these advances, most existing initiatives have primarily focused on technical, environmental and management aspects of climate resilience. Comparatively little attention has been given to the knowledge, skills, and competencies required of professionals responsible for the conservation, rehabilitation, and management of heritage assets (Sesana et al., 2018). Consequently, a disconnect remains between research outcomes and their practical implementation by architects, engineers, conservators, facility managers, planners and public authorities.

From a technical perspective, there remains a need for methods and tools to assess climate risks in heritage buildings and identify appropriate adaptation measures. Professionals require knowledge on climate hazards, building pathology, material behaviour, energy efficiency, environmental performance and sustainable retrofitting solutions. However, these topics are often addressed separately, limiting the development of integrated strategies.

Professional skills gaps are also evident. The conservation and management of cultural heritage buildings require contributions from engineers, architects, urban planners, building managers, facility managers, consultants, public authorities and heritage specialists. However, these professionals may not share the same technical language, priorities or decision-making frameworks. This creates difficulties in interdisciplinary collaboration and in the practical implementation of climate-resilient solutions.

Educational gaps are equally important. Existing higher education and professional training programmes often address heritage conservation, energy efficiency, sustainability and climate adaptation as separate fields. As a result, students and professionals may complete their education without receiving targeted training on adapting cultural heritage buildings to climate change while preserving their cultural significance.

The ECOHERITAGE project was developed in response to these gaps. Its training framework is based on five thematic modules: eco-design and social needs in retrofitting; energy efficiency and economic assessment in heritage buildings; nature-based and waste-based solutions; cultural heritage buildings and climate change; and risk assessment in heritage buildings. Together, these modules aim to provide an integrated educational response to the sector's emerging needs.

3. The Need for New Skills and Competencies

The transition towards climate-resilient and sustainable cultural heritage buildings requires new knowledge, skills, and competencies that are not yet adequately addressed in existing educational and professional training systems. As climate change increasingly affects the built environment, professionals responsible for the conservation, rehabilitation and management of heritage assets must be able to integrate climate adaptation, sustainability and heritage preservation objectives into their decision-making processes. The ECOHERITAGE project is based on the premise that education and capacity building are fundamental enablers of this transition. The project recognises that the challenges associated with cultural heritage buildings cannot be addressed through a single disciplinary perspective. Instead, they require the integration of technical, environmental, social, and management-related competencies that can respond to increasingly complex and interconnected challenges.

3.1 Technical Competencies

One of the main needs identified during the design of the ECOHERITAGE project is the development of technical competencies in climate resilience and the sustainable retrofitting of cultural heritage buildings. Climate risk assessment is becoming an essential competence for professionals involved in heritage conservation and building management. Understanding how climate hazards affect heritage assets and how vulnerability can be assessed is fundamental for the development of adaptation strategies and risk-informed decision-making processes. The ability to identify risks, evaluate exposure and support resilience planning is therefore a key area for future training.

Building pathology and performance assessment also play a critical role. Professionals require a better understanding of deterioration mechanisms, material behaviour and building performance in changing environmental conditions. Knowledge of how climate-related stressors interact with traditional construction materials and systems is increasingly necessary to support conservation and rehabilitation interventions.

Energy efficiency constitutes another important area of competence. While European policies encourage reducing energy consumption and greenhouse gas emissions in buildings, heritage assets present specific constraints and opportunities. Professionals need the ability to evaluate energy performance, identify appropriate improvement measures and balance environmental objectives with conservation requirements.

The project also highlights the importance of nature-based and innovative solutions as part of future professional competencies. These approaches can contribute to climate adaptation, environmental sustainability and improved building performance while supporting broader objectives related to resource efficiency and sustainable development. The integration of such solutions within heritage contexts requires specialised knowledge and critical evaluation skills.

3.2 Cross-Disciplinary Competencies

In addition to technical expertise, the ECOHERITAGE project recognises the growing importance of cross-disciplinary competencies. Heritage conservation increasingly requires collaboration between architects, engineers, planners, conservation specialists, researchers, public authorities and building managers. Professionals must therefore understand not only their own disciplinary field but also the perspectives, priorities and constraints of other stakeholders involved in decision-making processes.

Sustainability assessment represents another emerging competence. Climate resilience and sustainable retrofitting cannot be evaluated solely through technical indicators. Environmental, economic, social and cultural dimensions must be considered simultaneously. Future professionals need to develop the capacity to assess interventions from multiple perspectives and understand their broader impacts on heritage assets and communities.

Digital competencies are also becoming increasingly relevant. The ECOHERITAGE project includes the development of a digital learning platform and online educational resources, reflecting the growing role of digital technologies in knowledge sharing, professional development and lifelong learning. Familiarity with digital tools and online learning environments is, therefore, considered an important component of future skills development.

Stakeholder engagement is another critical competence addressed by the project. Effective adaptation and conservation strategies depend on the participation and cooperation of multiple actors. Professionals must be capable of communicating with diverse audiences, facilitating collaboration, and promoting shared understanding among technical experts, decision-makers, and local communities.

3.3 Educational Challenges

The need for new competencies is closely linked to existing educational challenges. Current educational provision often remains fragmented, with heritage conservation, sustainability, energy efficiency and climate adaptation addressed as separate topics. This fragmentation limits learners' opportunities to develop integrated approaches capable of addressing the complexity of real-world heritage challenges.

The lack of interdisciplinary programmes represents another significant challenge. Many existing curricula focus on specific disciplinary perspectives and offer limited opportunities for cross-disciplinary collaboration across fields such as architecture, engineering, environmental sciences, conservation, and management. As a result, graduates may possess strong technical expertise but limited experience in interdisciplinary problem-solving. Furthermore, opportunities for continuing professional development remain limited in this emerging field. Professionals already working in the sector frequently require access to up-to-date knowledge, specialised training, and flexible learning opportunities that support lifelong learning and adaptation to evolving professional demands.

The ECOHERITAGE project was designed to respond directly to these educational challenges. Through its needs assessment activities, training framework, digital learning platform and pilot courses, the project seeks to establish an integrated educational approach that combines technical knowledge, interdisciplinary collaboration and practical application. The five training modules developed within the project provide a structured response to the identified skills gaps and help strengthen the capacity of higher education institutions and professional communities to address climate resilience in cultural heritage buildings. Ultimately, the project views education and skills development as essential components of climate adaptation strategies, supporting both the preservation of cultural heritage and the sustainable transformation of the built environment.

4. The ECOHERITAGE Project

4.1 Project Objectives

The ECOHERITAGE project was developed in response to the growing need for specialised knowledge and skills in climate resilience and the sustainable retrofitting of cultural heritage buildings, thereby strengthening higher education and professional training capacities in this emerging field. The project is based on the recognition that climate change is creating new challenges for the conservation, management and rehabilitation of heritage assets, while current educational provision remains fragmented and insufficiently adapted to these evolving needs. ECOHERITAGE therefore aims to support the development of innovative educational approaches that address the intersection of heritage conservation, sustainability, climate adaptation, and building performance.

More specifically, the project pursues four complementary objectives; i) to identify emerging educational and professional needs related to climate resilience in cultural heritage buildings through a comprehensive needs assessment involving higher education institutions and relevant stakeholders; ii) to develop a structured training framework and educational resources capable of addressing identified skills gaps; iii) to create a digital learning environment that facilitates access to knowledge, training materials and good practices; and iv) to strengthen cooperation among higher education institutions, researchers and professionals, contributing to the development of a multidisciplinary learning community focused on sustainable heritage conservation. Through these objectives, ECOHERITAGE seeks to contribute to both educational innovation and the broader European transition towards a more sustainable and climate-resilient built environment.

4.2 Partnership

The ECOHERITAGE consortium brings together six partner organisations from five European countries with complementary expertise in cultural heritage, engineering, architecture, sustainability, higher education, digital learning and professional training. The consortium is coordinated by the Instituto Superior Técnico, Universidade de Lisboa (Portugal) and includes RWTH Aachen University (Germany), Universidad Politécnica de Madrid (Spain), the National Technical University of Athens (Greece), the Institute for Entrepreneurship and Economic Development – IECE (North Macedonia), and CRETHIDEV (Greece).

The partnership combines academic institutions with organisations experienced in training, dissemination and stakeholder engagement, ensuring a multidisciplinary perspective throughout the project. This diversity of expertise enables the project to address the technical, educational, and societal dimensions of climate resilience in cultural heritage buildings while promoting international cooperation and knowledge exchange. The consortium structure also supports the development of educational materials that can be adapted and transferred across different European contexts, contributing to the wider impact and sustainability of project outcomes.

4.3 Methodological Approach

The ECOHERITAGE project follows a progressive and interconnected methodology consisting of four main phases. Each phase contributes to the development of the subsequent activities, ensuring that project outputs are grounded in identified needs and validated through practical implementation.

Phase 1 – Needs Assessment

The first phase focuses on the identification of educational and professional needs related to climate-resilient cultural heritage buildings. This activity involves the analysis of existing courses and training programmes, the identification of skills gaps and the collection of information regarding current

educational provision across partner countries. Attention is given to understanding how topics such as climate adaptation, energy efficiency, risk assessment, sustainability and heritage conservation are currently addressed within higher education and professional training programmes. The findings of this phase will provide the evidence base for developing the training framework and educational materials.

Phase 2 – Training Framework Development

The second phase involves designing a comprehensive training framework to address the needs identified during the assessment phase. The framework is organised around five thematic modules that address key aspects of climate resilience and the sustainable retrofitting of cultural heritage buildings. This phase includes defining learning outcomes, curriculum structure, educational content, and training methodologies. The training framework is designed to support both higher education students and professionals seeking to develop specialised competencies in this field. The educational approach adopted by the project promotes interdisciplinarity, combining engineering, architecture, sustainability, heritage conservation and risk management perspectives.

Phase 3 – Digital Platform

The third phase focuses on developing a digital learning environment that will provide access to educational resources and facilitate knowledge exchange among participants. The platform will serve as a repository for project materials, training resources, good practices and dissemination outputs. It will also support the visibility of project activities and provide opportunities for interaction among different stakeholder groups. It represents an important component of the project's strategy to ensure accessibility, scalability and long-term sustainability of the developed educational resources.

Phase 4 – Pilot Courses and Evaluation

The final phase involves implementing and testing the developed training materials through pilot courses, workshops, and learning activities. These pilot actions will allow partners to evaluate the relevance, quality and effectiveness of the educational framework and to collect feedback from participants. The evaluation process will support the refinement of training materials and contribute to the validation of the proposed approach. In addition to supporting quality improvement, the pilot activities will promote stakeholder engagement and facilitate the dissemination of project results among higher education institutions, professionals and other relevant actors involved in cultural heritage conservation and management.

Together, these four phases provide a coherent methodological framework that links needs assessment, educational design, digital innovation, and practical validation, thereby supporting the overall objective of strengthening capacities for climate-resilient cultural heritage buildings across Europe.

5. Proposed Educational Framework

The educational framework proposed within the ECOHERITAGE project was designed (Figure 1) to address the skills gaps identified in relation to climate resilience, sustainability and cultural heritage conservation (UNESCO 2015, Lucchi et al. 2024). The framework adopts an interdisciplinary perspective and seeks to provide learners with the technical, environmental, social and management-related competencies required to address contemporary challenges affecting cultural heritage buildings. It is structured around five complementary modules that collectively cover the main dimensions of climate-resilient retrofitting and heritage conservation. Rather than addressing isolated technical topics, the modules have been conceived as interconnected components of a broader learning pathway, enabling participants to understand the relationships between environmental performance, climate adaptation, social needs, heritage values and risk management.

5.1 Learning Outcomes

The proposed framework aims to equip participants with a set of integrated learning outcomes that combine knowledge acquisition, analytical skills and practical application. At the end of the training programme, participants are expected to:

- Understand the main climate-related challenges affecting cultural heritage buildings.
- Identify and assess climate risks associated with heritage assets.
- Analyse building performance from environmental, technical and conservation perspectives.
- Evaluate energy efficiency measures suitable for heritage contexts.
- Understand the application of nature-based and circular economy approaches in retrofitting interventions.
- Integrate sustainability principles into conservation and rehabilitation strategies.
- Apply risk assessment methodologies to support decision-making processes.
- Develop interdisciplinary approaches to climate adaptation and heritage management.
- Communicate and collaborate effectively with different stakeholder groups involved in heritage conservation and building management.

The framework, therefore, moves beyond purely technical training and seeks to promote holistic problem-solving capabilities.

5.2 Interdisciplinary Approach

One of the defining characteristics of the ECOHERITAGE educational framework is its interdisciplinary nature. The challenges associated with climate resilience in cultural heritage buildings cannot be adequately addressed through a single disciplinary perspective. Effective solutions require the integration of knowledge from architecture, engineering, sustainability sciences, heritage conservation, environmental assessment and management. Module 1 introduces eco-design principles and social dimensions of retrofitting, highlighting the importance of user needs and societal expectations in heritage interventions. Module 2 focuses on the technical and economic dimensions of energy performance improvement. Module 3 explores innovative solutions, including nature-based and waste-based approaches that support sustainability objectives. Module 4 addresses the broader relationship between climate change and cultural heritage buildings, providing a contextual understanding of climate impacts and adaptation needs. Finally, Module 5 focuses on risk assessment methodologies and decision-support processes. Together, the modules create opportunities for learners to develop integrated perspectives and understand how different disciplinary domains contribute to climate-resilient heritage conservation.

5.3 Expected Competencies

The proposed framework aims to strengthen three complementary categories of competencies. The first category comprises technical competencies related to climate risk assessment, building performance evaluation, energy efficiency, sustainable retrofitting and the application of innovative solutions in heritage buildings. The second category includes analytical and decision-making competencies. Participants are expected to develop the ability to assess alternative interventions, evaluate risks and opportunities, and support evidence-based decision-making processes within complex heritage contexts. The third category encompasses transversal competencies, including interdisciplinary collaboration, stakeholder engagement, sustainability thinking and communication skills. These competencies are increasingly recognised as essential for professionals operating in environments characterised by multiple objectives, competing priorities and diverse stakeholder interests.

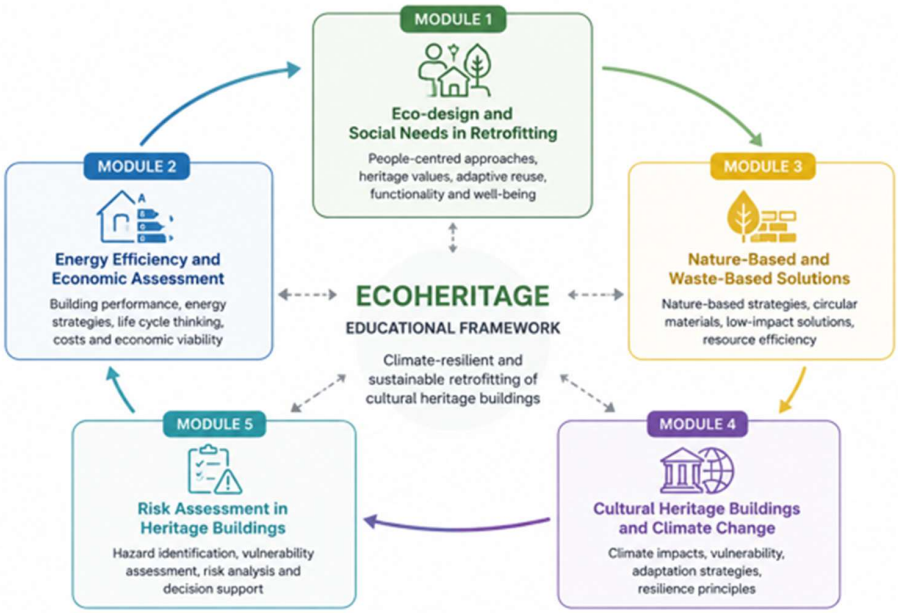

Figure 1 – ECOHERITAGE – Educational Framework – 5-modules

By combining these different dimensions, the framework seeks to contribute to the development of a new generation of professionals capable of addressing climate adaptation challenges while safeguarding the cultural significance and long-term value of heritage buildings (ESA 2020; UNESCO UK 2023; ICOMOS 2019). The educational framework, therefore, represents a structured response to the emerging needs identified by the project and provides a foundation for future training, knowledge transfer and capacity-building activities in the field of climate-resilient cultural heritage conservation.

6. Expected Impact

The ECOHERITAGE project is expected to generate impacts at multiple levels, including higher education, professional practice, the cultural heritage sector and broader sustainability policies. By addressing identified skills gaps and developing innovative educational resources, the project seeks to strengthen capacities for climate-resilient and sustainable management of cultural heritage buildings.

Higher Education

One of the main expected impacts of the project concerns the enhancement of higher education provision in the field of cultural heritage buildings. Through the development of a structured training framework and specialised educational materials, ECOHERITAGE will contribute to the introduction of new curricular content that addresses climate resilience, sustainability, and heritage conservation. The project also promotes innovative teaching and learning methodologies, combining interdisciplinary approaches, digital learning resources, and practical applications to support both academic programmes and lifelong learning initiatives.

Professional Practice

The project is expected to contribute to the development of better-qualified professionals capable of addressing the complex challenges associated with climate change and cultural heritage conservation. By strengthening competencies in climate risk assessment, energy efficiency, sustainable retrofitting, nature-

based solutions, and risk management, the training programme will support more informed decision-making and interdisciplinary collaboration among professionals in the built environment sector.

Cultural Heritage Sector

For the cultural heritage sector, ECOHERITAGE aims to improve the capacity of organisations and professionals to respond to climate-related challenges affecting heritage assets. The project promotes a more integrated understanding of resilience, combining conservation principles with sustainability and adaptation objectives. In the long term, this is expected to contribute to the preservation, functionality and resilience of cultural heritage buildings while supporting their continued social and cultural value.

Policy and Sustainability

The project is also aligned with broader European priorities related to sustainability, climate adaptation and the green transition of the built environment. By supporting capacity building and educational innovation, ECOHERITAGE contributes to the objectives of the European Green Deal and to the implementation of climate adaptation strategies within the cultural heritage sector. Through its educational framework, digital learning platform and dissemination activities, the project seeks to facilitate knowledge transfer and support the adoption of more sustainable and climate-resilient approaches across different European contexts. Overall, ECOHERITAGE views education and professional development as essential components of climate adaptation, providing a foundation for future actions to safeguard cultural heritage buildings in a changing climate.
