7. Conclusions

Climate change is creating new and increasingly complex challenges for the conservation, rehabilitation and management of cultural heritage buildings. Rising temperatures, extreme weather events, flooding, moisture-related deterioration and other climate-related hazards may compromise the physical integrity, functionality and cultural value of heritage assets. These challenges require approaches that go beyond conventional conservation and retrofitting practices. The ECOHERITAGE project responds to this need by placing education, capacity building and interdisciplinary cooperation at the centre of climate adaptation for cultural heritage buildings. The project recognises that professionals and students require new competencies that combine heritage conservation, climate risk assessment, energy efficiency, sustainability, nature-based and waste-based solutions, and risk-informed decision-making.

The proposed educational framework, structured around five thematic modules, provides an integrated response to these emerging needs. By combining technical knowledge with cross-disciplinary skills, the framework aims to support learners in understanding the complexity of heritage buildings under climate stress and in selecting appropriate, compatible and sustainable retrofitting strategies. ECOHERITAGE also emphasises the importance of digital learning and international cooperation. The development of a digital training platform, pilot courses, workshops, and dissemination activities will support knowledge transfer among higher education institutions, professionals, and stakeholders across different European contexts.

Overall, the project contributes to strengthening the cultural heritage sector's capacity to respond to climate change. By developing new curricula, training resources and learning methodologies, ECOHERITAGE supports the preparation of a new generation of professionals capable of preserving cultural heritage while contributing to climate adaptation, sustainability and the objectives of the European Green Deal.

Abstract: The use of interlocking concrete block pavements has expanded in Brazilian urban areas, particularly on local and collector roads, due to their ease of maintenance, durability, and associated environmental benefits. However, the functional performance of these pavements is directly related to construction quality and traffic conditions, making periodic evaluations essential to support maintenance planning. In this context, the Pavement Condition Index (PCI) stands out as an objective and standardized tool for assessing pavement surface condition. This study aimed to characterize the functional condition of interlocking concrete block pavements located in the central area of a city in northeastern Brazil using the PCI. The methodology consisted of a case study based on field surveys, in which the study area was subdivided into 23 Sample Units (SUs). In each SU, distress types, severity levels, and extents were identified, enabling the calculation of deduction values and, subsequently, PCI values. The results indicated that approximately 60% of the SUs presented PCI values between 85 and 55, corresponding to conditions classified as Satisfactory or Fair, indicating adequate functional performance under prevailing local traffic conditions. Conversely, approximately 40% of the sample units were classified as Poor or Very Poor, indicating functional deterioration. The most recurrent distresses were depressions, widened joints, and loss of jointing material, mainly associated with construction deficiencies. Overall, the results indicate that, although the evaluated pavements still present acceptable service conditions in most sections, the results highlight the need for localized corrective interventions and preventive actions to avoid accelerated distress progression. The PCI method proved to be effective as a support tool for urban infrastructure management, supporting the prioritization of critical sections and guiding maintenance decision-making compatible with traffic conditions and road use.

Keywords: Surface distresses; Segmental pavement systems; Pavement condition assessment.

1. Introduction

Road infrastructure plays a fundamental role in social and economic development, directly influencing the movement of people, goods, and access to essential services (Santos 2020). In Brazil, the transportation matrix is predominantly road-based, which underscores the need for continuous investment in construction, maintenance, and rehabilitation. According to CNT (2024), 67% of evaluated roads present conditions classified as Fair (40.4%), Poor (20.8%), or Very Poor (5.8%), including pavement-related deficiencies. This scenario underscores the need for appropriate technical solutions and systematic methods for assessing the structural and functional condition of pavements.

Among the alternatives employed in urban paving, interlocking concrete block pavement stands out as a widely adopted solution for low- and medium-traffic roads. This system combines advantages such as ease of maintenance, the possibility of reusing the individual units, thermal comfort, and contributions to sustainable urban drainage management (ABCP 2012). In the state of Ceará, in northeastern Brazil, the use of this pavement type has been increasingly adopted across several municipalities, driven by its operational and environmental benefits (ABCP 2025).

The performance of interlocking concrete block pavement is directly related to the quality of the materials used, the proper construction of the structural layers, and the adequate interlocking of the concrete units. Construction deficiencies or the absence of periodic monitoring may compromise pavement durability and increase maintenance costs (Ferreira Neto 2023). In this context, the application of objective methodologies capable of quantifying pavement functional condition over time becomes essential.

The Pavement Condition Index (PCI), developed by the United States Army Corps of Engineers and standardized through ASTM E2840-11 (ASTM 2024), is one of the most widely applied tools for surface evaluation of pavements. The method relies on the identification of distress types, their severity levels, and extents, yielding a numerical index ranging from 0 to 100 that enables standardized classification and technical support for maintenance prioritization.

In the municipality of Quixadá, state of Ceará, the installation of interlocking concrete block pavements in the central area has been growing since 2019, when urban renewal works carried out in partnership between the State of Ceará and the Municipal Government introduced this solution to streets in the city center (Ceará 2019). However, systematic studies evaluating the functional performance of these roads after their entry into service remain scarce. This gap hinders the consolidation of data-driven preventive maintenance practices grounded in technical and field evidence.

Against this backdrop, the present study aims to characterize the functional condition of interlocking concrete block pavements in the central area of Quixadá, CE, by applying the PCI method, identifying the predominant distresses, and classifying the functional condition of the sample units surveyed. This characterization is intended to contribute to intervention planning and to the improvement of local urban infrastructure management.

2. Technical Background and Regional Context

2.1 Interlocking Concrete Block Pavement in Urban Applications

Interlocking concrete block pavement generally behaves as a flexible pavement whose structure typically comprises a subgrade (foundation), an optional sub-base course, a base course, a bedding sand layer, and a surface course consisting of closely fitted concrete units with sand-filled joints and lateral edge restraints responsible for the interlocking of the system (ABNT 2011). Despite having a concrete block surface, its structural behavior is governed by the redistribution of vertical stresses applied at the surface, with progressive attenuation of loads toward the subgrade, a characteristic feature of flexible pavements (Balbo 2007).

The performance of this system depends on the interaction among three fundamental interlocking mechanisms: horizontal, vertical, and rotational. Horizontal interlock resists acceleration and braking forces; vertical interlock governs the transfer of shear stresses between adjacent units; and rotational interlock prevents eccentric movement under concentrated loads (ABNT 2011; ICPI 2023). The absence or deterioration of these mechanisms may result in horizontal displacement of units, excessive joint widening, and loss of surface stability (ABCP 2022). Figure 1 illustrates the typical cross-section of interlocking concrete pavement and the associated interlocking mechanisms.

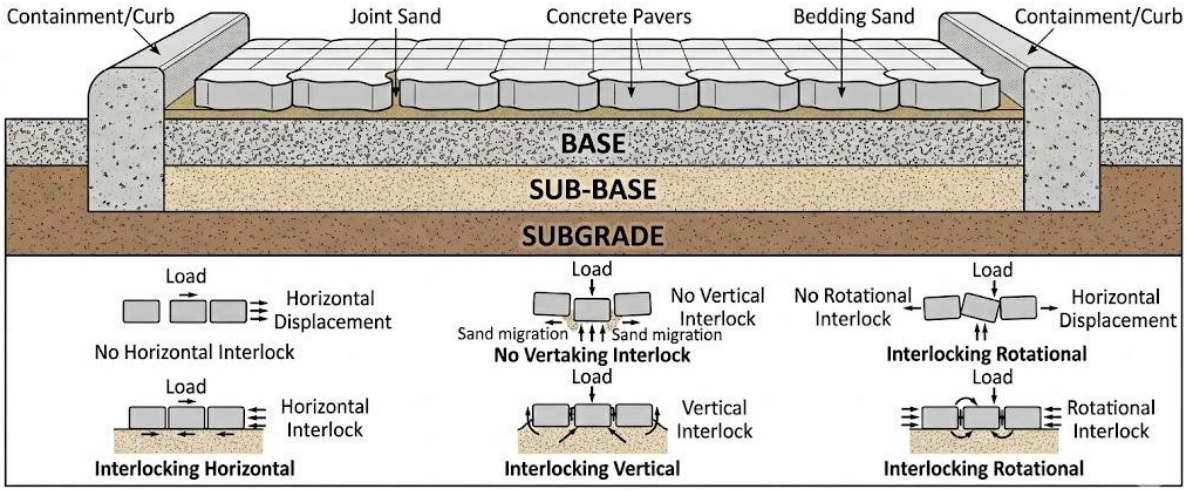

Figure 1 – Typical cross-section of interlocking concrete pavement and load distribution mechanism (adapted from ABCP 2022; ICPI 2023)

Proper construction of the structural layers is critical for system performance. The base course must exhibit sufficient strength and evenness to ensure uniform support for the concrete units, while the bedding sand layer must have controlled gradation and uniform thickness and must not be used to compensate for base course irregularities (ABCP 2010; ABNT 2011). Studies indicate that construction deficiencies, such as inadequate compaction or deficient edge restraints, are among the primary causes of premature distresses in interlocking concrete pavements (Ferreira Neto 2023; Alencar 2024).

In the Brazilian urban context, this pavement type has been employed on local streets, commercial areas, and moderate-traffic zones, owing to its ease of maintenance, potential for unit reuse, and contribution to sustainable urban drainage strategies (ABCP 2012). However, its long-term durability is contingent on the periodic monitoring of functional condition, as distresses such as depressions, loss of jointing material, horizontal displacement, and rutting tend to emerge when construction deficiencies are present or when operational loading exceeds design thresholds (ASTM 2024; Bernucci et al. 2022).

Therefore, while interlocking concrete block pavement offers notable technical and environmental advantages, its long-term performance depends on sound design, construction, and management practices. Systematic assessment of surface condition is thus an essential step towards ensuring system longevity and optimizing maintenance interventions.

2.2 Pavement Condition Index (PCI) Applied to Interlocking Concrete Pavements

The PCI is a standardized functional assessment method based on the systematic visual inspection of existing surface distresses (Páez 2015). Originally developed by the U.S. Army Corps of Engineers and subsequently standardized by the American Society for Testing and Materials, the specific procedure for interlocking concrete pavements is established in ASTM E2840-11 (ASTM 2024).

The method is based on the subdivision of the road segment into sample units, followed by the identification of observed distresses, their classification according to severity level (low, medium, or high), and the measurement of the affected area. From these data, Deduct Values (DVs) are calculated, representing the loss of condition associated with each identified distress. Subsequently, a correction procedure is applied to obtain the Corrected Deduct Value (CDV), enabling the calculation of the final index, which ranges from 0 to 100 (ASTM 2024). On this scale, values approaching 100 indicate pavements in better functional condition, while values approaching 0 represent a critical condition associated with significant loss of surface performance. The operational sequence of the method is summarized in Figure 2, which illustrates the steps from visual inspection through to the determination of the final PCI value.

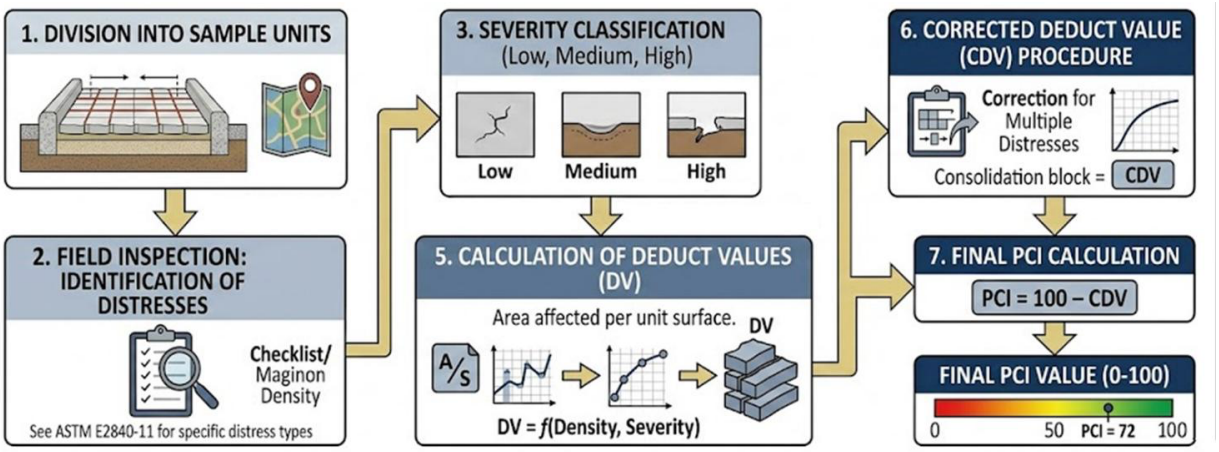

Figure 2 – Simplified flowchart of the PCI calculation procedure according to ASTM E2840-11

As noted by Berbel (2016), the PCI allows the functional state of a pavement to be classified into qualitative categories such as Good, Satisfactory, Fair, Poor, Very Poor, Serious, and Failed, providing a basis for defining preventive or corrective maintenance strategies. Páez (2015) emphasizes that the standardization of the procedure enables comparability across different road segments and constitutes a relevant tool for urban pavement management systems.

For interlocking concrete pavements specifically, ASTM E2840-11 establishes a set of characteristic distress types, including damaged blocks, missing blocks, horizontal displacement, edge restraint damage, excessive joint spacing, rutting, block height difference, and depressions (ASTM 2024; ICPI 2007). The accurate identification of these manifestations is essential, as many are directly associated with construction deficiencies or with the deterioration of the interlocking mechanisms discussed previously.

Studies conducted in municipalities in the interior of Ceará, northeastern Brazil, demonstrate the viability of the PCI as a technical diagnostic tool and a support instrument for municipal management of interlocking concrete pavements (Cunha 2024; Ferreira Neto 2023). Sousa et al. (2025) further reinforce that the adoption of standardized functional evaluation methods contributes to the rationalization of resources and the prioritization of network-level interventions. The PCI therefore constitutes a suitable method for the functional evaluation of the pavements analyzed in this study, enabling the objective quantification of surface condition and the identification of the predominant deterioration mechanisms in the urban context under investigation.

3. Methodology

3.1 Study Area

The study was conducted on interlocking concrete block pavement roads located in the central area of the municipality of Quixadá, CE, in northeastern Brazil, comprising a road network of significance for local urban traffic. Figure 3(a) presents the location of the study area within its urban context, showing its integration within the city's road network. Figure 3(b) provides an enlarged view of the analyzed area, with the boundary delineating the evaluated segments, covering a total area of 5,732.8 m².

(a) (b)

Figure 3 – (a) Location of the study area within the urban context of Quixadá; (b) Enlarged view of the study area (Adapted from Google 2025)

The selection of this area is justified by its strategic importance for urban mobility, characterized by high volumes of vehicles and pedestrians on weekdays. The roads also serve as parking areas, particularly for buses and vehicles from neighboring municipalities and rural zones. On Sundays, although traffic levels are reduced, religious activities sustain continuous use of the parking spaces. Figure 4 presents photographic records illustrating typical road usage conditions. This pattern of use makes the area well suited for evaluating the functional performance of interlocking concrete block pavement under real urban traffic demands.

(a) View of Section A (b) View of Section B (c) View of Sections D and E

Figure 4 – Road usage conditions in the study area on a typical weekday

3.2 Mapping and Definition of Sample Units

For the evaluation, a detailed mapping of the roads comprising the study area was carried out. Given that the study area consists of a compact network of interconnected streets, full coverage was adopted, encompassing all sample units and thereby eliminating the need for the statistical sampling procedure specified by ASTM (2024), since 100% of the sample units were inspected. The roads were subdivided into sections according to the direction of traffic flow and their geometric characteristics. Figure 5 presents the section mapping and the spatial distribution of the 23 sample units.

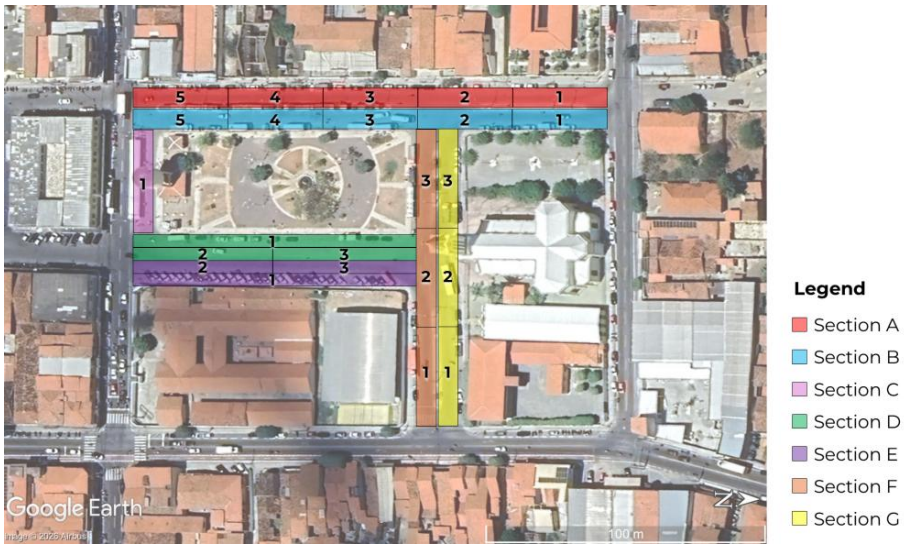

Figure 5 – Mapping of the evaluated segments and sections (Adapted from Google 2025)

The subdivision of sample units complied with the area limits recommended by ASTM (2024), which establishes values of 225 m² ± 90 m² per inspected unit. The dimensions were varied and adjusted to reflect the actual geometric characteristics of each of the 23 sample units analyzed.

3.3 Field Data Collection

Data collection consisted of the identification, classification, and quantification of distresses present in the sample units, in accordance with the criteria established by ASTM (2024). Inspections were conducted through systematic visual assessment and direct field measurements.

Owing to the high traffic volume in the area, inspections were conducted during periods of reduced traffic to ensure greater safety and measurement precision. Preliminary site visits were carried out for area reconnaissance and activity planning. During each inspection, the types of distresses observed, their severity levels (low, medium, or high), and their respective extents were recorded on field data sheets specific to each section. The following instruments were used:

- 50 m tape measure for the demarcation of sample unit boundaries;
- 10 m tape measure for detailed distress measurements;
- wooden straightedge for the severity assessment of depressions and rutting;
- mobile phone for photographic documentation.

3.4 PCI Determination and Data Processing

Following the field survey stage, the collected data were organized and processed using electronic spreadsheets developed to systematize the PCI calculation, in accordance with ASTM (2024) guidelines. The procedure involved converting the affected areas into density values, determining the deduct values, and applying the correction procedure to obtain the PCI for each sample unit.

3.5 Analysis and Interpretation of Results

The PCI values obtained for each sample unit were first analyzed individually. The results were then consolidated by section, enabling assessment of pavement performance at a broader scale. The interpretation was conducted exclusively from a diagnostic perspective, using the PCI as a technical tool for classifying the functional condition of the surveyed roads, without proposing specific interventions or making executive recommendations.

4. Results and Discussion

4.1 PCI Values by Section

The application of the PCI method to the 23 sample units enabled the determination of individual pavement condition values and, subsequently, the mean values by section. Table 1 presents the consolidated results, including the PCI value per sample unit, the corresponding condition classifications, and the mean value obtained for each section analyzed.

Table 1 – PCI values of the sample units and mean value by section

Section	Sample units	PCI per sample unit	Condition	Mean section PCI	Standard deviation	Section condition
A	1	55	Fair	44	20.5	Poor
	2	57	Fair			
	3	57	Fair			
	4	44	Poor			
	5	9	Failed			
B	1	52	Poor	60	7.4	Fair
	2	72	Satisfactory			
	3	59	Fair			
	4	57	Fair			
	5	60	Fair			
C	1	74	Satisfactory	74	-	Satisfactory
D	1	30	Very Poor	44	12.1	Poor
	2	53	Poor			
	3	48	Poor			
E	1	45	Poor	61	18.4	Fair
	2	81	Satisfactory			
	3	56	Fair			
F	1	60	Fair	57	6.4	Fair
	2	50	Poor			
	3	62	Fair			
G	1	81	Satisfactory	53	30.8	Poor
	2	20	Serious			
	3	58	Fair			

The results indicate heterogeneous performance among the evaluated sections. Mean PCI values ranged from 44 (Sections A and D) to 74 (Section C), indicating differences in pavement functional performance

within the same urban area. Section C exhibited the best overall performance, classified as Satisfactory, with a PCI of 74. This section consists of a single sample unit whose surface condition showed a lower incidence of high-severity distresses. Similarly, Section E returned a mean PCI of 61, classified as Fair, albeit with internal variation among its sample units.

By contrast, Section D returned the lowest mean value (PCI = 44), classified as Poor, reflecting a higher level of surface deterioration. This section concentrated sample units with the simultaneous presence of multiple distresses and a greater incidence of medium and high severity levels.

Section A was classified as Poor (mean PCI = 44), a result primarily influenced by Sample Unit 5, whose PCI of 9 characterizes localized functional failure. The presence of extreme values within the same section highlights that pavement condition is not uniform, and localized degradation may occur even when other sample units present intermediate condition ratings. Sections A, E, and G exhibited the highest standard deviations (20.5, 18.4, and 30.8, respectively), indicating considerable internal heterogeneity and reinforcing the need for individual sample unit analysis, since section-level mean values may underestimate localized critical conditions.

Overall, approximately 60% of the sample units presented PCI values between 55 and 85, classified as Fair or Satisfactory, indicating that the majority of the study area still maintains acceptable functional condition. However, approximately 40% of the sample units returned PCI values below 55, evidencing deterioration in specific segments. Three sample units with critical performance are particularly noteworthy:

- Section A – Sample Unit 5 (PCI = 9): characterized by a high concentration of distresses and evident functional impairment;
- Section G – Sample Unit 2 (PCI = 20): associated with construction deficiencies and inadequate repairs;
- Section D – Sample Unit 1 (PCI = 30): located in a parking area, presenting simultaneous occurrence of multiple high-severity distresses.

These extreme values significantly influence section-level mean values and indicate that deterioration does not occur homogeneously, but rather in a localized manner. The analysis of mean values reveals that, although some sections present globally acceptable performance, the existence of critical sample units within the set suggests the need for targeted interventions and continuous monitoring. Consequently, simple mean-based evaluation may underestimate localized severe conditions, reinforcing the importance of individual sample unit analysis. Figure 6 allows a comparative visualization of the mean PCI performance across the evaluated sections.

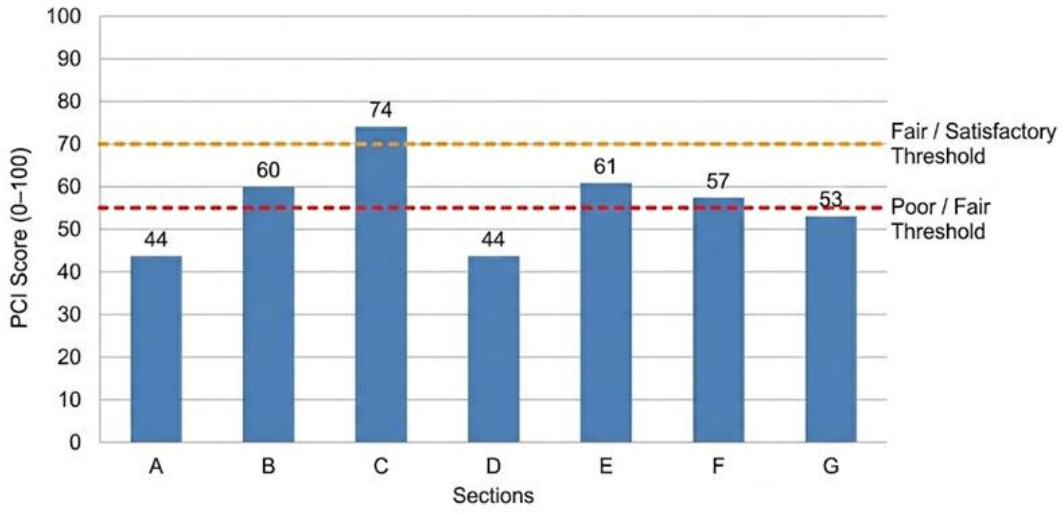

Figure 6 – Mean PCI values by section

Sections A, D, and G are observed to fall below the PCI threshold of 55, indicating Poor condition, while Section C stands out with Satisfactory performance. The remaining sections exhibit intermediate behavior, falling within the Fair range. The quantitative results presented provide the basis for the analysis of predominant deterioration patterns, which will be examined in greater depth in the following subsection, with a focus on the most recurrent distresses and their severity levels.

4.2 Predominant Distresses and Severity Patterns

The analysis of the sample units revealed recurrent deterioration patterns, demonstrating that PCI reduction is more closely related to the nature and severity of distresses than to their frequency of occurrence alone. Figure 7 presents examples of the eight distress types identified during the field inspection, illustrating the manifestations that underpinned the quantitative analysis carried out.

(a) (b) (c) (d) (e) (f) (g) (h)

Figure 7 – Examples of distresses identified during field inspection: (a) Damaged blocks; (b) Depressions; (c) Edge restraint damage; (d) Excessive joint spacing; (e) Block height difference; (f) Loss of jointing material; (g) Missing blocks; (h) Rutting

Table 2 presents the frequency of occurrence of distresses across the 23 sample units, enabling visualization of the overall distribution of manifestations throughout the study area.

Table 2 – Frequency of occurrence of distresses across the 23 sample units

Distress type	Number of occurrences in sample units (n/23)	Impact on PCI value
Damaged blocks	10	Medium
Depressions	23	High
Edge restraint damage	1	High
Excessive joint spacing	23	High
Block height difference	4	Medium
Loss of jointing material	23	Low
Missing blocks	3	High
Rutting	7	High

Of the eight distress types identified, three were present in all evaluated sample units: depressions, excessive joint spacing, and loss of jointing material. Their universal occurrence is indicative of typical behavior of interlocking concrete pavements subjected to urban traffic with repeated loading and prolonged parking, conditions that promote progressive joint widening, pumping of the bedding sand, and the formation of depressions due to differential settlement of the bedding layer (ABCP 2022). It was observed that:

- Depressions occurred in 100% of the sample units (23/23);
- Excessive joint spacing was also present in 100% of the sample units;
- Loss of jointing material likewise occurred in all sample units;
- Damaged blocks were identified in 10 sample units;
- Rutting occurred in 7 sample units;
- Missing blocks and edge restraint damage were less frequent but were associated with the most critical cases.

Despite the high frequency of loss of jointing material, its isolated impact on the PCI proved to be moderate. Across the 23 inspected sample units, this distress covered a total of 4,519.92 m², corresponding to 78.8% of the total inspected area (5,732.8 m²), without a proportional reduction in the index. This indicates that, although the loss of jointing material progressively compromises block interlocking, its immediate effect on functional performance tends to be less severe when compared to structural distresses.

Depressions, on the other hand, exerted a greater influence on PCI reduction, particularly when classified at medium or high severity. Even in areas of limited extent, this distress generated substantial deduct values, significantly affecting the final index. This behavior highlights that surface deformations associated with localized settlement carry greater weight in functional performance assessment.

Distresses such as missing blocks, edge restraint damage, and rutting were directly associated with the sample units presenting the lowest PCI values. In these situations, beyond the structural impact, there is an immediate compromise of pavement functionality and user safety.

The combined assessment of frequency and severity indicates that the deterioration observed in the study area follows two distinct patterns:

- Diffuse pattern, characterized by widely occurring distresses with moderate impact on the index (e.g., loss of jointing material);
- Localized pattern, associated with less frequent distresses but with high impact on PCI reduction (e.g., severe depressions, missing blocks, and edge restraint damage).

This behavior reinforces that distress counting alone is insufficient to characterize pavement functional performance. The severity and the weight assigned to each manifestation in the PCI calculation play a determining role in the final classification. Therefore, the variability observed among sample units stems not merely from the number of distresses present, but from the combination of distress type, severity, and extent, which accounts for the occurrence of extreme values within sections exhibiting intermediate mean ratings.

Although the results obtained are representative of the investigated context, certain methodological limitations should be considered when interpreting the data. The cross-sectional nature of the survey, with inspections conducted at a single point in time, does not allow inferences to be drawn regarding the rate of distress progression over time, which would constrain the development of deterioration models. Furthermore, the evaluation was conditioned by the specific characteristics of the central area of Quixadá, with a mixed-use pattern comprising urban traffic and prolonged parking, which may limit the direct generalization of the PCI values obtained to contexts with distinct loading profiles. Nevertheless, the deterioration patterns identified, particularly the intra-section heterogeneity, the disproportionate influence of localized high-severity distresses, and the universal occurrence of distresses associated with the interlocking system, are consistent with results reported in similar studies conducted in municipalities in the interior of northeastern Brazil (Cunha 2024; Ferreira Neto 2023), suggesting that such patterns may be representative of interlocking concrete pavements installed under analogous urban conditions. In this regard, the methodology employed and the evidence generated contribute to the consolidation of technical references applicable to urban infrastructure management in medium-sized municipalities, particularly those lacking formalized pavement monitoring systems.

5. Conclusions

The application of the PCI method to interlocking concrete block pavements in the central area of Quixadá, CE, demonstrated that surface deterioration does not occur uniformly, but rather in a localized and progressive manner, even within segments presenting apparently acceptable mean performance. This behavior confirms the importance of sample unit-level analysis as a diagnostic instrument more sensitive than aggregate segment-wide assessments.

The results indicate that distresses associated with localized structural capacity loss, such as depressions, rutting, and failures in the interlocking system, exert a disproportionate influence on pavement functional performance compared to more extensive distresses of lower immediate functional severity. This highlights that distress type may be a more decisive factor in pavement condition than frequency of occurrence.

Areas subjected to prolonged parking and vehicle maneuvering were found to be more susceptible to the development of permanent deformations, suggesting that urban loading patterns influence the behavior of interlocking concrete block pavement. This finding reinforces the need to consider actual road use patterns in performance evaluation and maintenance planning.

It is concluded that the PCI is capable of identifying consistent deterioration patterns in urban interlocking concrete pavements, serving as a tool for maintenance prioritization. Beyond classifying road segments, the method enables the recognition of degradation trends and the anticipation of structural failure progression. Consequently, preventive strategies focused on controlling localized settlements and ensuring adequate jointing material maintenance may delay distress progression, thereby contributing to greater pavement durability and improved functional performance throughout the service life.

Abstract: Interlocking concrete block pavements have become a well-established alternative in Brazilian urban roads due to their durability and ease of maintenance. To monitor the performance of this type of pavement, functional evaluation can be performed using the Pavement Condition Index (PCI). However, as the method relies on visual inspections and the interpretation of charts, the results may vary due to evaluator subjectivity. With the increasing use of digital technologies, there is a growing need for tools that make this evaluation process more efficient and standardized. In this context, this study aimed to enhance the application of the Pavement Condition Index (PCI) for the functional condition assessment of interlocking concrete block pavements by means of an Artificial Neural Network–based computational tool. The adopted methodology initially involved the collection and digitalization of data and charts from ASTM E2840-11. Subsequently, the ANN was built and trained, followed by the development of a web-based application for practical use of the tool. Finally, the system was validated using hypothetical data and a field case study. The results showed that the ANN achieved high predictive performance, with an R^2 value of 0.99. The proposed tool correctly reproduced the PCI calculation steps, demonstrating consistency for both hypothetical and field data. In addition, the developed interface enabled the generation of maps and reports for the analysis of sample units. It is concluded that the proposed tool has strong potential to support Pavement Management Systems by contributing to standardized evaluations and reducing interpretation errors.

Keywords: Surface distresses, Computational tools, Pavement condition assessment.

1. Introduction

Road transport is the primary mode of travel in Brazil, accounting for approximately 65% of cargo flow and 95% of passenger transport, making the road network a strategic element for the national economy. Surveys conducted on major Brazilian highways have consistently identified deficiencies in maintenance and signage, reinforcing the need for effective monitoring and management strategies for road infrastructure (CNT 2024).

Among the tools used to assess pavement functional condition, the Pavement Condition Index (PCI) stands out. This methodology is internationally established and applied in Brazil to support pavement management practices (Cunha 2024; Lima 2025). Based on field inspections, the method provides information for maintenance and rehabilitation (M&R) planning, contributing to the efficient use of resources allocated to road infrastructure (ABCP 2022a). The PCI can be applied to different pavement types, including road, airport, and interlocking concrete block pavements. In the context of this work, interlocking concrete block pavement is highlighted as a solution whose use has expanded in Brazil, particularly in small municipalities, due to characteristics such as ease of construction, durability, and simplified maintenance (ABCP 2022b). For this pavement type, the ASTM E2840-11 standard (ASTM 2024), developed by the American

Society for Testing and Materials, is adopted; it systematically establishes distress types, severity levels, and calculation procedures.

Despite the contributions of ASTM (2024), the application of the PCI to interlocking concrete block pavements still presents limitations. The determination of deduct values, carried out through the interpretation of graphical curves, may vary depending on the inspector, introducing subjectivity into the process and compromising the standardization of results. In this context, Artificial Neural Networks (ANN) emerge as an alternative to support pavement condition assessment methodologies, as they are computational models capable of identifying patterns in complex datasets and performing inferences from data with varying levels of uncertainty (Silva et al. 2010).

Given this context, the present study aimed to develop a computational tool based on ANN to support the application of the PCI to interlocking concrete block pavements, seeking to reduce the subjectivity inherent to the procedure. The developed tool, named B-PAVI (*Blocos – Plataforma de Análise de Vias Intertravadas*), was implemented as a web application and validated using both hypothetical and field data.

2. Theoretical Background

The Pavement Condition Index (PCI) is a numerical indicator developed by the United States Army Corps of Engineers (USACE) to assess the surface condition of pavements through the visual identification and quantification of distresses (Shahin 2005). The index ranges from 0 (failed pavement) to 100 (perfect condition), and its rating scale enables categorization into levels ranging from "Failed" to "Good", allowing comparison between pavement sections and rational planning of maintenance and rehabilitation interventions (Shahin 2005). Originally developed for airport pavement evaluation, the method was subsequently adapted for roads and parking lots and standardized by ASTM. In the context of this work, focusing on interlocking concrete block pavements, the PCI method follows the ASTM E2840-11 standard (ASTM 2024). The absence of a specific Brazilian standard for this purpose led to the adoption of American guidelines as reference in national studies.

The significance of the PCI lies in its ability to provide objective, standardized, and low-cost diagnostics based on field visual inspections. By integrating evaluation results into a single interpretable index, the method serves as a tool within Pavement Management Systems (PMS), guiding prioritization decisions for interventions and financial resource allocation (Shahin 2005). It is worth noting that the PCI directly contributes to the development of more effective maintenance strategies, reducing long-term costs associated with accelerated pavement deterioration (Albuquerque 2017).

Despite its contributions, the method presents limitations inherent to its qualitative nature. The primary limitation is its dependence on the inspector's judgment when reading the deduct value (DV) curves, a process that involves the graphical interpretation of continuous values from normative representations. This step tends to introduce variability into results, compromising the reproducibility of assessments across different professionals and over time. Manual pavement condition inspections are slow, labor-intensive, and prone to errors, and inter-rater consistency in distress classification and quantification can be a significant concern. This limitation, inherent to the conventional PCI calculation process, demands technical expertise and is subject to errors arising from the subjectivity of the method, which justifies the development of alternative computational approaches (Attoh-Okine and Adarkwa 2013; Issa, Samaneh, and Ghanim 2022).

The application of the PCI to pavements in the Brazilian context has been gradually documented in urban case studies. Although most studies focus on asphalt pavements, the PCI can serve as a pavement management support tool regardless of the surface type (Berbel 2016).

In the state of Ceará, recent studies have expanded the scope of application of the method to interlocking concrete block pavements. In Quixadá, the evaluation of a section of Avenida José de Freitas Queiroz using the PCI in accordance with ASTM (2024), across ten Sampling Units (SU), indicated a heterogeneous and predominantly degraded structural condition, with four SU classified as Poor, four as Satisfactory, one as

Serious, and one as Failed. The most recurrent distresses, damaged blocks, excessive joint spacing, and loss of joint sand, were present in all units, indicating failures associated with construction quality and the absence of preventive maintenance (Cunha 2024).

In another assessment of streets in downtown Quixadá, approximately 60% of the SU presented PCI values between 55 and 85, with poor construction practice, inadequate design, and lack of preventive maintenance identified as the main deterioration factors (Lima 2025). Comparatively, an evaluation conducted in Quixeramobim across two surveys with a five-month interval recorded a reduction in average PCI from 50 to 34, reinforcing the need for periodic monitoring even in recently maintained sections (Sousa 2025).

Given the limitations inherent to the manual PCI calculation process, researchers have investigated the use of Artificial Neural Networks (ANN) as an alternative to automate and standardize steps that depend on graphical interpretation and technical judgment. In this context, the development of ANN-based predictive models has shown potential for estimating the index from field-observable variables. One example is the Multilayer Perceptron (MLP) model developed to estimate the PCI from distress type and severity in urban roads in Nablus, Palestine, whose results demonstrated the ability of such networks to capture nonlinear relationships between input variables and the condition index (Issa, Samaneh, and Ghanim 2022).

This trend is not limited to isolated studies, being corroborated by broader analyses. A systematic review of 143 papers published over the past three decades identified the main ANN architectures and applications in pavement engineering, along with persistent challenges such as obtaining representative datasets, hyperparameter optimization, and model transferability across different operational contexts (Yang et al. 2021).

The consolidation of the PCI as a reference indicator for interlocking concrete block pavements and the advancement of machine learning techniques thus constitute the context motivating the present work. The developed tool automates the calculation of deduct values from objective inputs, eliminating the graphical curve reading step required by the normative procedure and reducing the variability associated with inspector interpretation. Figure 1 summarizes the complete PCI calculation procedure in accordance with ASTM (2024).

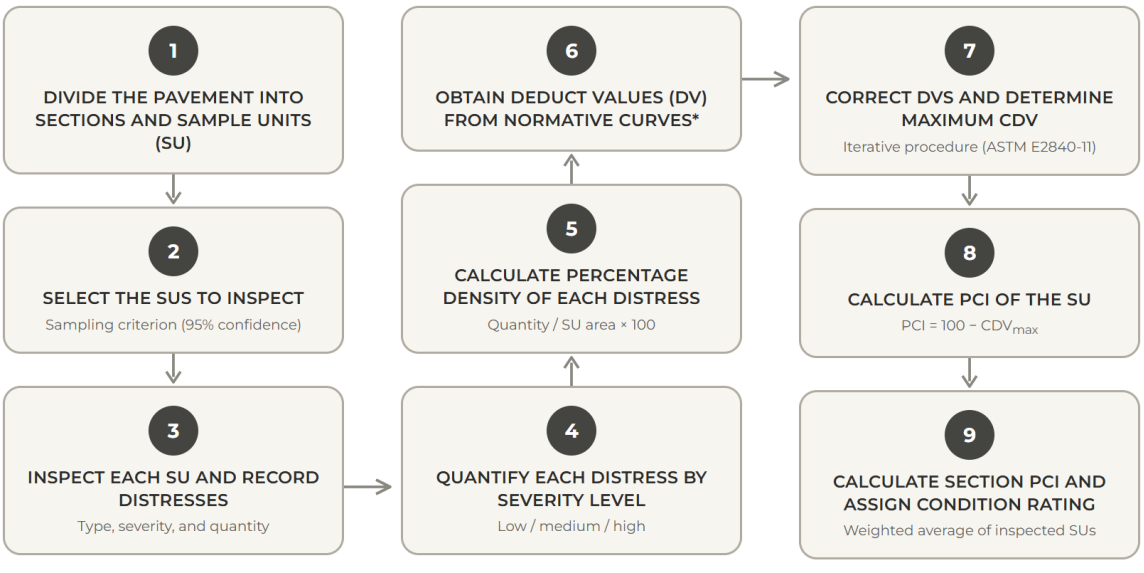

Figure 1 – PCI calculation procedure for interlocking concrete block pavements. (Source: based on ASTM 2024)

3. Methodology

The methodology comprised three stages: (i) data foundation and structuring; (ii) ANN development and training; and (iii) tool implementation and validation. These stages were organized sequentially to ensure consistency between the dataset used, the model construction, and the performance evaluation of the proposed tool.

3.1 Data Foundation and Structuring

The initial stage consisted of converting the deduct value curves, presented in graphical format in ASTM E2840-11, into numerical format. Fixed points were selected along each curve and their coordinate pairs (x-axis: distress density; y-axis: deduct value) were transcribed into spreadsheets, resulting in a structured dataset covering the eleven distress types across the three severity levels, totaling 791 data entries. Table 1 presents an excerpt of the dataset.

Table 1 – Example of data structuring: Distress Corrugation

Distress	Severity	Density (%)	Deduct Value
Corrugation	L	1	3.00
	L	5	6.90
	L	10	10.20
	M	1	12.00
	M	5	26.10
	M	10	34.50
	H	1	34.00
	H	5	44.60
	H	10	53.60

The same procedure was applied to the Corrected Deduct Value (CDV) curves, which relate the Total Deduct Value (TDV) to the coefficient q, defined as the number of distresses whose individual deduct values exceed a minimum threshold stipulated by the standard. For each value of q, a distinct equation is fitted, enabling the iterative calculation of the Maximum Corrected Deduct Value (CDV max).

3.2 ANN Development and Training

For the ANN development, an algorithm was implemented in Python using the TensorFlow library with the Keras API. The dataset is characterized by three input variables: distress type (categorical), severity level (categorical), and percentage density (numerical); and one output variable: the deduct value (numerical). For preprocessing, One-Hot Encoding (binary encoding of categorical variables) was applied to the categorical variables, MinMaxScaler was used for numerical data normalization, and the data were split into an 80% training and 20% testing ratio.

The ANN was structured according to the MLP model, comprising: (a) an input layer with 15 neurons, resulting from the application of One-Hot Encoding to the 11 distress types (11 binary neurons) and to the 3 severity levels (3 binary neurons), plus 1 neuron for the percentage density; (b) a first hidden layer with 32 neurons and ReLU activation (Rectified Linear Unit, a function that retains only positive values); (c) a second hidden layer with 16 neurons and ReLU activation; and (d) an output layer with 1 neuron and linear activation. The number of neurons in each hidden layer was determined through systematic testing, seeking to minimize error and maximize the coefficient of determination (R^2).

3.3 B-PAVI Implementation and Validation

The B-PAVI implementation adopted an architecture divided into backend and frontend. The backend was developed in Python using the FastAPI framework, with endpoints for SU calculation (minimum number of SUs and their positions) and for the PCI calculation of each SU. The frontend was developed with HTML, CSS, and JavaScript, allowing the user to enter road parameters, manage SUs, add distresses, and request PCI calculation. The tool also enables the generation of a georeferenced map in KML format and a technical report in PDF format.

Validation was carried out in two stages. In the first stage, the B-PAVI was tested with hypothetical data covering all eleven distress types across the three severity levels. A hypothetical section of 1,000 m x 5 m was defined, subdivided into 10 SUs of 225 m² each. In the second stage, a field survey was conducted on a real interlocking concrete block pavement section in an urban perimeter measuring 800 m x 7 m (Figure 2). In this section, distresses were manually identified, measured, and classified, and the same data were entered into B-PAVI for comparison of results.

Figure 2 – Analyzed section in urban perimeter

4 Results and Discussion

The results are presented in three parts: the predictive performance of the ANN during training, the tool validation with hypothetical data, and the validation with field data. Together, these analyses allowed for the evaluation of both the generalization capacity of the model and the consistency of B-PAVI under real application conditions.

4.1 ANN Performance

ANN training was performed with 80% of the data reserved for training and 20% for testing. Figure 3 presents the learning curves, showing the evolution of loss (MSE) over the training epochs.

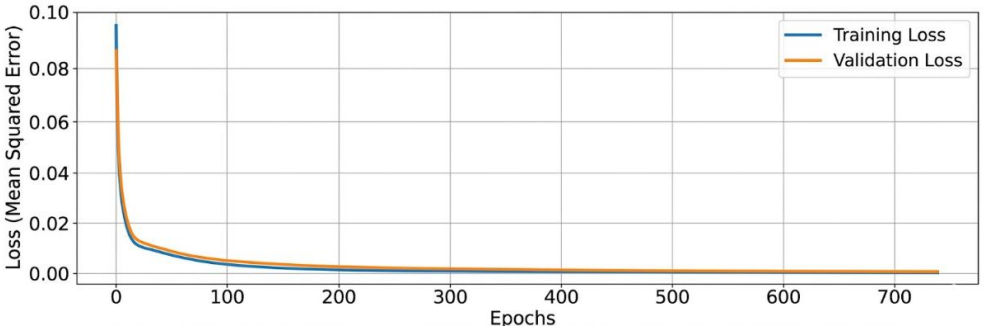

Figure 3 – ANN model learning curves (MSE Loss and Epochs)

The loss decreased from an initial value close to 0.10 to approximately 0.013 within the first 50 epochs, stabilizing gradually from epoch 400 onward. The absence of divergence between the training and validation curves confirms that the model did not suffer from overfitting. Table 2 presents the comparative performance metrics between the training and testing sets.

Table 2 – ANN performance metrics (training and testing sets)

Metric	Training	Test
R^2	0.99	0.99
MAE	0.54	0.91
RMSE	0.86	1.75

The Coefficient of Determination (R^2) reached 0.99 in both the training and testing sets, indicating that the model explains 99% of the variability in deduct values and presents adequate generalization capacity, with no evidence of overfitting. The Mean Absolute Error (MAE) of 0.91 in the testing set means that, on average, the tool produces an error of less than 1 point on the PCI scale, a negligible error for practical purposes of classification and decision-making in pavement management M&R strategies. The Root Mean Square Error (RMSE) of 1.75 confirms that even the largest isolated errors remain below 2 points on the 0-to-100 scale, keeping the tool within an acceptable precision range. The fact that the RMSE is approximately twice the MAE indicates the presence of some more pronounced but isolated deviations, without compromising the overall performance of the model.

Qualitative error analysis also identified that eight of the ten worst predictions belong to two distress types: Block Loss (5 occurrences) and Damaged Blocks (3 occurrences), with a predominance of high severity cases. For Block Loss at high severity, the probable cause is the low representativeness in the dataset (20 samples). For Damaged Blocks at high severity, the greater model uncertainty can be attributed to the inherent variability of this distress type, which represents a limitation to be considered in practical application. From a practical standpoint, these results indicate that predictions associated with these distresses at high severity should be interpreted with caution and, whenever possible, supplemented by direct technical assessment, while also highlighting the need for dataset expansion and balancing to improve model performance.

4.2 Validation with Hypothetical Data

Figure 4 presents the PCI values calculated manually by the standard procedure and those generated by B-PAVI, for each SU and for the average of the hypothetical section. The results demonstrated agreement between the tool and the standard procedure. SUs 1, 7, and 8 produced identical results. The remaining SUs exhibited isolated discrepancies not exceeding 2 PCI points in most cases, with the exception of SU 4 (comprising Damaged Blocks at low severity, Excessive Joint Spacing at high severity, and Loss of Joint Sand at high severity), in which a difference of 4 points resulted in distinct classifications: the manual procedure classified the SU as Serious (PCI = 22), while B-PAVI classified it as Very Poor (PCI = 26). Nevertheless, the validity of the algorithm is confirmed by the overall section average, with a PCI of 47 by the tool and 48 by the standard procedure.

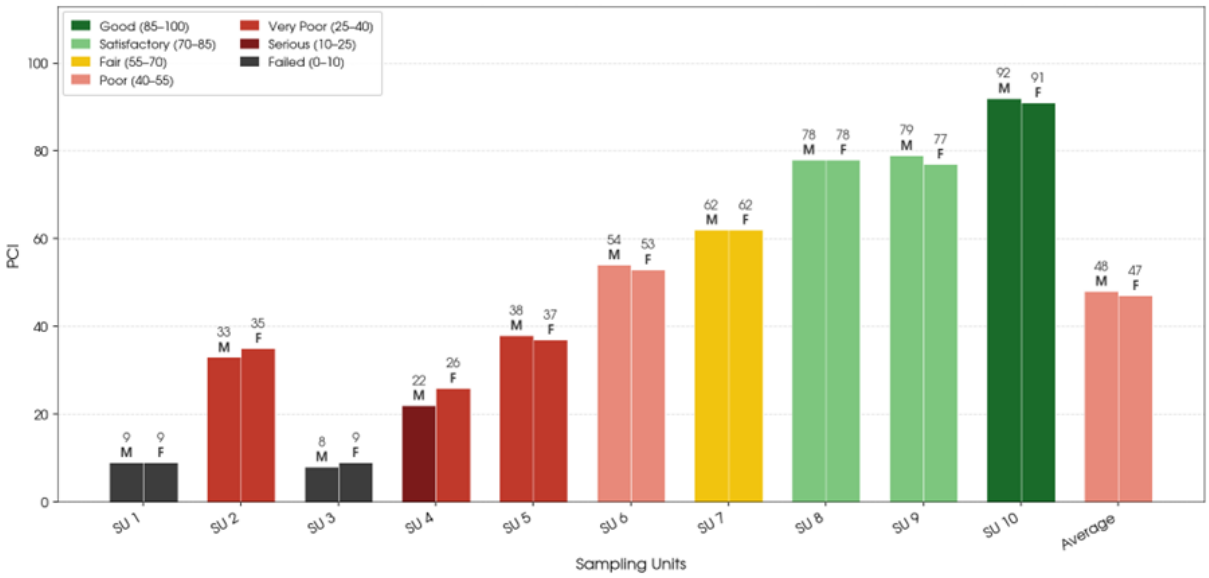

Figure 4 – Comparison between manual procedure and B-PAVI tool results (hypothetical data)

4.3 Field Validation

During the urban section inspection, the most recurrent distresses were Loss of Joint Sand, Excessive Joint Spacing, and Damaged Blocks, observed in all SUs. Figure 5 presents examples of the identified distresses.

Figure 5 – Distresses identified in the section: (a) Loss of joint sand; (b) Excessive joint spacing; (c) Damaged blocks; (d) Depression

Figure 6 presents the comparison between the results of the manual survey and those generated by B-PAVI. Similarities were also observed between the results in most SUs. The differences in SUs 2, 4, 9, and 10 can be attributed both to the subjectivity of the manual method, which depends on the inspector's judgment to select the deduct value from the standard curves (Shahin 2005; Attoh-Okine and Adarkwa 2013), and to the isolated limitations of the ANN for distresses such as Damaged Blocks and Block Loss. The results confirmed

the consistency of the tool, as the manual survey classified the section as Fair with an average PCI of 58, while B-PAVI classified it equally as Fair, with an average PCI of 57.

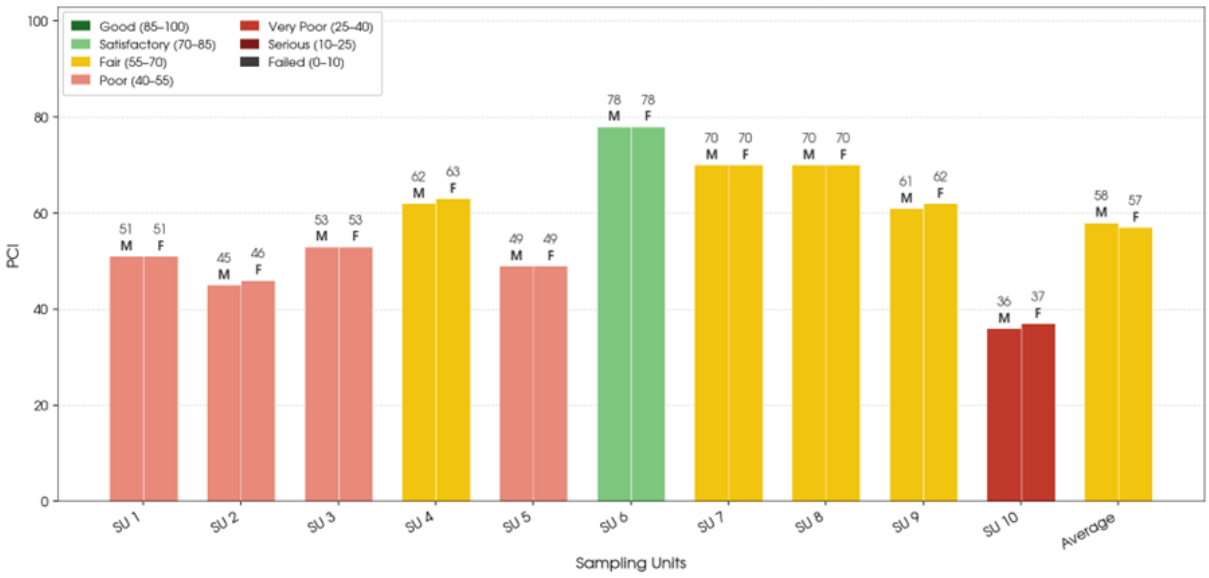

Figure 6 – Comparison between manual procedure and B-PAVI tool results (field data)

Figure 7 presents the geospatial visualization of results in the KML map exported by the tool, with each SU identified by its position and PCI value. Unlike the bar chart, which summarizes results numerically, the georeferenced map allows for the identification of the exact location of sections in worse condition, constituting a direct decision-support resource for maintenance and rehabilitation activities. This functionality represents a distinctive feature of B-PAVI in relation to conventional manual survey approaches, in which results are typically not integrated into spatial visualization systems.

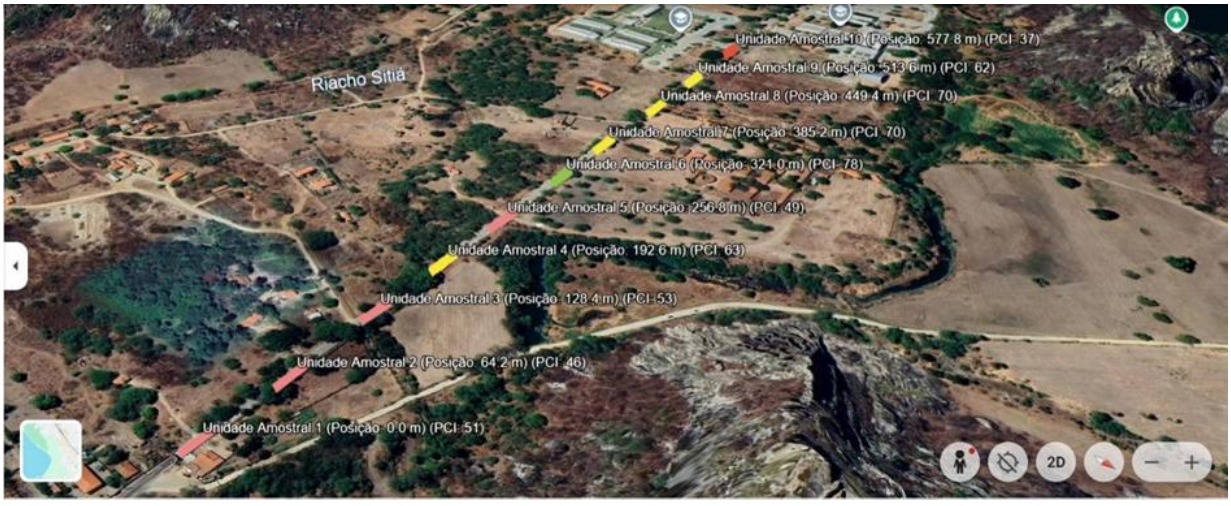

Figure 7 – KML map of the analyzed urban section with the respective PCI values per SU

5 Conclusions

This study showed that PCI calculation can be systematized for interlocking concrete block pavements through an ANN-based computational tool, reducing the dependence on subjective inspector interpretation in the graphical curve reading steps. The developed model presented satisfactory predictive performance, with R^2 of 0.99 in the testing set, and consistently reproduced deduct values for the eleven distress types established by ASTM E2840-11 across the three severity levels. The discrepancies observed for distresses such as Damaged Blocks and Block Loss, although isolated, have traceable causes in the inherent variability of these distress types and did not compromise the overall reliability of the model.

Validation with hypothetical and field data confirmed the consistency of B-PAVI under real application conditions. In the field data, the tool classified the analyzed section as Fair (average PCI of 57), in agreement with the result of the manual procedure (average PCI of 58), with a difference of less than 2% between the methods. Beyond index calculation, B-PAVI integrates complementary functionalities, such as technical report generation in PDF format and georeferenced KML map export, that directly connect field-collected records to the steps of the normative procedure, supporting the communication of results and decision-making in maintenance and rehabilitation activities.

The contribution of this work lies in the consolidation of an approach that transforms a traditionally manual procedure, subject to interpretive variability, into a standardized, reproducible, and operationally applicable process. By integrating predictive modeling, routine automation, and data systematization resources into a single platform, the tool expands the practical applicability of the method and contributes to making interlocking concrete block pavement assessment more consistent and aligned with the demands of a PMS.

Abstract: In the context of climate change, it is relevant to investigate the relationship between rainfall variability and the functional performance of road pavements. This study investigates the relationship between annual average precipitation and the functional condition of the road network in the state of Ceará, northeastern Brazil, from 2012 to 2024, by integrating data from the *Confederação Nacional do Transporte* (CNT) Road Survey and historical precipitation series. The analysis considered the five evaluation classes defined by the CNT (excellent, good, fair, poor, and very poor) across four components: pavement condition, signage, roadway geometry, and overall road condition. Statistical analysis was performed using Pearson's correlation coefficient, adopting a 5% significance level with a two-tailed approach. The results indicated a strong negative correlation between annual average precipitation and the proportion of pavements classified as excellent, both for pavement condition ($r = -0.90$) and overall road condition ($r = -0.71$), indicating a reduction in higher performance levels during wetter periods. Conversely, positive correlations were observed between increased precipitation and the growth of good ($r = 0.73$) and poor ($r = 0.76$) pavement condition classes, suggesting a gradual shift from higher to intermediate and lower condition levels. For road signage, correlations were predominantly moderate, indicating lower direct sensitivity to rainfall variability. Roadway geometry exhibited a distinct behavior, with a positive correlation for the fair condition class ($r = 0.69$) and a negative correlation for the very poor class ($r = -0.67$). Overall, the results indicate an association between rainfall variability and the loss of pavement performance, reflected in the overall condition of the road network. It is concluded that the integration of functional condition surveys and precipitation data contributes to the diagnosis of pavement distresses and to the prioritization of road infrastructure maintenance actions.

Keywords: pavement distresses, rainfall variability, functional condition of pavements, road infrastructure.

1. Introduction

The Brazilian road network constitutes the primary infrastructure supporting the transport of goods and passengers in the country, accounting for more than 60% of total freight volume (CNT 2024). In the context of northeastern Brazil, particularly the state of Ceará, roads play a strategic role in regional connectivity, given the limited capacity of other transport modes. Adequate maintenance of road infrastructure is therefore a fundamental condition for the socioeconomic development of these regions.

The functional performance of asphalt pavements is governed by multiple interacting factors, among which traffic volume and composition, subgrade characteristics, pavement structural materials, and climatic conditions throughout service life are particularly prominent (Bernucci et al. 2022). Among climatic agents, rainfall plays a central role in accelerating deterioration mechanisms. The presence of water can

compromise the load-bearing capacity of the subgrade and promote processes such as infiltration, fatigue cracking, and interlayer debonding (Nazzal et al. 2021; Caro et al. 2008).

In the context of climate change, rainfall variability has been identified as an increasingly relevant factor in pavement design and maintenance. Rising frequency and intensity of extreme precipitation events are projected to shorten the service life of flexible pavement structures (Qiao et al. 2020). In this regard, Stoner et al. (2019) quantified the impacts of climate change on the performance of flexible pavements across the United States, demonstrating that projected increases in precipitation may lead to significant reductions in pavement surface life.

In Ceará, the precipitation regime is characterized by pronounced interannual variability, driven by phenomena such as the El Niño–Southern Oscillation (ENSO) and the Intertropical Convergence Zone (ITCZ) (Da Silva et al. 2020). This climatic irregularity creates favorable conditions for investigating the association between rainfall fluctuations and the functional condition of the road network over time.

Against this background, the present study aims to examine the influence of annual precipitation variability on the functional condition of asphalt pavements in the state of Ceará road network from 2012 to 2024. To this end, data from the *Confederação Nacional do Transporte* (CNT) Road Survey are integrated with historical precipitation series from the *Fundação Cearense de Meteorologia e Recursos Hídricos* (FUNCEME), with statistical analysis based on the Pearson correlation coefficient.

2. Literature Review

Asphalt pavement is a multilayer structure designed to distribute traffic loads so as not to exceed the bearing capacity of the constituent materials (Bernucci et al. 2022). Throughout its service life, this structure undergoes progressive deterioration as a result of the interaction between repeated loading and environmental agents, most notably water.

The principal deterioration mechanisms include fatigue cracking, permanent deformation, surface wear, and disintegration of asphalt layers. Water affects several of these processes: it weakens the adhesive bonds between the asphalt binder and aggregates, reduces subgrade bearing capacity, and promotes the propagation of pre-existing cracks (Caro et al. 2008). At the microscopic scale, moisture induces stripping damage in asphalt mixtures, compromising the internal cohesion of the wearing course, a mechanism that intensifies with prolonged and repeated exposure to precipitation (Nazzal et al. 2021). Figure 1 illustrates the main water-induced deterioration mechanisms in asphalt pavements, highlighting the interactions among precipitation, pavement structure, and functional degradation.

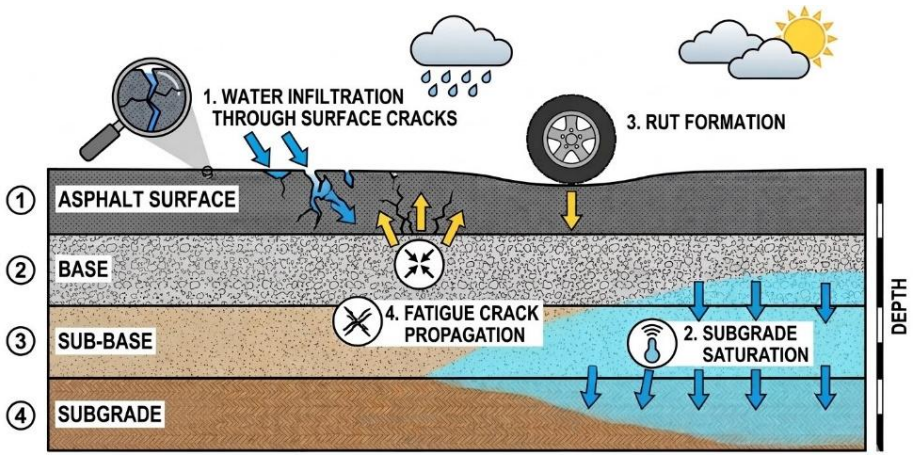

Figure 1 – Schematic cross-section of asphalt pavement deterioration mechanisms induced by water (based on Bernucci et al. 2022; Nazzal et al. 2021)

This vulnerability to water-induced damage becomes more critical in the context of climate change. Extreme precipitation events are projected to increase in both frequency and intensity across numerous regions, with direct impacts on transport infrastructure (IPCC 2023). Higher precipitation levels have been associated with accelerated surface fatigue and increased permanent deformation (Qiao et al. 2020), highlighting the need to incorporate climate projections into pavement design models in order to ensure adequate performance throughout the design life.

At the road network scale, negative correlations between accumulated precipitation and the Pavement Condition Index (PCI) have been identified for urban roads (Llopis-Castelló et al. 2020), corroborating the hypothesis that water acts as an accelerator of pavement degradation. For the North American context, regions facing projected increases in precipitation are expected to record reductions in pavement service life, with direct implications for maintenance and rehabilitation costs (Stoner et al. 2019).

Systematic road condition assessment and climatic monitoring support the diagnosis of road infrastructure and the formulation of pavement maintenance and rehabilitation strategies. In Brazil, various public agencies and sectoral entities conduct periodic surveys of the road network and climatic variables at national, regional, and state scales. Among these initiatives, the CNT Road Survey and the rainfall monitoring network of the FUNCEME are particularly relevant to the present study.

The CNT Road Survey is an annual assessment carried out by the CNT, the representative body of the Brazilian transport sector, which evaluates the condition of the country's paved road network. It constitutes a comprehensive road condition inventory covering federal and state highways, both public and private, across all states, with an assessed extent exceeding 100,000 km per survey cycle (CNT 2024). Due to its regularity, geographic coverage, and methodological standardization, the survey is one of the primary references for diagnosing Brazil's road infrastructure and informing public policies on pavement maintenance and rehabilitation.

The CNT Road Survey methodology considers three dimensions: pavement condition, signage conditions, and road geometric characteristics. Each dimension is classified into five categories (excellent, good, fair, poor, and very poor) with results expressed as a percentage of the assessed extension. The assessment encompasses surface distresses such as cracking, rutting, corrugation, potholes, and patching, as well as longitudinal roughness.

The CNT Road Survey enables the construction of comparable historical time series, facilitating trend analyses and correlation studies with variables of interest such as climatic and socioeconomic indicators. This feature distinguishes the survey from one-off assessments, making it well suited for longitudinal studies on the performance of Brazilian road infrastructure, a context in which the state of Ceará stands out as a particularly relevant unit of analysis for investigating associations between climatic variability and road functional conditions.

Located within the semiarid region of northeastern Brazil, one of the most climatically vulnerable areas on the continent, the state of Ceará is characterized by pronounced interannual rainfall variability and a high frequency of extreme events, including prolonged droughts and intense rainfall episodes. This regime is primarily modulated by the El Niño–Southern Oscillation (ENSO) and the Intertropical Convergence Zone (ITCZ), whose interactions produce years with precipitation well below or well above the historical mean. Mean annual precipitation in the state ranges from less than 400 mm in the driest interior areas to approximately 1,600 mm in the highland zones, with interannual coefficients of variation exceeding 30%, markedly higher than those observed in temperate regions (Da Silva et al. 2020).

This irregularity does not follow a random temporal distribution. Research on the Northeast Brazilian climate identifies the existence of multi-year cycles associated with the warm and cold phases of ENSO, with direct impacts on the intensity and spatial distribution of rainfall: El Niño years tend to produce severe droughts in the semiarid zone, while La Niña years are frequently associated with above-average rainy seasons (Da Silva et al. 2020). This cyclical pattern, in combination with long-term trends and global climate change, creates

a scenario of increasing pressure on the regional road infrastructure. The IPCC (2023) projects that these changes are likely to intensify hydrological extremes in tropical regions.

Systematic monitoring of this climatic behavior in Ceará is carried out by the FUNCEME, a state public agency responsible for maintaining long-term precipitation records for the Ceará territory. These datasets constitute a key reference for climatic studies in the Brazilian semiarid zone. This structural climatic irregularity creates exceptional conditions for investigating how medium-term rainfall oscillations are reflected in the functional performance of road infrastructure. In this context, Ceará presents itself as a case study with the potential to contribute both to regional pavement management and to the broader debate on the adaptation of transport infrastructure to climate change.

3. Research Method

This study is grounded in the integration of secondary data on road functional condition and precipitation. The state of Ceará was adopted as the unit of analysis due to its distinctive climatic characteristics, particularly its pronounced interannual rainfall variability, which makes it a suitable context for investigating associations between precipitation and pavement functional performance. The research was organized into seven sequential steps, summarized in Figure 2 and described in detail below.

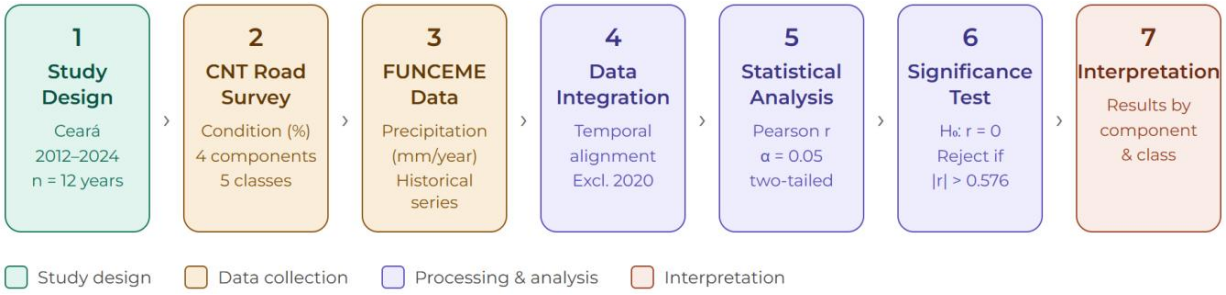

Figure 2 – Methodological framework of the research

Step 1 involved defining the spatial and temporal scope of the study: the state of Ceará over the period from 2012 to 2024. The year 2020 was excluded from the analysis due to the suspension of the CNT Road Survey during the COVID-19 pandemic, resulting in a final sample of 12 annual observations.

Steps 2 and 3 corresponded to the collection of the two datasets employed. The first was the CNT Road Survey (CNT 2024), from which annual data on pavement condition, signage, road geometry, and overall condition, classified as excellent, good, fair, poor, and very poor, were extracted. The results for each category are expressed as a percentage of the assessed extension, comprising the dependent variables of the analysis. The second dataset consisted of historical precipitation series for the state of Ceará, obtained from FUNCEME (2025). Rainfall records, originally provided at daily or monthly resolution, were aggregated into annual averages (mm/year) to enable direct comparison with the annual CNT Road Survey data. The data were subjected to prior outlier screening; all records were retained in the series given the impossibility of precisely determining the collection dates of the CNT Road Survey, which would have precluded any well-founded exclusion. These data constitute the independent variable of the study, representing the mean annual precipitation fluctuations over the period analyzed.

Step 4 organized and aligned the datasets of the two series, ensuring correspondence between the year of road functional assessment and the respective recorded precipitation volume. This allowed the calculation of the Pearson correlation coefficient (r) for each pair formed by annual average precipitation and the percentage of roads in each condition class, across each of the four assessed components, totaling 20 variable pairs (Step 5). The Pearson coefficient ranges from −1 to +1, where values close to −1 indicate strong

negative correlation, values close to +1 indicate strong positive correlation, and values near zero indicate the absence of linear correlation.

Step 6 tested the statistical significance of the obtained correlations. To this end, a significance level of α = 0.05 was adopted with a two-tailed approach, with the null hypothesis defined as H_0: r = 0 — the absence of linear correlation between precipitation and pavement functional condition. The critical value for n = 12 observations is |r| = 0.576, derived from the critical value table for the Pearson correlation coefficient at 10 degrees of freedom (df = n − 2) and a two-tailed significance level of α = 0.05 (Neter et al. 1996), so that correlations with absolute values exceeding this threshold were classified as statistically significant and retained for interpretation in the subsequent step. Finally, Step 7 involved interpreting the results, with analysis of statistically significant and non-significant correlations by component and condition class.

4. Results and Discussion

This section presents and discusses the results across four subsections. The first two separately characterize rainfall variability and the evolution of road functional conditions. The subsequent two integrate both series through Pearson correlation analysis, with interpretation by component and condition class.

4.1 Rainfall Variation in Ceará (2012–2024)

Figure 3 presents the evolution of mean annual precipitation in the state of Ceará between 2012 and 2024, based on FUNCEME data.

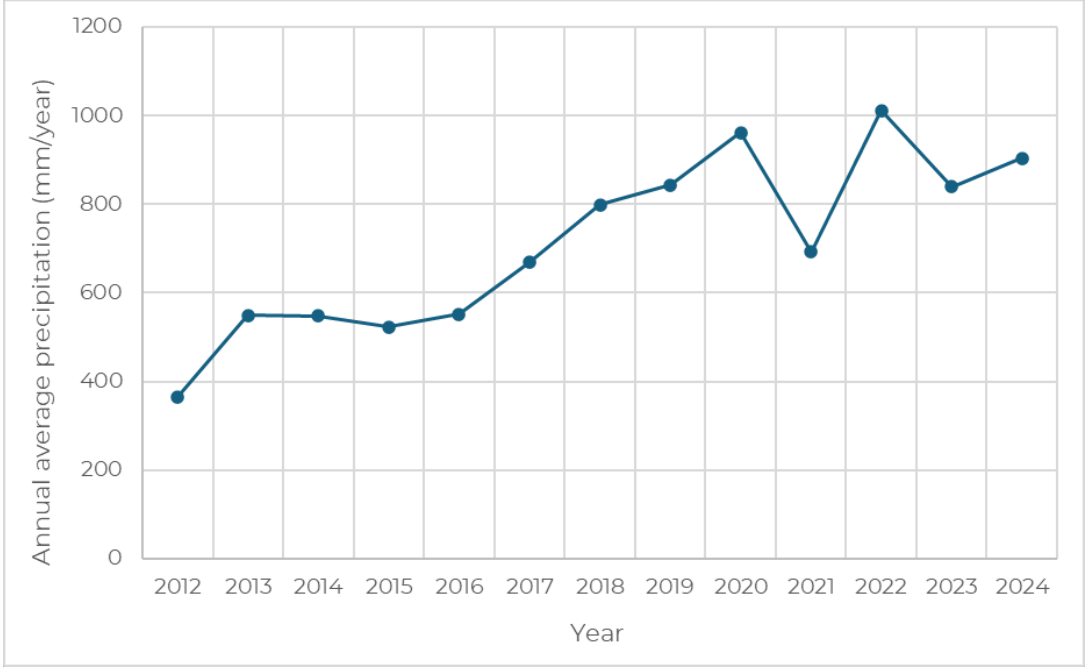

Figure 3 – Annual average precipitation in the state of Ceará, 2012–2024 (adapted from FUNCEME 2025)

The year 2012 recorded the lowest precipitation index of the series (~375 mm/year), associated with an intense El Niño episode that affected the northeastern semiarid zone during that period. From 2013 to 2016, precipitation remained relatively stable, ranging between 510 and 540 mm/year, followed by a rising trend from 2017 onwards. From 2018, an increase in annual rainfall volumes is observed, with greater interannual variability, reaching the highest values in the series in 2020 (~955 mm/year) and 2022 (~1,000 mm/year). This

behavior is consistent with IPCC (2023) projections indicating intensification of hydrological extremes in tropical regions, as well as with the climatic variability patterns associated with ENSO (Da Silva et al. 2020).

4.2 Evolution of Road Functional Conditions — Pavement, Signage, and Geometry

Figure 4 presents the temporal evolution of asphalt pavement conditions in Ceará's road network between 2012 and 2024, by condition class**.** A reduction in the proportion of roads classified as excellent is observed throughout the period, becoming more pronounced from 2018 onwards, coinciding with the period of higher precipitation (Figure 3). Concurrently, a gradual increase in the poor and very poor categories is evident, indicating a progressive shift in pavement condition toward lower performance levels over the historical series.

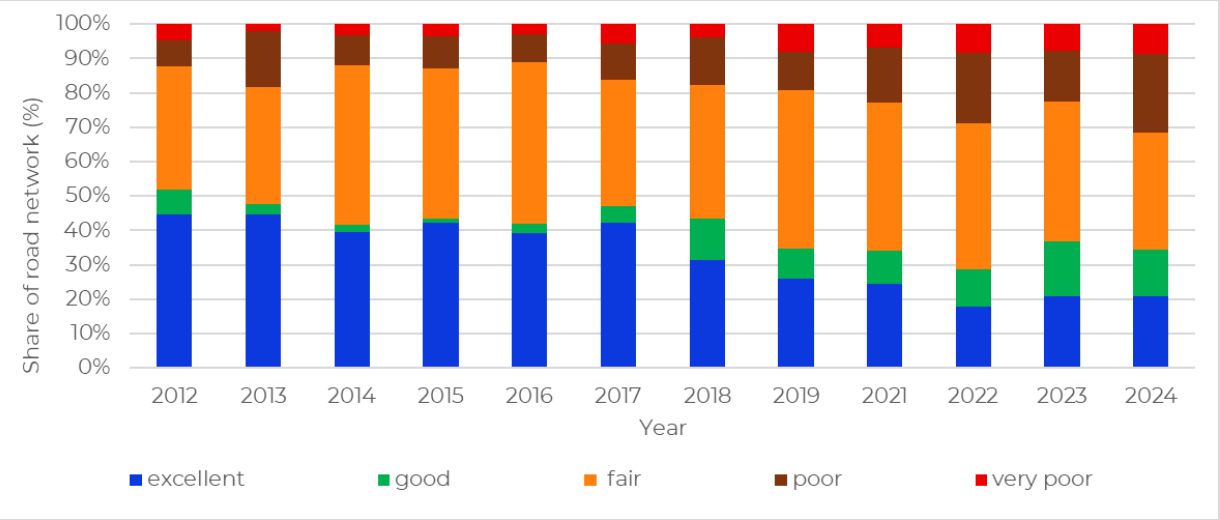

Figure 4 – Pavement condition classification in Ceará road network, 2012–2024 (adapted from CNT 2024)

The fair condition class remained notably stable throughout the entire period. This pattern suggests that this category functions as a transitional zone between higher and lower states, absorbing part of the variation without exhibiting marked oscillations, a behavior consistent with the dynamics of progressive degradation (Bernucci et al. 2022), in which road segments tend to migrate from good to poor conditions while remaining in the fair classification for extended periods. The contemporaneity between increasing precipitation and deteriorating pavement conditions suggests a possible association between the two trends, a hypothesis that is tested statistically and presented subsequently.

Figure 5 presents the temporal evolution of signage conditions in Ceará's road network between 2012 and 2024. Unlike pavement, signage does not exhibit a clear trend of deterioration or improvement throughout the historical series, with the condition classes alternating without a consistent pattern. This behavior suggests that signage is governed by factors distinct from those acting on the asphalt surface, such as periodic maintenance policies and targeted interventions, rather than continuous degradation processes.

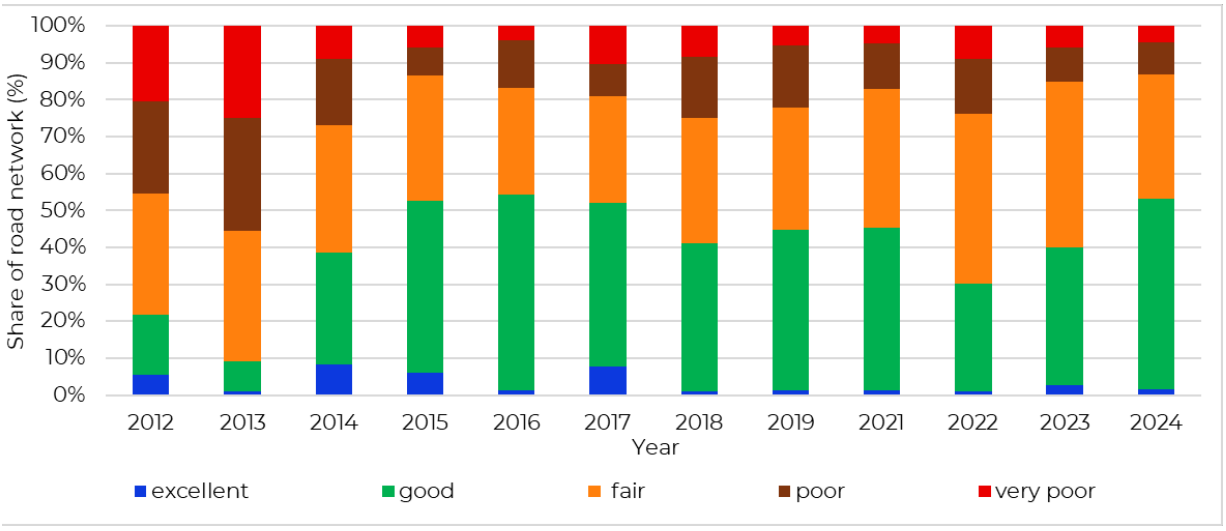

Figure 5 – Signage condition classification in Ceará road network, 2012–2024 (adapted from CNT 2024)

Figure 6 presents the evolution of road geometric conditions over the same period. Road geometric characteristics (such as alignment, carriageway width, curves, and grades) are defined at the design stage and tend to remain stable over time, which explains the lower variability observed compared to pavement. The fluctuations identified primarily reflect localized structural interventions and adjustments carried out on specific road segments, rather than a systematic trend associated with climatic factors.

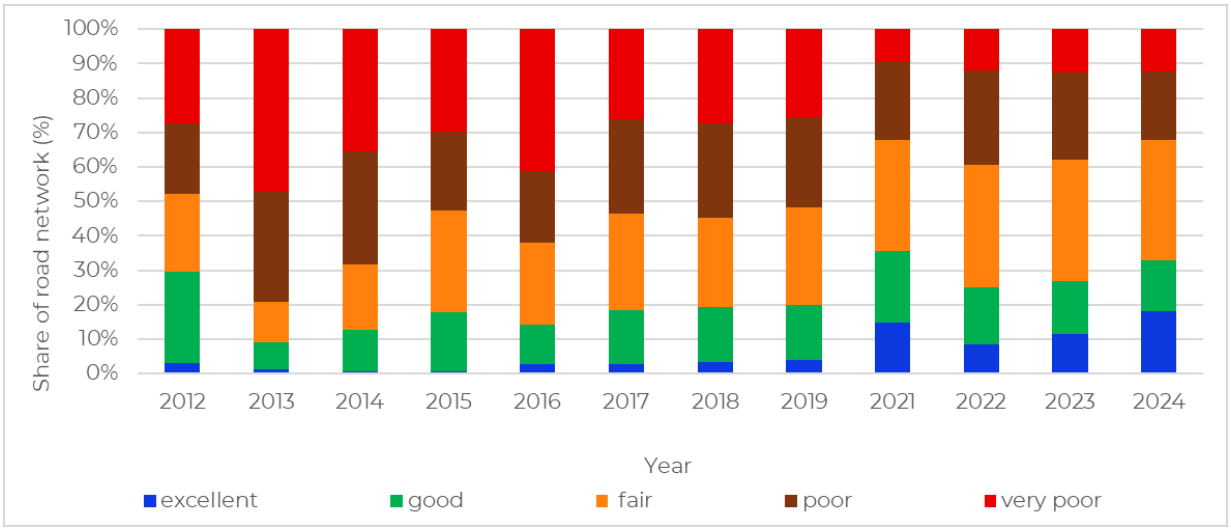

Figure 6 – Road geometry condition classification in Ceará road network, 2012–2024 (adapted from CNT 2024)

4.3 Evolution of Overall Road Condition

Figure 7 presents the evolution of the overall road condition in Ceará between 2012 and 2024. Since it integrates the three assessed components (pavement, signage, and geometry), the overall condition tends to predominantly reflect the behavior of the component with the greatest weight in the global assessment, which, as will be demonstrated, is pavement. A reduction in the proportion of roads classified as excellent is observed throughout the period, accompanied by a growth of intermediate and lower categories, a pattern analogous to that identified in Figure 4 for the pavement component.

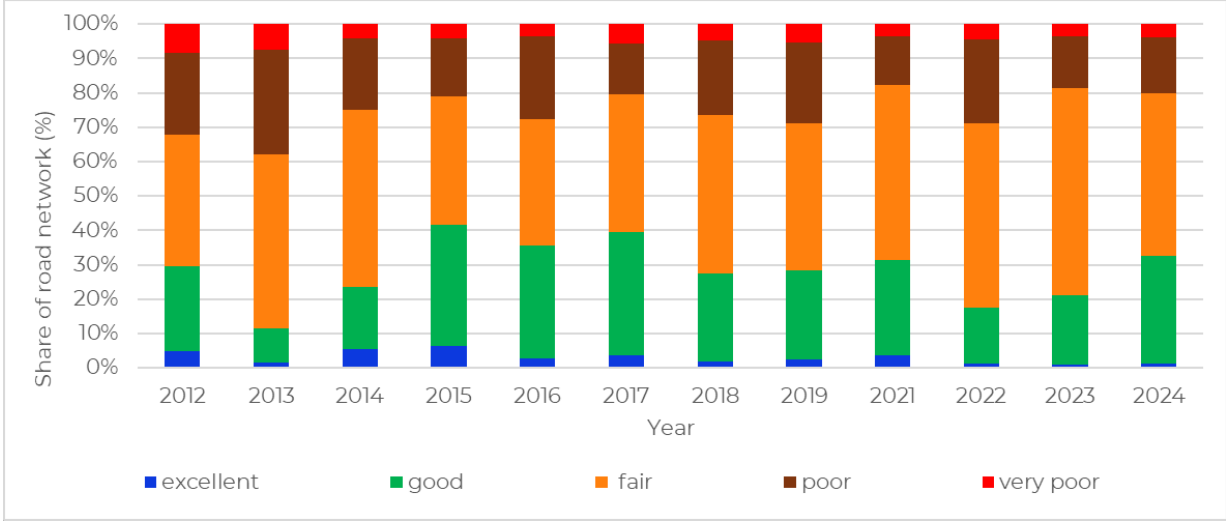

Figure 7 – Overall road condition classification in Ceará road network, 2012–2024 (adapted from CNT 2024)

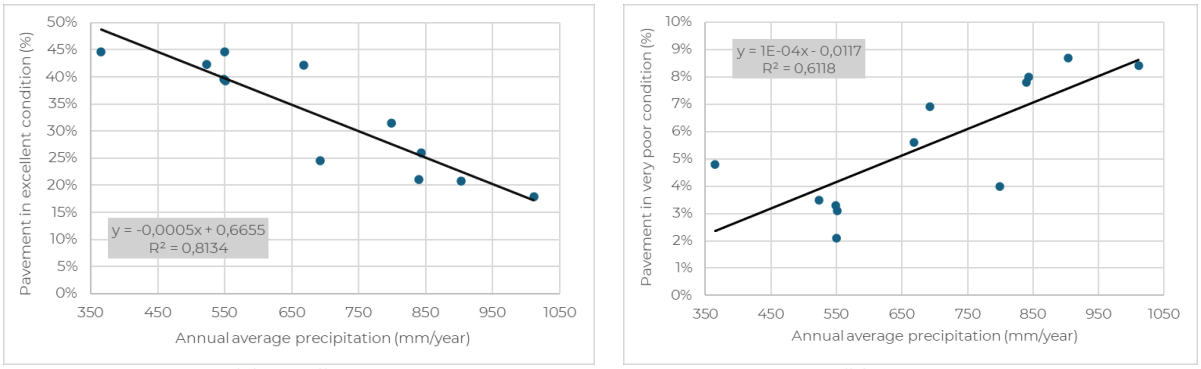
The similarity between the evolution patterns of overall road condition and pavement reinforces the hypothesis that asphalt surface condition exerts a dominant influence on the global road assessment, representing the most sensitive component to external factors acting during the analyzed period. This observation will be corroborated by the correlation coefficients presented in the following subsection.

4.4Correlation Analysis

Table 1 presents the Pearson correlation coefficients calculated between mean annual precipitation and the condition classes of each component assessed by the CNT Road Survey. Values marked with an asterisk indicate statistically significant correlations ($|r| > 0.576$, $\alpha = 0.05$, two-tailed, $n = 12$).

Table 1 – Pearson correlation coefficients between annual precipitation and CNT condition classes (n = 12, significance level 5%)

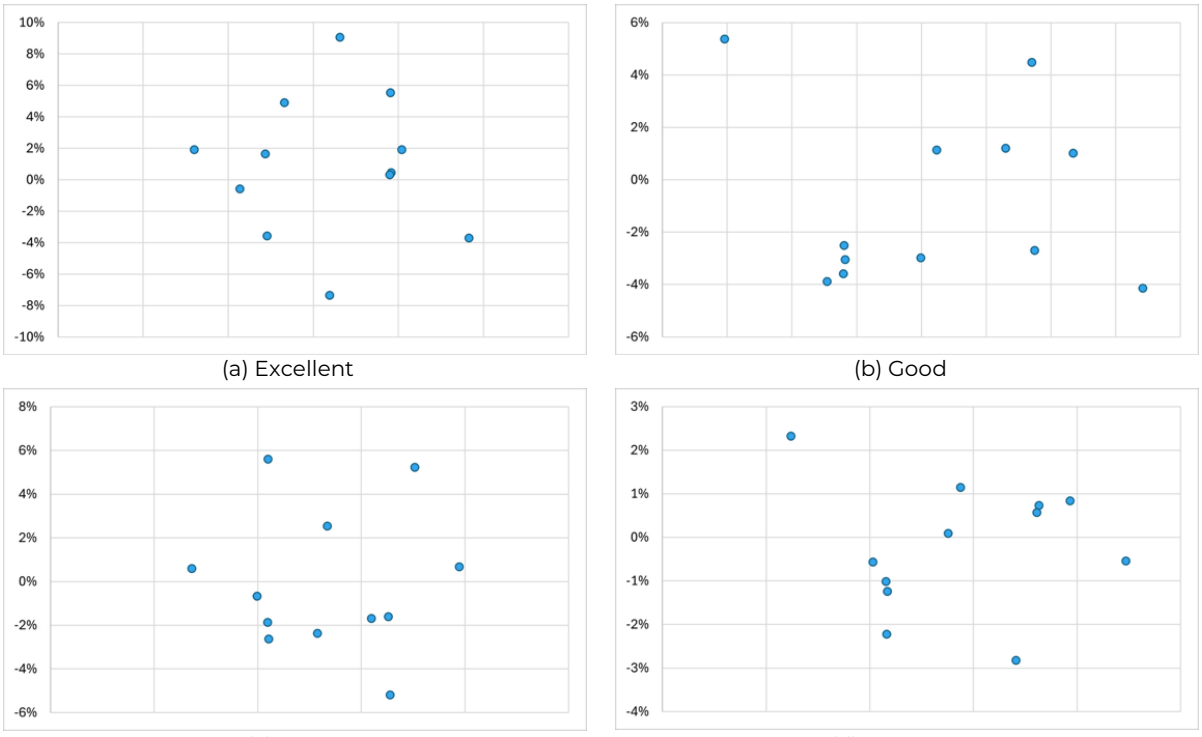


Component	Excellent	Good	Fair	Poor	Very Poor
Pavement	−0.90*	+0.73*	+0.02	+0.76*	+0.78*
Signage	−0.52	+0.34	+0.57	−0.41	-0.50
Geometry	+0.60*	−0.14	+0.69*	+0.06	-0.67*
Overall Condition	−0.71*	−0.11	+0.54	−0.22	-0.47

(*) Statistically significant correlation ($|r| > 0.576$).

Overall, the results indicate that the pavement component is the most sensitive to rainfall variability, followed by overall road condition (which predominantly reflects pavement behavior), while signage and geometry exhibit lower sensitivity to precipitation fluctuations.

The pavement component yielded the most pronounced correlations with annual precipitation. The negative correlation of $r = -0.90$ for the excellent class indicates that, in years of higher precipitation, there is a reduction in the proportional extent of roads in excellent condition, the coefficient with the highest magnitude in the entire analysis. Conversely, the poor and very poor classes presented significant positive correlations ($r = +0.76$ and $r = +0.78$, respectively), indicating a progressive migration of road segments across



performance categories over time. Figure 8 illustrates this opposite trend between the excellent and very poor classes as a function of rainfall variation, with $R^2 = 0.8134$ and $R^2 = 0.6118$, respectively.

(a) Excellent (b) Very Poor

Figure 8 – Scatter plots of excellent and very poor pavement condition classes versus annual precipitation

The correlation of r = +0.73 for the good class suggests that, as pavements previously classified as excellent degrade, a portion migrates to the good category before reaching the lower classes, a pattern of progressive deterioration consistent with the mechanisms described by Bernucci et al. (2022). An analogous result was reported by Llopis-Castelló et al. (2020) for urban roads, where the Pavement Condition Index (PCI) exhibited a negative correlation with accumulated precipitation. The statistical validity of these correlations is further supported by the residual plots (Figure 9), which display approximately random distributions around zero for the excellent, good, poor, and very poor classes, indicating the absence of systematic patterns that would violate the assumptions of the linear correlation model.

(a) Excellent (b) Good

(c) Poor (d) Very Poor

Figure 9 – Residual plots of pavement condition classes versus annual precipitation, Ceará, 2012–2024

From a management perspective, these results underscore the importance of preventive interventions on road segments still classified as good, to prevent their migration to poor conditions, which require more costly and complex rehabilitation measures. This finding is consistent with the recommendations of Qiao et al. (2020), who emphasize the need to incorporate climate projections into the design and management models of flexible pavements.

The signage component exhibited predominantly moderate and statistically non-significant correlations with annual precipitation, with the highest coefficient being r = +0.57 for the fair class, a value at the threshold of statistical significance. This behavior is explained by two complementary factors: i) the CNT Road Survey is conducted in the second half of the year (the dry season in Ceará), which minimizes the direct effect of rainfall on the observed conditions; and ii) signage degradation is more closely associated with physical wear from traffic and periodic maintenance policies than with climatic variables. The residual plots confirm the inadequacy of linear correlation for most signage classes, reinforcing the limited sensitivity of this component to precipitation.

In turn, the geometry component displayed a distinct behavior, with significant correlations in the fair (r = +0.69) and excellent (r = +0.60) classes, and a significant negative correlation for the very poor class (r = −0.67). This apparently contradictory pattern is explained by the structural nature of road geometry: alignment, carriageway width, curves, and grades are defined at the design stage and tend to remain stable throughout the pavement life cycle, exhibiting low sensitivity to annual climatic fluctuations. The correlations observed in the fair and excellent classes may reflect indirect precipitation impacts, such as shoulder erosion and drainage failures that occasionally affect geometric assessment. The residual analysis for geometry revealed a lack of homoscedasticity across most classes, indicating that linear correlation is not the most appropriate statistical method for this component, a result that reinforces the structural nature of road geometry and its lower responsiveness to climatic factors.

Finally, the overall road condition component displayed a pattern analogous to that of pavement, with a negative correlation of r = −0.71 for the excellent class, the only statistically significant result for this component. This finding confirms the dominant contribution of pavement to the overall condition index and indicates that higher precipitation is associated with a gradual decline in the overall quality of Ceará's roads. The moderate positive correlation of r = +0.54 for the fair class, although not statistically significant, suggests a migration of segments from higher conditions to intermediate levels in wetter years, a behavior consistent with the pavement degradation dynamics described by Qiao et al. (2020).

Taken together, the results demonstrate that precipitation does not act in isolation on road infrastructure but exerts a measurable and statistically verifiable influence on pavement functional performance and, consequently, on the overall condition of roads. These findings provide technical grounds for the incorporation of climatic variables into maintenance and rehabilitation prioritization models for Ceará's road network — an approach that aligns with the IPCC (2023) recommendations for adapting transport infrastructure to climate change.

5. Conclusions

This study has demonstrated that rainfall variability exerts a measurable influence on the functional performance of the road network in the state of Ceará, with impact concentrated in the pavement component and, consequently, in the overall road condition. It was established that the precipitation regime acts as an accelerating factor in functional deterioration, promoting a shift in network conditions toward poor and very poor categories over time. This finding reinforces the importance of incorporating climatic variables into pavement management and maintenance prioritization models, particularly in semiarid regions subject to high interannual precipitation variability.

The lower sensitivity of signage and geometry to precipitation, in turn, suggests that these components are governed by factors of a different nature, such as maintenance policies, structural interventions, and design

adjustments. This distinction may have direct implications for resource allocation in road conservation programs: while pavement maintenance demands climate-sensitive planning, signage and geometry require maintenance cycles independent of the precipitation regime. From a management standpoint, the results reinforce the relevance of preventive interventions on segments still classified as good, anticipating deterioration before the network migrates to conditions requiring higher-cost and more complex interventions.

The integration of the assessed datasets proved feasible and informative for diagnosing road infrastructure conditions, constituting a replicable approach for other Brazilian states. Nevertheless, the absence of information on maintenance history, traffic volume, pavement structural data, and precise collection dates by road segment limits the explanatory power of the adopted model, precluding the isolation of precipitation as an independent causal variable. These limitations do not invalidate the results but rather indicate directions for advancing knowledge in the field.

Abstract: Building conservation is a determining factor for safety and real estate appreciation; however, the current appraisal methodology in Brazil relies excessively on qualitative classifications and the subjective perception of the appraiser. To fill this gap, this article investigates the influence of structural pathologies on market value and proposes replacing the subjective classification of the state of conservation with a quantifiable index. The proposed methodology integrates the Dutch standard NEN 2767, which qualifies anomalies based on their importance, intensity, and extent, along with adaptations from other researchers, creating a Degradation Index. This technical index is then incorporated into the economic calculation of global depreciation. A demonstrative analysis using a database from a local neighborhood highlighted the limitations of the current system and confirmed the positive elasticity between perceived quality and estimated value. It is concluded that the technical parameterization of the state of conservation establishes a direct and rigorous relationship between physical degradation and property performance, allowing the market value to reflect the actual depreciation caused by pathologies and ensuring greater precision and replicability for expert reports.

Keywords: Structural pathologies; Real estate appraisal; Building condition; Property value appreciation.

1. Introduction

Building conservation is a determining factor for the longevity, safety, and appreciation of real estate assets. ABNT NBR 5674 establishes that building maintenance must be continuous, preventing premature disposability and ensuring adequate conditions of use. ABNT NBR 15575 complements this approach by defining performance requirements throughout the design service life.

However, in Brazil, building maintenance does not always receive due priority, which results in accelerated degradation and the occurrence of structural pathologies, compromising both market value and safety. Data reported by Andrade (2023) indicate that, between January 2014 and July 2023, 540 structural incidents occurred, with approximately BRL 1.75 billion spent on reconstruction works.

During my training as a real estate appraisal expert, I identified an important gap in the databases used to classify the state of conservation: the absence of detailed and standardized criteria. This shortcoming compromises the accuracy of appraisals and may lead to significant distortions in the values assigned to properties. The methodology currently used in the Statistical System of Appraisal Data (SISDEA), based on NBR 14653, uses generic qualitative classifications that depend excessively on the appraiser's subjective perception. This superficiality compromises the accuracy and replicability of reports, generating significant distortions in the values assigned to properties.

This article proposes the combined adoption of the Dutch Standard NEN 2767 and the parameters proposed by Martinatti (2021) and Oliveira (2023) as references for classifying the state of conservation. This approach aims to overcome the current subjectivity by introducing the quantification of degradation through measurable technical parameters. NEN 2767 is an internationally recognized building inspection methodology that allows pathologies to be qualified and quantified based on three fundamental parameters: importance (degree of relevance of the anomaly to performance and safety), intensity (magnitude or severity of the damage), and extent (scope of the affected area).

The dissertation by Martinatti (2021) and the doctoral thesis by Oliveira (2023) advance in this direction by adapting the rigor of NEN 2767 to the Brazilian context and proposing a parameterization of the degradation condition that generates a standardized numerical value. This classification matrix creates a Degradation Index (DI), which establishes a direct and precise relationship between physical degradation and property performance/value. By replacing subjective classification with a quantifiable index, this research offers an original contribution to the Brazilian real estate market. The practical application of this methodology, combined with the Ross-PP (KG) Method for calculating global depreciation, will allow market value to technically reflect the actual depreciation caused by pathologies.

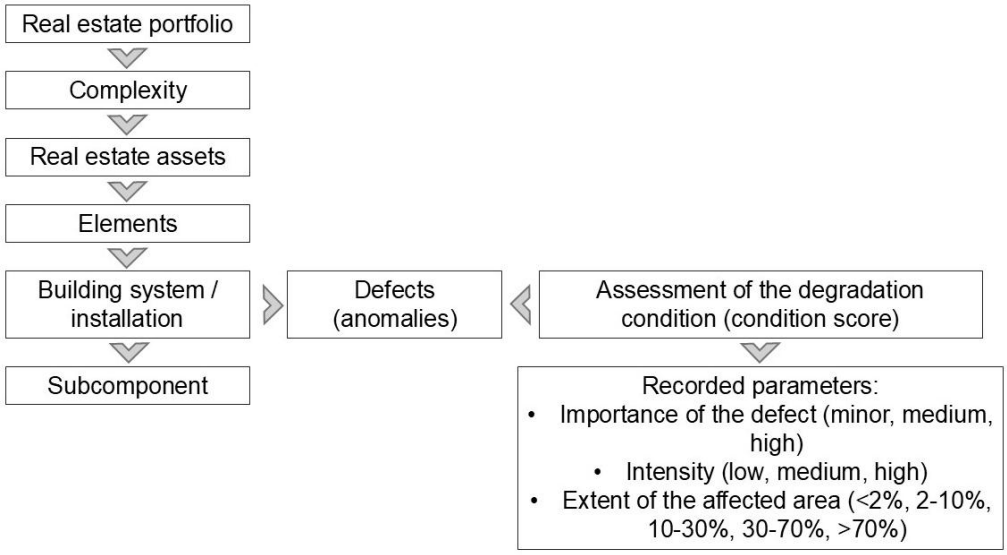
As a methodological contribution, this article proposes transforming the “state of conservation” variable, traditionally treated qualitatively in real estate appraisal databases, into a quantitative variable obtained through a systematized technical inspection. To this end, the assessment by building systems and subsystems is adopted, taking as reference the structure proposed by Silva (2022), who organizes the inspection into systems such as roofing, fire protection and emergency systems, electrical installations, sealing/envelope systems, hydraulic-sanitary installations, and structural systems. In addition, the external environment variable is added, considering that common areas, accesses, facades, sidewalks, and surroundings also influence the perception of conservation, functionality, and market value. Thus, the state of conservation is no longer a general grade assigned subjectively by the appraiser and becomes the result of the technical composition of the conditions observed in each building system.

2. Literature Review

Structural pathologies include manifestations such as cracks, infiltrations, reinforcement corrosion, differential settlements, and construction defects, which affect the integrity, performance, and safety of buildings beyond purely aesthetic problems. They are caused by design failures, execution failures, inappropriate use, or the action of environmental agents.

For an objective analysis of pathologies, several methodologies have been developed to standardize the assessment of building degradation. These methodologies seek to quantify and qualify damage, providing essential data for maintenance and rehabilitation planning.

NEN 2767 offers a systematic approach to determining and recording the condition of building components and systems. The “Condition Assessment” process is an indirect method that quantifies anomalies and contributes to degradation analysis. The standard covers levels ranging from the real estate portfolio to subcomponents, including the assessment of elements, building systems, and defect identification.



This score is obtained through a detailed inspection during which the anomalies present in each building element are identified, with three fundamental parameters being observed:

- Importance: degree of relevance of the anomaly to the performance and safety of the element;
- Intensity: magnitude or severity of the observed damage;
- Extent: scope of the area affected by the pathology.

Silva (2022) contributes to the operationalization of this assessment by proposing the analysis of the state of conservation by building systems and subsystems, allowing the overall condition of the building to be obtained from the composition of the partial conditions identified in the field. In his dissertation, the author adapts national and international building inspection methodologies, such as NBR 16747, IBAPE, GUT, NEN 2767, MAEC, and GADH, with the objective of calculating the state of conservation of the components and of the building as a whole. This approach is relevant to real estate appraisal because it allows a general and subjective classification to be replaced by a technical reading structured by systems, such as roofing, electrical installations, sealing systems, floors, walls and ceilings, hydraulic-sanitary installations, and structural systems.

The scope of NEN 2767 is hierarchically structured, as represented in Figure 1, starting with the real estate portfolio and progressing to more specific levels: real estate assets, elements, building systems or installations, subcomponents, and, finally, the defects themselves. This model provides a broad and overall view of the construction process, making it possible to assess the performance of a single subcomponent as well as the general condition of the development.

Figure 1 – Simplified flow of the application of NEN 2767 for condition assessment. Source: adapted from NEN 2767:2017 and Martinatti (2021).

Martinatti's dissertation (2021) represents an important adaptation of NEN 2767 to the Brazilian context, proposing the parameterization of the degradation condition based on the combination of these three parameters.

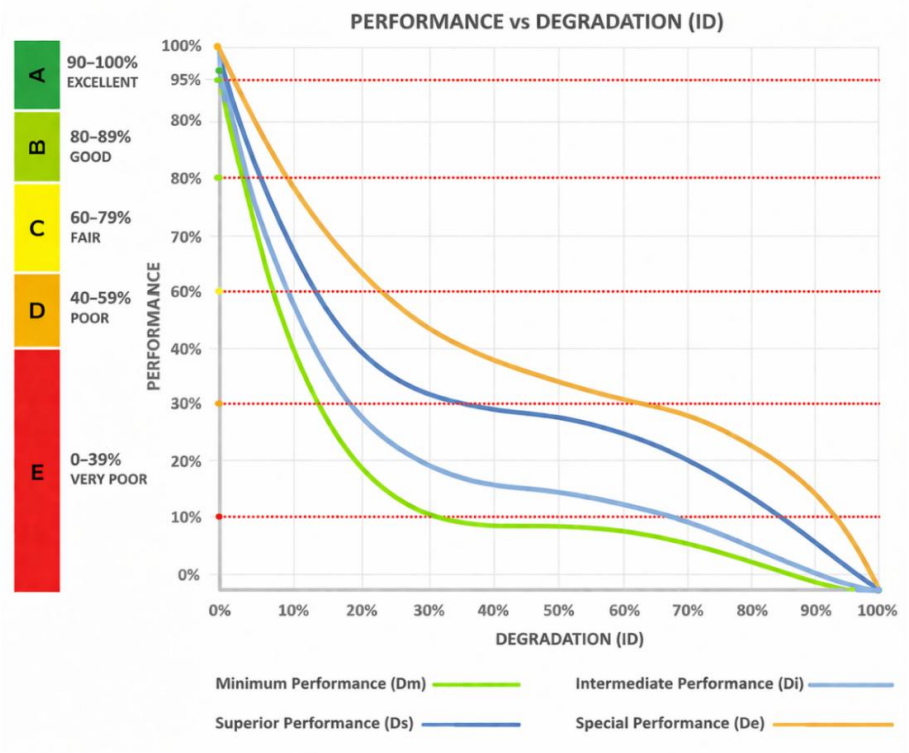


Table 1 – Classification of the parameterized condition. Source: Oliveira (2023) after Martinatti (2021).

Defect	Intensity	Extent				
		<2%	2% - 10%	10% - 30%	30% - 70%	>=70%
Minor	Low	0,17	0,17	0,17	0,17	0,33
	Medium	0,17	0,17	0,17	0,33	0,5
	High	0,17	0,17	0,33	0,5	0,67
Severe	Low	0,17	0,17	0,17	0,33	0,5
	Medium	0,17	0,17	0,33	0,5	0,67
	High	0,17	0,33	0,5	0,67	0,83
Critical	Low	0,17	0,17	0,33	0,5	0,67
	Medium	0,17	0,33	0,5	0,67	0,83
	High	0,33	0,5	0,67	0,83	1

Table 1 presents the classification matrix, in which each intersection between variables generates a standardized numerical value, making it possible to quantify the level of degradation of components and building systems.

This approach reduces subjectivity and enables consistent results among different appraisers. In addition, the method establishes a direct relationship between the degradation index and the overall performance of the property, as shown in Graph 1. In this graph, the lower the degradation index, the higher the performance, and vice versa. The curves are segmented into color ranges (A, B, C, D, and E), which indicate building certification levels by associating physical performance with the classification of the state of conservation.

Graph 1 – Performance x Degradation Index. Source: Oliveira (2023).

Thus, the proposal by Martinatti and Oliveira creates a link between technical assessment and market appraisal, allowing the analysis of the state of conservation to be incorporated more precisely into real estate pricing processes.

Quantifying the impact of pathologies on market value requires a depreciation model that goes beyond simple subjective classification and linear methods. Traditionally, the market uses models such as the Ross-Heidecke Table, but these may be limited when incorporating the complexity of degradation.

In this context, the project adopts the Method for Global Depreciation via the Ross-PP (KG) Method, as detailed by Oliveira (2023). This method presents an improved approach to calculating the physical depreciation of a development, defining the Global Depreciation Factor as a key element in the appraisal.

The KG factor is influenced by the state of conservation of the property. By integrating the Degradation Index (DI), the Ross-PP (KG) model allows depreciation to be calculated objectively and technically, overcoming the limitations of the appraiser's subjective judgment. The detailed formulation of this method will be used in the economic validation stage of the methodology proposed in this study.

3. Methodology

This research adopts as its starting point the methodology currently used for real estate appraisal through the Statistical System of Appraisal Data – SISDEA. This approach will be described in its current configuration and, subsequently, the proposed change will be presented, based on the methodologies and parameters of NEN 2767, Martinatti's dissertation (2021), and Oliveira's doctoral thesis (2023).

3.1 Current Method

For illustrative purposes, a database of apartments located in the Noroeste neighborhood of Brasília is presented, collected from several real estate agencies and brokers. It is important to note that these data are not part of the definitive research sample, being used only to demonstrate how SISDEA works and to show how the system currently deals with the “state of conservation” variable.
Each record contains information such as address, total value, private area, number of bathrooms, view of Burle Marx Park, state of conservation, and number of parking spaces (Table 2).

Table 2 – Database. Source: personal archive

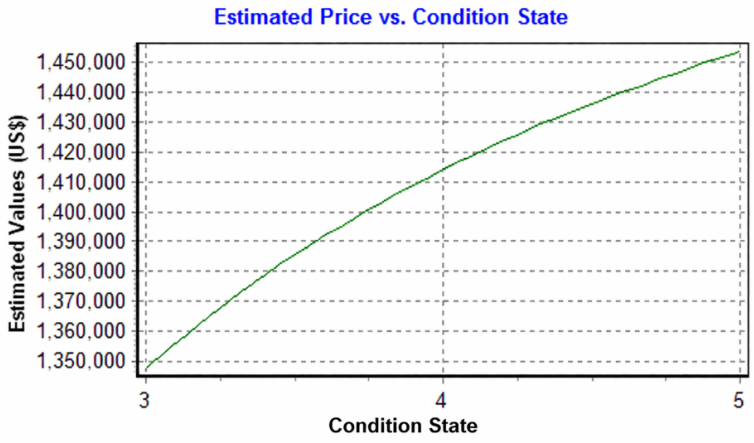
The state of conservation follows the classification provided by NBR 14653, which establishes qualitative concepts assigned to SISDEA numerical codes (Table 3).

Table 3 – State of conservation classification chart. Source: didactic material from the Real Estate Appraisal Expert Course, ConstruMove, 2024.

	CONCEPT	BUILDING	UNIT
6	Under construction or off-plan	Paradigm property / Not yet delivered.	Paradigm property / Not yet delivered.
5	Good (New appearance)	Recently delivered property, with a new appearance.	Recently delivered property, with a new appearance.
4	Good (Used appearance)	Property that does not need repairs, but has a used appearance.	Property that does not need repairs, but has a used appearance.
3	Fair (Minor repairs)	Need for minor repairs, painting, and cleaning.	Need for minor repairs, painting, and cleaning.
2	Fair (Major repairs)	Need for recovery on the facades, watertightness problems; infiltrations, need to redo installations (gas, electrical, fire, plumbing, etc.), need for structural recovery, cumulative or not, within the scope of the common areas.	Need for recovery on the facades, watertightness problems; infiltrations, need to redo installations (gas, electrical, fire, plumbing, etc.), need for structural recovery, cumulative or not, within the scope of the private areas.
1	Poor	Compromised stability and solidity, impaired habitability and/or healthiness, with a high cost of recovery.	Compromised stability and solidity, impaired habitability and/or healthiness, with a high cost of recovery.



In the system, the “state of conservation” variable is numerically coded for application in statistical models (Table 4), ranging from 1 (Poor) to 6 (Under construction or off-plan).

Table 4 – Description of the variables used in the SISDEA system based on the author's personal database. Source: elaborated by the SISDEA system (2024) based on the author's personal database.

Name	Type	Type	Classification	Variable Description	Enabled
City	Text	Text	Text	Complement to the property address	Yes
Address	Text	Text	Text	Full property address	Yes
Neighborhood	Text	Text	Text	Neighborhood where the property is located	Yes
Informant	Text	Text	Text	Name or identification of the informant	Yes
Informant Phone	Text	Text	Text	Informant's phone or contact number	Yes
Private Area	Numeric	Numeric	Quantitative	Private area of the unit measured in m²	Yes
Bathrooms	Numeric	Numeric	Dichotomous	Bathrooms in service area, Social, and suites	Yes
View of Parque Burle Max	Numeric	Numeric	Dichotomous	View of the park (Has = 1, Does not have = 0)	Yes
Condition	Numeric	Numeric	Qualitative (Assigned Codes)	Property condition (scale based on assigned codes listed as: 1 –Poor 2-Major Repairs 3–Minor Repairs 4–Signs of Use 5–Like New 6–Under Construction)	Yes
Parking Spaces	Numeric	Numeric	Quantitative	Total number of parking spaces including covered, uncovered, and enclosed	Yes
Total Value	Numeric	Numeric	Dependent	Total property value	Yes

The influence of this variable on market value is evidenced in Graph 2, which presents the elasticity of the function at the midpoint of the state of conservation, indicating a positive correlation between perceived quality and estimated value.

Graph 2 – Elasticity of the function at the midpoint. Source: elaborated by the SISDEA system (2024) based on the author's personal database.

3.2 Limitations of the Current Method

Although consolidated and widely used, the current method has a subjective character in the classification of the state of conservation, since the assessment is based mainly on the appraiser's perception and on generic qualitative descriptions. This approach, although fundamental, may result in a superficial analysis, failing to accurately capture the severity and extent of building pathologies.

The example of using the database prepared with properties from the Noroeste neighborhood highlights this limitation, reinforcing the need for more objective criteria.

4. Proposed Improved Methodology

The reformulation of the state of conservation variable in real estate appraisal is proposed by integrating objective technical criteria to improve the Statistical System of Appraisal Data (SISDEA) and the application of NBR 14653. The methodology replaces subjective classification with a quantifiable index, maintaining the numerical compatibility required by SISDEA while increasing the accuracy of the final report.

The inspection proposed in this article will be structured by building systems, adopting as reference the organization presented by Silva (2022), with adaptations to the context of urban real estate appraisal. Initially, the following analysis groups will be considered: roofing; electrical installations; sealing systems, floors, walls and ceilings; hydraulic-sanitary installations; structural systems; and external environment. The fire protection and emergency system may be incorporated when the property typology, the use of the building, or the inspection scope requires such assessment.

Table 5 – Preliminary structure of the inspection form by Building systems for parameterizing the state of conservation. Source: prepared by the author, based on Silva (2022).

System assessed	Examples of components	Urgency level	Parameterization	
			Component condition	System condition
Roofing	Roof covering, structure, gutters, flashings, waterproofing	Classification as priority 1, 2, or 3	Partial component index	Partial system index
Electrical installations	Panels, circuits, finishes, lightning protection system, grounding	Classification as priority 1, 2, or 3	Partial component index	Partial system index
Sealing/envelope systems	Facades, internal walls, frames, ceilings, floors	Classification as priority 1, 2, or 3	Partial component index	Partial system index
Hydraulic-sanitary installations	Reservoirs, water supply, sewage, inspection boxes	Classification as priority 1, 2, or 3	Partial component index	Partial system index
Structural system	Columns, beams, slabs, joints, collapse risk	Classification as priority 1, 2, or 3	Partial component index	Partial system index
External environment	Accesses, sidewalks, common areas, immediate surroundings	Classification as priority 1, 2, or 3	Partial component index	Partial system index

This adaptation is consolidated into four interdependent stages: structuring the inspection form by systems, quantifying degradation, objectively classifying conservation, and incorporating the technical index into the calculation of depreciation and final value. The first stage adopts as reference the organization by building systems and subsystems proposed by Silva (2022), while the subsequent stages use NEN 2767, the works of Martinatti (2021) and Oliveira (2023), and the Ross-PP (KG) Method as their basis.

4.1 Structure of the System-Based Inspection Form

Table 5 presents the preliminary structure of the inspection form proposed for quantifying the “state of conservation” variable. The organization is based on an individual assessment of building systems and their respective components, associating each inspected item with an urgency level and a parameterization of the observed condition. Thus, the condition of the property becomes composed of partial indices, initially calculated by component and subsequently consolidated by system.

For each inspected component, the occurrence of the anomaly, its location, intensity, extent, and degree of impact on performance, safety, functionality, and the perception of property value must be recorded. At the end of the inspection, the partial results of each system will be consolidated to compose the technical conservation index, which may be used as an objective variable in the real estate appraisal process.

4.2 Quantification of Degradation

This stage eliminates the subjectivity of building inspection, providing an exact numerical datum for the state of conservation.

4.2.1 Basis: Application of the Dutch Standard NEN 2767, which proposes a systematic approach to building inspection by quantifying and qualifying anomalies based on technical parameters.

4.2.2 Adaptation: Use of the adaptation by Martinatti (2021), which structures a parameterized condition that relates the intensity and extent of anomalies to different degrees of defects (minor, serious, critical), enabling the attribution of a Numerical Degradation Index (DI).

4.3 Objective Classification of Conservation

The numerical value (DI) is translated into a qualitative classification compatible with the market vocabulary and NBR 14653.

4.3.1 Basis: Consolidation of the Degradation Index (DI) into performance ranges (A-E) by Oliveira (2023), relating degradation percentages to the residual performance of the element or system.

4.3.2 Adjustment: This conversion allows the research to replace subjective descriptions (good, regular, and poor) with measurable technical parameters, without compromising the calculation structure required by SISDEA.

4.4 Depreciation and Final Value

The technical index obtained is inserted into the economic calculation, quantifying its impact on the property value in accordance with the global depreciation calculation.

4.4.1 Calculation Tool: The Method for Global Depreciation via Ross-PP (KG) (Oliveira, 2023) will be employed as an improved approach to calculating the physical depreciation of a development.

4.4.2 Integration: The Degradation Index (DI) from stage 1 will be used as an objective input variable to determine the Global Depreciation Factor (KG) of the Ross-PP Method.

4.4.3 Result: The application of this method will result in a market value that accurately and technically reflects the actual depreciation caused by pathologies, providing support for the economic validation of the methodology.

The new classification structure, to be applied in the next stage of the research, will maintain the numerical compatibility required by SISDEA. The database presented, referring to the Noroeste neighborhood, is used only to exemplify the structure and demonstrate the limitation of the current analysis. The case studies and

practical assessment of this research will be carried out in properties located in another Administrative Region of the Federal District, Brazil.

5. Conclusion

This study presented a proposal to reformulate the state of conservation variable used in the Statistical System of Appraisal Data (SISDEA), seeking to overcome the limitations of the currently employed method, which is predominantly based on subjective descriptions.

The analysis showed that, although the current classification is practical and quick to apply, its qualitative and insufficiently parameterized nature restricts the accuracy of appraisals and makes it difficult to compare properties, especially in contexts of partial or heterogeneous degradation.

The incorporation of consolidated methodologies, such as NEN 2767, the adaptation developed by Martinatti (2021), and the classification by ranges proposed by Oliveira (2023), makes it possible to integrate measurable parameters—intensity, extent, and importance of anomalies—into the field analysis. This approach enables not only a more faithful measurement of the physical condition of the property, but also better integration with statistical appraisal models, as demonstrated by the relationship between state of conservation and estimated value.

The database used in this stage, referring to apartments in the Noroeste neighborhood, served as an example to present how the current method works and to demonstrate its limitations. The proposed methodology will be applied to properties located in other administrative regions, allowing its practical applicability and gain in accuracy to be verified.

It is expected that the adoption of objective technical criteria, combined with the systematic recording of building conditions, will contribute to fairer, more transparent, and more replicable appraisals, in addition to strengthening the reliability of the reports issued.

Abstract: On February 6th, 2018, part of the South Road Axis viaduct (*Eixo Rodoviário Sul*, known as "*Eixão Sul*") collapsed in Brasilia, Brazil. Although no deaths occurred, the partial failure imposed high costs on the city and its residents, alarming authorities about the safety and maintenance of other essential viaducts and bridges (built during the same construction period as *Eixão*) across the capital. The *Eixão* repair was carried out following detailed investigation and mechanical characterization. However, the type of failure – a sudden shear failure – has not been adequately addressed, even though many other important viaducts have been built with the same structural characteristics as the South Road Axis in the city. This paper presents the full details of the partial collapse of the Eixão, identifying the main components and mechanical sources that led to the brittle failure, particularly regarding the behavior of prestressed concrete members subjected to high shear and cyclic demands. The repair and retrofitting techniques implemented after the disaster are described, and this work concludes with an examination of how this case study can be applied in a broader context to the rehabilitation of similar structures in Brazil's capital.

Keywords: Concrete structures, bridges, maintenance, retrofit, shear failure.

1. Introduction

1.1 Brasilia Historical Context

Brasilia is the capital of Brazil and the 3rd-largest city in the country, with around 3 million people in the city center and about 5 million in the metropolitan area. The city is marketed by its unique set of robust, reinforced and prestressed concrete curved monuments that combine brutalist architectural identity with modernist philosophy. This city is located within the Federal District (DF), serving as the country's administrative center of power, and was designed by the urban planner Lúcio Costa and the famous architects Oscar Niemeyer and Roberto Burle Marx in 1957. Important structural engineers, such as Joaquim Cardoso and Bruno Contarini (among others), made possible many structural challenges imposed by the city concept. Brasilia stands out for its iconic urban plan, a 20th-century modernist city emphasizing functionality, rationality, zoning, open spaces, and a futuristic vision of progress.

The city is considered young (about 66 years old) and was built as part of an ambitious national development program launched in 1956 by the Juscelino Kubitschek administration. The main goal of this program was to rapidly industrialize and modernize Brazil, shifting the capital from the coast to the heart of the country – a known protection strategy dating back to the late 18th century. Construction began in 1956, and the city was inaugurated in 1960, built in an astonishing 41 months with the aid of a massive national labor force, which eventually contributed to the city's social diversity. Initially, the city was planned to support 500,000 people, but it grew 6 times its population in 60 years. The first engineering public company of the city, *Nova Companhia Urbanizadora da Nova Capital* (NOVACAP), was created during this period to participate in the construction of the new Federal District.

The city master plan (today called *Plano Piloto*) designed the city into a plane-like shape, with two main arterial roads (that cross each other at the heart of the city) – the Monumental Axis (*Eixo Monumental via N1*) and the Road Axis (*Eixo Rodoviário DF 002*) – in combination with a hierarchical multi-lane system. This system of roads is integrated with smaller streets, connected by strategic curved access ramps, underpasses and overpasses (called "*tesourinhas*" – cloverleaf ramps) and roundabouts, which effectively increase mobility within the city center, granting (almost) congestion-free automobile circulation. In addition to the absence of traffic lights and the smart function-zoning idea, these decisions promote the 15-minute city concept, which gave the city many elements that helped it earn UNESCO World Heritage status in 1987 as a unique expression of modernist urban principles.

1.2 Rapid Growth of Vehicles and Impact on Viaducts in Brasilia after the Incident

Due to the city's urban planning, which includes large spaces, zoning, and wide roads, the possession of self-owned vehicles is a common demand among city residents. Data from the 2020 Department of Roads and Highways DER/DF (2021) reports an average of 120,000 vehicles per day crossing the capital via the main arterial roads (Monumental Axis and Road Axis), which can be tracked instantaneously using the feature tool available on the DER/DF web page.

Recent public reports from the Department of Roads and Highways state that the city reached over 2 million vehicles in 2024, far exceeding its initial intended design. Some records indicated that the car expectancy was about 1 vehicle per family, which would mean about 125,000 planned vehicles in the 60s (which grew about 16 times according to today's demand).

Lastly, according to NOVACAP, over 96 viaducts were to be retrofitted after the 2018 incident (with investments over USD $ 1.42 million), and 40 strategic viaducts also received investments (over USD $ 30 million) for maintenance, with resources allocated to building 4 extra bridge highways, according to the Brasilia Agency (2019) . In other words, city planning naturally created high demand for car use, which was not expected to reach that many vehicles daily. After the 2018 incident, NOVACAP has inspected more than 360 special structures, the DER/DF inspected over 679 special structures and over 111 of those received immediate requirements, maintenance and strengthening.

1.3 Significance of the Partial Collapse

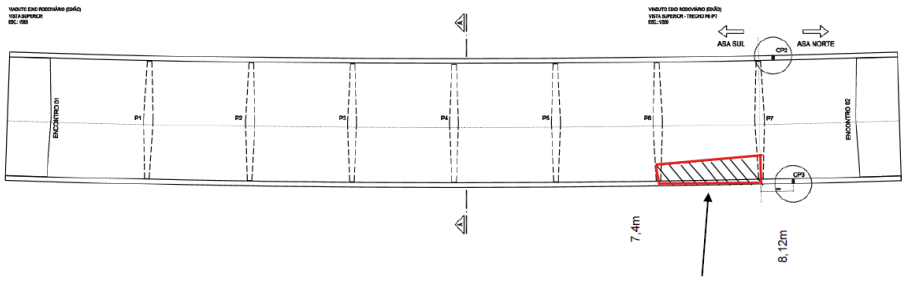
The sudden partial collapse of the Road Axis Viaduct occurred on February 6th, 2018, around 11:45 am, on a Tuesday, blocking the main road to the city center. It took significant investment and workforce over approximately 2 years to solve the problem. This failure is one of the major examples of bridge highway collapse, due to its complexity and impact. After the structural failure, teams from the public company NOVACAP/DER, in partnership with the Brasilia University Structural team and Engineering Companies, began an in-depth investigation of the collapse by mechanical characterization of debris. This followed a necessary emergency protocol involving structural stabilization, the interruption of traffic, and a traffic detour from the viaduct. Since many other viaducts were built similarly during the city's inauguration and expansion, this investigation marked the beginning of a large maintenance protocol that has been underway ever since, including the creation of a multisectoral committee responsible for managing and monitoring the maintenance of public infrastructural assets in the Federal District.

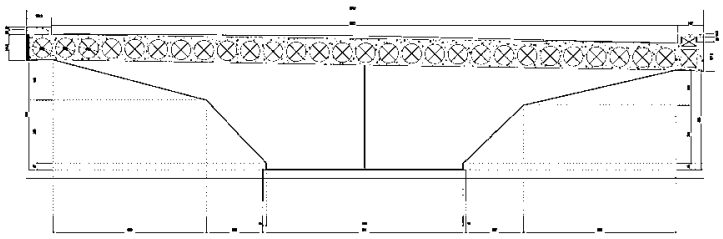
This proposed work focuses on the forensic analysis of the failure, exploring specific aspects of the shear theory of failure to explain the disaster. This work is an attempt to better understand older structures and hidden structural features that may be part of similar structures built during the same period in the city's capital.

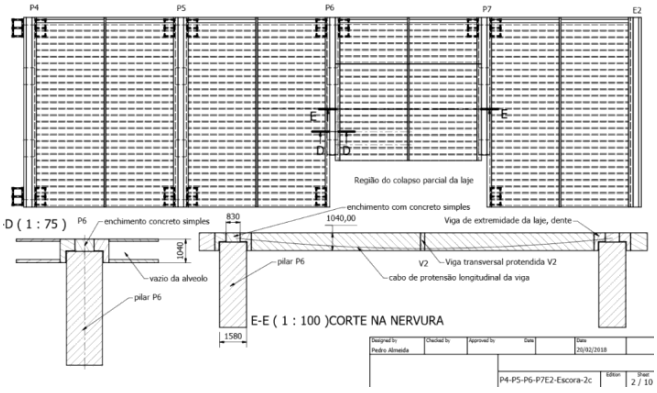
2. South Road Axis Viaduct Engineering Characteristics

The South Road Axis Viaduct (located in the *Galeria dos Estados*) was inaugurated in 1960 and was 58 years old when the incident happened. The viaduct is a critical component of the main road system of the DF 002 highway axis, providing vital access to the central bus station and various commercial, banking, and hospital sectors through the South Wing (*Asa Sul*) of the plan-shape capital.

Its structure was composed of 7 massive delta-shape reinforced concrete column-walls (with cantilevered extensions of 7.4 m prestressed crossbeams) that supported 8 prestressed hollow core slabs (road deck), and two abutments at the viaduct's free ends. The total structure length was about 194 meters, the width about 27 meters, and the distance from the columns about 22 meters. Slabs were about 1 meter-deep with 80 cm-diameter hollow cores, and about 29 ribs, 15 cm thick, spaced 95 cm per slab, with 3 prestressed transversal beams (one at each end and one intermediate). The plan view of the whole viaduct can be seen in Figure 1, while the deck details can be seen in Figure 2.







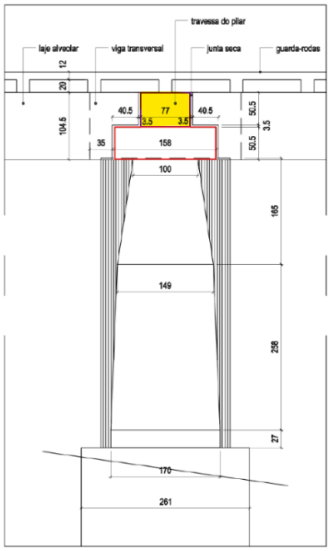


Figure 1 –Plan view of the Road Axis Viaduct in *Galeria dos Estados*, highlighting plan of failure (NOVACAP, Relatório Técnico, 2018).

(a) Delta-wing Column-Wall with hollow deck (section view).

(b) Deck plan view with section cuts.

(c) Delta wing column wall detail highlighting the top crossbeam.

Figure 2 –Structural drawings from the Road Axis Viaduct at *Galeria dos Estados* (NOVACAP, Relatório Técnico, 2018).

Delta wing-shaped column walls were expressively large, 150 to 170 cm thick (varying) section by 27 meters wide (total wingspan) – Figure 2 (a). The top crossbeam of the pillar had an inverted T shape format with 16 prestress cables (containing 12 wires of 5mm, 1500 Mpa in strength – within the red area in Figure 2-c), which was used as support (as a Gerber teeth) for the slabs by bearing pads – Figure 2 (b) and (c). These supporting crossbeams had transverse smooth reinforcements 16 mm in diameter, spaced 8 cm on center. No other longitudinal rebars were used in this section but the prestressing steel.

An important detail of the T inverted shape crossbeam, however, was that it was originally a rectangular section (red rectangle in Figure 2) with a top free space (designed as a center joint on top of the pillars, where there was an 80 cm free space between the faces of the slab and crossbeams for construction purposes used for hydraulic jacking of tendons) that was subsequently filled with plain concrete, forming a 54 cm x 83 cm prismatic bar (highlighted in yellow in Figure 2-c). This element was unreinforced and served to physically isolate the reinforcing from the pavement road in an attempt to prevent water infiltration.

Lastly, the main structural drawings were absent since the city's inauguration in the 60s; however, NOVACAP developed as-built structural drawings (only geometrical properties) in 2013 for information collection, which helped the forensic crew assess debris in 2018. Some older signs of cracking and water infiltration were noted within the bridge main deck and column walls during this period, but reported as "not alarming".

3. South Road Axis Forensics Investigation

3.1 Response Measurements

After the initial partial collapse, the large concrete deck (approximately 7 to 7.8 meters wide) was partially dismantled for investigation. No injuries were reported, and the transportation and fire departments isolated the area and blocked the Road Axis viaduct, creating detours to maintain traffic flow during the emergency protocol. This was only possible because Brasilia's plan was based on large spaces, which wouldn't have been possible if the accident had happened in densely populated areas like the centers of São Paulo or Rio de Janeiro.

Shortly after, engineering teams from NOVACAP and other federal agencies arrived for initial damage assessment. Fire department experts, backed by structural civil engineers from these institutions, recommended emergency structural shoring of the remaining viaduct in locations beneath the delta-shaped column wall extensions, and continuous monitoring of the viaduct (by installing instrumentation to monitor displacements and daily thermal variations to ensure structural stability).

Once the structure was secure and the area was isolated, the Local Government authorized immediate funds for assessment and interventions to ensure the structure's safety and to resolve the problem. Some private engineering companies, aligned with NOVACAP and the structural engineering team from the University of Brasilia, began the forensic investigation of the partial collapse the day after the incident.

3.2 Chronology of Failure

The event is categorized as a "fragile partial collapse" since it occurred suddenly and without prior visible warning signs (excessive deformations or crack development) detectable by visual inspection. Also, there was a restaurant underneath the viaduct, with large kitchen equipment and wall finishes that hid the column-walls. The visual obstruction of parts of the viaduct and the lack of warning signs prevented local authorities from detecting and implementing measures that could have prevented the failure.

The failure started at column wall 7 (P7, the furthest column on the east side of the viaduct), as indicated by shear failure, as shown by the smooth, diagonally shaped section plan in Figure 3(b). All column walls were severely deficient at this time (an endemic problem). Once this element failed, the right portion of the road deck fell, pulling the other support provided by column-wall P6. Since prestressing cables from the hollow core slabs were adhered to the prismatic (plain concrete) element over the prestressed crossbeam on top

of the column walls, the falling of a large section of the deck generated significant kinetic energy, which was partially absorbed by the crossbeam. This immense unbalanced lateral force, in addition to the column wall degradation, exhausted the remaining load-bearing capacity of the cantilever prestressed extension, which fractured in pullout and shear, resulting in concrete spalling (creating a destroyed, unsmoothed surface, seen in Figure 3-a). The last components in trying to self-equilibrate the absence of supporting conditions were the transversal prestressed beams within the deck hollow slab, which also failed under shear, creating a smooth plan of failure (Figure 3-a).

(a) Deck collapse indicating column-wall P6 and transversal beams fractures.

(b) Column-wall P7 fracture.

Figure 3 –Visual inspection of structure fractures right after collapse (NOVACAP, Relatório Técnico, 2018).

3.3 Debris Investigation

The space underneath column-walls P5, P6, and P7 housed an improvised restaurant with utilities and refrigeration equipment fixed directly to the viaduct's pillars and slabs. After the partial collapse and removal of the infill walls, the forensics team was able to assess the structure from different angles. Also, several elements from the failed deck were dismantled by employing jackhammers for visual inspections and reinforcing steel investigation. Drilling core samples and cut steel bar samples were extracted for testing at the University of Brasilia (UnB) structural engineering lab.

During the dismantling of the prestressed crossbeams and prestressed hollow slabs, engineers observed many aspects of the concrete structure: many prestressing wires within cables presented signs of corrosion; some prestressing cables lacked cementitious mortar protection around the steel wires; there were little (if any) non-prestressed steel rebars in the crossbeam over the column-wall, and transversal beams from the slabs; little (if any) transversal reinforcements were observed within the massive cross-section of the wing-shape extensions (cantilevers) from the columns; transversal reinforcements were only noted within the (red rectangular) part of the cross beams (16 mm-diameters, spaced 8 cm on centers); the use of rounded river gravel instead of regular crushed aggregates (like granite or limestone) was detected within the concrete composition; transversal and longitudinal rebars were made of smooth reinforcements; center joint (over the crossbeam, isolating deck cables) as unreinforced and it presented signs of chronic water infiltration, and; the smooth plan section from the diagonal-like crack of the column-wall P7 presented signs of worn out due to cyclic degradation and chronic water infiltrate (descendant from cables). These structural deficiencies (characteristics) from the viaduct concrete elements are indicated in Figure 4 from (a) to (d).

Historical records from Joaquim Cardozo specification notes (from NOVACAP archives) stated that the general concrete strengths employed at the time of construction was between 15 and 18 MPa, with even higher values of 25 MPa for special constructions, like the Alvorada Palace, Planalto Palace, National Congress, and the Cathedral of Brasilia (due to their singularly shaped columns and slender slab systems). For the Road Axis Viaduct at the Galeria dos Estados, concrete specimens were extracted from columns P6 and P7, and their nominal strengths were about 30 MPa after crushing tests conducted at the University of

Brasilia (UnB, 2018). It is believed that the original concrete compressive strength was about 20 MPa or higher at the time, which is similar to the construction period. A similar protocol was used to assess prestressing wires, which had tension strengths of 1500 MPa, typical for the use of high-strength steel in prestressing cables at the time, given the use of normal relaxation wires.

(a) Lack of Cementitious mortar within the cable and use of rounded river gravel aggregates in concrete

(b) Use of smooth rebars

(c) Lack of longitudinal non-prestressed rebars and evidence of water infiltration from the top center joint.

(d) Smooth section cut ("clean" shear) and no transverse reinforcement.

Figure 4 –Debris investigation after the partial collapse (NOVACAP, Relatório Técnico, 2018).

3.4 Standard Recommendations in 1960.

Construction of the viaduct of Galeria dos Estados took place between 1956 and 1960. At this time, the national codes in Brazil for the design of prestressed bridges were absent (only in 1989 did the Brazilian authorities publish the first standard for these structural systems: NBR 7197 - Design of Structures made with Prestress Concrete – ABNT, 1987). Before that, however, engineers would design structures according to NB2 (1941 and 1961 versions — Design and Construction of Concrete Bridges – ABNT, 1960) and NB1 (1940 and 1960 versions — Design of Concrete Structures – ABNT, 1960), which did not address the use of prestressing. Chronologically stating, civil engineers at the time of the viaduct's construction had to follow other international structural design guidelines for designing special structures.

Late records from design guidelines from DNER/DNIT, however, explicitly recommended the use of German Standards in the design of special structures (like bridges) by employing the DIN 1045:1952 "*Beton - und Stahlbetonbau – Bemessung und Ausführung*" (Design and Construction of Concrete and Reinforced

Concrete Structures), DIN 4227:1953 "*Spannbeton – Richtlinien für Bemessung und Ausführung*" (Design of Prestressed Concrete Structures) and DIN 1072:1950 "*Straßen- und Wegbrücken – Lastannahmen*" (Loads on road and pedestrian bridges) and equivalents. Many of these codes at the time were based on admissible stress principles of design, and they served as fundamental guidelines for the development of international recognized codes in the European context (such as the CEB/fib series after the 70s, for example).

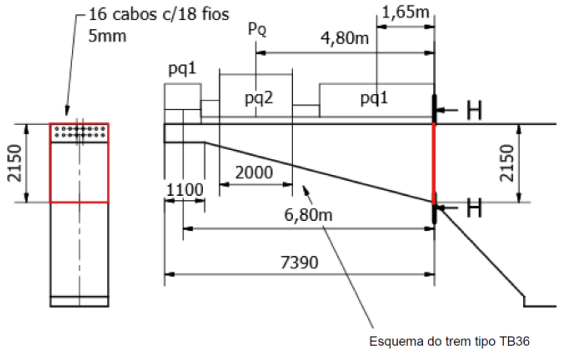
Regarding the available Brazilian specifications at the time (NB1 and NB2), shear design was based on principal stresses and checked for the use of required transverse reinforcements, limiting maximum spacing but not the minimum amount of transverse reinforcements. On the other hand, longitudinal reinforcements were determined for tension reinforcing steel using either Rupture Methods (equivalent to USL) or Allowable Stress Method, which could be made of bars or wires (but no mentions are made about minimum non-prestressing steel in avoiding progressive collapse) with minimum amounts of tensions reinforcements varying from 0.15% to 0.2% based on the steel strength type. In addition, these early Brazilian codes had no comments on size effects, cyclic depreciation, nor progressive collapse at the time of the construction of the viaduct, leaving engineers with little technical guidance, in a time when testing is labs was scarce.

4. Failure Anatomy

4.1 Reinforced Concrete Shear Theory

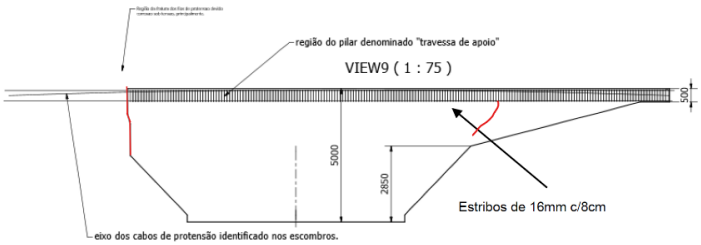
Concrete shear strength of linear prismatic RC elements is essentially sustained by the shear mechanisms of concrete and steel, namely: the concrete intrinsic self-shear strength, aggregate interlocking, dowel action (from longitudinal reinforcing bars), and the transversal strength of stirrups. These mechanisms vary their share on the load-carrying capacity according to the strain state to which the concrete element is subjected. For instance, when shear cracks (characterized by inclined, curved shapes, originating from bending moments and shear forces) start to open, the friction interfaces from concrete interlocking tend to slide and separate as crack width increases, diminishing their contribution. On the other hand, if prestresses are present, the shearing interfaces tend to be squeezed together, increasing their effective shear resistance. If tension is applied or cyclic loading is experienced, the aggregate interlocking tends to wear, decreasing its internal friction resistance.

For regular RC sections, if shear deformations continue to rise, the shear from interlocking action is absorbed by dowel action (through longitudinal steel bars deformation), concrete self-shear strength, and stirrup action. If shear loads continue to increase, the element fails when the transverse reinforcement strains reach their yield limits, and most mechanisms, then, fail simultaneously. Notably, the dowel action, stirrup strength, and concrete shear strength are related to the quantity (in terms of steel area) and quality (concrete and steel strength) of the reinforced concrete specimen. Also, the dowel action is not only a source of shear strength but also a redundant component when failure is reached, since it prevents progressive collapse once elements reach their ultimate capacity by preventing sections from falling as they hang by these bars after concrete fracture (a structural redundancy principle).



Moreover, the shear strength mechanisms' participation can be affected by cyclic loading, which inherently degrades their mechanical properties (reducing material resistance and increasing microcrack development in concrete and cumulative damage in steel crystals).

However, the behavior of linear prismatic RC elements when subjected to high shear forces is notably different in the absence of transversal reinforcements. The failure mode is predominantly related to the capability of the dowel action to remain elastic. After yielding, the strain deformations are entirely absorbed by the concrete self-shear strength, which can trigger brittle failure. Besides, when linear RC elements lack transverse reinforcement, size effects tend to magnify stress within the section, greatly reducing their apparent strength. This phenomenon does not occur in RC sections with transverse reinforcement (Wight and MacGregor, 2012).



In other words, large concrete sections without transverse reinforcement and few longitudinal rebars are critical to shear loads, as they can produce brittle failure, reduced apparent shear capacity, and little structural redundancy. Even more, cyclic loading in combination with prestress losses can be catastrophic for RC elements.

4.2 Viaduct Failure Explained

The partial collapse was triggered by corrosion under tension of the active (prestressed) reinforcement in the supporting crossbeams at the top of the pillars. This degradation was hidden from sight by the design of the “Gerber” teeth and simple concrete fillings, which obstructed direct visual inspection of the critical support elements. Also, this degradation was aggravated by chronic water infiltration (and cyclic loading) from the road deck cracks and a lack of structural maintenance over the viaduct’s 58-year lifespan. The subsequent collapse was enabled by the lack of passive reinforcement bars (both longitudinal and transverse) and absence of structural redundancy, since steel rebars could have prevented progressive collapse through dowel action. These hidden design flaws were original design vulnerabilities not known to the city authorities, especially given the absence of original drawings, the age of the structure, and outdated code requirements at the time. After the forensic investigation, the observed failure section and reinforcement steel detailing (used in the column-wall extended cross beam) were identified and portrayed in Figure 5.

(a) Column-wall cantilever extension (prestressed crossbeam) indicating its enormous section (without the presence of transversal shear reinforcements).

(b) As-built of the column-wall after collapse, indicating the failed sections in red and the other severely compromised side, with only transversal reinforcements in the crossbeam where prestresses were (absence non-prestressing rebars).

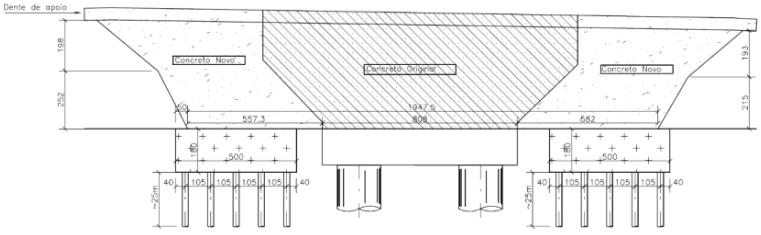
Figure 5 –Structural drawings from the Road Axis Viaduct at Galeria dos Estados indicating the failure sections (2,15 x 1,55 m) and reinforcing steels within the column-wall crossbeam (NOVACAP, Relatório Técnico, 2018).

Lastly, the viaduct collapse was a culmination of long-term systematic flaws, which are emphasized in 5 main points:

1. Notorious lack of structural safety redundancy by the absence of longitudinal reinforcing (non-prestressed) steel within the critical top section of the column-wall (which could have provided dowel action and prevented progressive collapse) and lack of transversal reinforcements in the plan section of the column wing extension (which magnified the size effects in reducing shear resistances);
2. The depreciation of mechanical properties in prestressed reinforcing steel cables due to the development of stress-corrosion (owing to the penetration of moisture through deck cracks, and the deficient cementitious protection within cables) reduced the effective counter-balancing forces

acting at the cantilever section of the delta-wing crossbeam extension, while also reducing the shear resisting mechanisms;

3. Construction and Project obstructions that obscured engineering judgment: presence of architectural features (such as infill walls and drainage gutters from the restaurant), use of permanent concrete joint (preventing the access to the core of the floor system and prestresses), and lack of original structural design drawings, which hid essential signs of distress (opening of cracks and water infiltration) and project deficiencies;
4. Poor quality of materials (compared to today's requirements): use of steel reinforcements made of smooth bars, and poor concrete composition (made with rounded river gravel instead of regular crushed aggregates like granite or limestone). This practice could have substantially altered the performance of sections under high shear loads (by reducing bond strength and thus shear capacity), especially under heavy (unforeseen) vehicle traffic.
5. Large cyclic demands that extrapolated expected demands over time, which were difficult to predict by engineering tools and methods available at the time of construction.



Although time effect decays (like steel relaxation and concrete creep) have not been mentioned, their contributions also impacted the materials performance over time. Their role in the whole failure, although to an extent, was not as significant as cyclic deterioration and shear deficiency.

5. Strengthening and Repairing

Following the emergency stabilization of the viaduct (with shoring and continuous monitoring), long-term structural recovery techniques, such as structural strengthening and repairs, were implemented, focusing on replacing failed components and enhancing the remaining structure to provide adequate performance.

For the column-wall delta-wing cantilever extensions (wings), the prestressed crossbeam was removed and reconstructed to meet current code requirements. The new crossbeams would feature sufficient prestressing and non-prestressing steel, as well as modern bearing pads, to support the road deck. Where the partial collapse occurred, the full deck segment was demolished and a new deck (with similar engineering characteristics, made of prestressed beams and hollow prestressed concrete slab) designed under elastic regime was built.

For the overall column-wall, a section enhancement concrete jacketing with prestressing ties was recommended (to increase its load-bearing capacity greatly). Also, beneath the old wings for columns, it was recommended to add a new section of concrete wall supported by massive foundation blocks over piles, as indicated in Figure 6 (a). Likewise, to create an adequate bond surface between the old and new concrete, reinforcing ties were uniformly distributed around the old column perimeters and attached to it using chemical adhesives.

(a) Column-wall cantilever extension (prestressed crossbeam) indicating its enormous section (without the presence of transversal shear reinforcements).

(a) Final view of the design project once completed.

Figure 6 –Structural drawings from the Road Axis Viaduct at Galeria dos Estados (NOVACAP, Relatório Técnico, 2018).

To prevent the chronic water infiltration that caused the original corrosion, the gap between slabs above the column walls at the crossbeam interface was recommended to be sealed with pre-molded concrete pieces, structural joints, or bolted steel plates, which would permit access for maintenance. This was a key repair requirement that enabled direct visual inspection of the bearing pads and support elements at a reasonable cost, a feature missing in the original 1960 design. The final goal of these combined techniques was to ensure a residual service life of at least 100 years for the recovered structure.

6. Lessons from the Rubble

The challenge of developing Brasilia in 4 years accelerated immensely its construction, putting engineers to the test in a period with limited resources, particularly from a standards perspective. Altogether, the early use of prestressing cable bridges, in addition to the reduced traffic predictability, made many important viaducts in Brasilia vulnerable to shear failures given their non-conforming construction methodologies, as this work indicated by the Road Axis Viaduct collapse forensics investigation. Accordingly, five main points were highlighted in this work regarding the brittle shear failure of the viaduct: absence of structural redundancy in RC details (not required by the codes from the period of construction); depreciation effect in materials over time (infiltration exposure and construction inadequacies); projected and construction obstacles that prevented effective maintenance and early flaw detection; poor quality of materials and methods available at the time of construction (concrete composition, use of smooth bars, absence of cement paste within many prestressing cables), and; unpredicted cyclic demands that extrapolated expected demands over time. Although catastrophic, this partial collapse reveals how older non-conforming heritage structures may be deficient under society's new demands, providing valuable insights and a singular reference for future (similar) engineering challenges within Brazil's capital.

Procedure for assessing the dynamic resistance of existing bridge structures located in seismically active mining areas

Janusz RUSEK[1], Leszek SŁOWIK[2], Henryk CIUREJ[3]

[1] AGH UST in Cracow, Faculty of Civil Engineering and Resource Management, Poland, rusek@agh.edu.pl
[2] ITB Building, Research InstituteDepartment of Building Structures, Geotechnics, and Concrete, Warsaw, Poland, l.slowik@itb.pl
[1] AGH UST in Cracow, Faculty of Civil Engineering and Resource Management, Poland, hciurej@agh.edu.pl

Abstract: This paper presents the results of computations intended to determine the dynamic resistance of an existing, non-standard Soil Steel Composite Bridge (SSCB) structure to the effects of paraseismic excitations induced by mining tremors. Within the developed method, the dynamic resistance of the structure is defined as the permissible component values of ground motion accelerations at its location. For this reason, it was necessary to conduct numerical dynamic analyses in accordance to the guidelines included in Eurocodes and local regulations concerning the design and erection of structures in mining areas. On this basis, a set of criteria was established that allowed for the determination of the permissible component values of ground accelerations. The range defined by these values, relative to an exceptional combination, can be interpreted as a safety reserve where the dynamic effects generated by a mining tremor can be accepted. It is important to emphasize that the identification of such a safety reserve is essential for existing structures that were designed without taking into account the dynamic effects generated by underground mining operations. Based on available data regarding the existing SSCB bridge structure, a 3D finite element model (FEM) was developed to determine reliable strength intensity measures under static and dynamic loads. Next, in accordance with the methodology used, and considering the design-stage load combinations and the exceptional load combination as separate cases, the allowable values of the component ground vibration accelerations were determined. While working on such an unusual structure, the following methods were adopted for dynamic loading: the response spectrum method for the vertical direction, and, for one of the horizontal directions, an approach based on the physical process of seismic wave propagation in the subsurface. The establishment of this particular research approach was based on the fact that the structure under analysis is sensitive to dynamic excitations, in which inertial effects manifest themselves only in the vertical direction. This approach cannot be applied in the horizontal plane because the inertia of the bridge itself is dominated by the covering layer of ground. Ultimately, the proposed approach made it possible to determine the load-bearing capacity reserve expressed in terms of the permissible values of ground acceleration components. In addition, the computational methods developed for specific directions of dynamic excitation provide guidance on how to proceed with the analysis of non-standard structures such as SSCB structures

Thermal behavior of urban pavements under the influence of tree shading: implications for pavement performance and durability

Nayara de Oliveira GURJÃO [1], Lara Sucupira FURTADO [2], Jorge Barbosa SOARES [3]

[1] Federal University of Ceará, Brazil, nayara.gurjao@det.ufc.br
[2] Federal University of Ceará, Brazil, lfurtado@det.ufc.br
[3] Federal University of Ceará, Brazil, jsoares@det.ufc.br

Abstract: The thermal behavior of urban pavements plays a fundamental role in urban microclimate dynamics and in the operational conditions of road infrastructure, especially in cities located in hot climate regions. Different pavement surface courses, such as asphalt mixtures, Portland cement concrete, and alternative surface treatments, exhibit distinct thermal responses as a result of their physical, optical, and thermal properties, influencing solar radiation absorption and heat dissipation. In this context, tree shading emerges as an external factor capable of modifying the energy balance of paved surfaces, with direct effects on roadway surface temperatures. This paper presents a literature review on the thermal influence of tree shading on urban pavements, with emphasis on the thermal response of different pavement surface materials. Studies employing in situ measurements, remote sensing, and thermal modeling are analysed to assess surface temperature variations associated with pavement materials and the presence of trees along the roadway network. The review also presents how reductions in surface temperatures may be associated with pavement performance and durability, related to the emergence of distresses or the need for repairs, considering temperature-sensitive degradation mechanisms. In addition to theoretical advances, the review seeks to analyze the transformation of scientific knowledge into applicable tools, technologies, and computational strategies, such as performance indices and criteria. This knowledge can support decision-making by public administrators and urban planners, aiming to identify applications validated with real data and the transfer of methodologies to different urban scenarios. The available literature suggests the existence of gaps in the integrated analysis of pavement materials, shading conditions, and surface damage, indicating the need for interdisciplinary approaches focused on the climate adaptation of urban infrastructure.

Keywords: Urban pavements; Thermal behavior; Tree shading; Surface materials; Pavement performance.

1. Introduction

Urbanization, population growth, and climate change are reshaping cities worldwide and creating increasingly complex challenges. Transportation infrastructure, in particular, plays a significant role in this context due to its extensive spatial coverage, including the environmental impacts associated with soil sealing, increased surface temperatures, and the intensification of urban heat island (UHI) effects (Santamouris, 2013; Ranagalage, Estoque and Murayama, 2017; Furtado et al., 2025). These challenges are closely aligned with the United Nations Sustainable Development Goals (SDGs), proposed by the United Nations (UN, 2015), particularly SDG 11 (Sustainable Cities and Communities) and SDG 13 (Climate Action), which emphasize the need for resilient, sustainable, and climate-adaptive urban infrastructure.

Among urban infrastructures, pavements represent a substantial portion of the built environment, and their material properties directly influence the absorption, storage, and release of solar radiation, especially in hot tropical cities (Benrazavi et al., 2016; Qin et al., 2022). Parameters such as albedo, emissivity, conductivity, and thermal capacity govern these interactions, affecting surface temperatures, pedestrian thermal comfort, and pavement durability (Ding et al., 2022; Yang et al., 2025).

In addition to thermal effects, elevated pavement temperatures influence the mechanical behavior of asphalt materials. Although thermal effects on the behavior of asphalt materials is well established in the literature, they are not much explored for urban scenarios. High temperatures can accelerate binder oxidative aging, increasing susceptibility to distresses and structural deterioration (McPherson & Muchnick, 2005; Matlack, Khoury and Naik, 2022; Liu et al., 2025).

Urban vegetation has been widely recognized as an effective strategy for mitigating urban thermal impacts and reducing surface temperatures (Speak et al., 2020; Cheela et al., 2021). In Brazil, public policies such as the National Urban Tree Plan (PlaNAU) reinforce its role in mitigating urban heat islands, improving thermal comfort, and enhancing urban resilience (Brazil, 2023).

Through shading and evapotranspiration processes, urban trees reduce the amount of solar radiation reaching paved surfaces and contribute to the cooling of the surrounding microclimate. Consequently, vegetation may also influence the thermal dynamics of pavements and may potentially contribute to reducing material degradation and maintenance demands, although direct evidence regarding long-term pavement performance remains limited. (Underwood et al., 2017; Cheela et al., 2021; Qin et al., 2022).

The literature presents extensive analyses of the thermal properties of urban surface materials and the role of vegetation in microclimate regulation, using approaches such as field monitoring, remote sensing, and numerical modelling (Napoli et al., 2016; Feng et al., 2020; Ahmad, Najar and Ahmad, 2024). However, the interaction between tree shading and the thermal and functional behavior of urban surfaces remains underexplored. Therefore, this study analyses the influence of urban vegetation, particularly tree shading, on surface temperature and its implications for pavement performance through a systematic literature review.

2. Methodology

2.1 Search strategy

An initial search was conducted using specific keyword combinations to identify studies that directly addressed the relationship between vegetation, shading, and the thermal and functional performance of pavements. However, this strategy resulted in a very limited number of studies, with only two articles directly addressing the combined topic.

To overcome this limitation, the scope of the search was broadened by adopting more comprehensive keyword combinations related to urban pavements, vegetation, and thermal behavior. Searches were conducted in the Scopus and Web of Science databases, applying filters to include only articles, review articles, and early access publications between 2000 and 2026. This search resulted in 79 documents in Scopus and 909 documents in Web of Science, which constituted the initial dataset for the screening process (Table 1).

Table 1 – Search strings used in the systematic literature review

List of databases	Search string	Number of documents
Scopus	("pavement" OR "road pavement" OR "road surface" OR "street pavement" OR "sidewalk pavement" OR "urban pavement") AND ("tree shade" OR "tree canopy" OR "urban trees" OR "street trees" OR "urban vegetation") AND ("surface temperature" OR "pavement temperature" OR "land surface temperature" OR "urban heat island" OR "thermal behavior")	79
Web of Science	(pavement OR "road surface" OR asphalt OR concrete) AND (tree OR vegetation OR shade OR shading) AND ("surface temperature" OR thermal OR heat OR "urban heat island")	909

Search strategies were adapted to each database to balance precision and recall, using a more restrictive string in Scopus and a broader approach in Web of Science to ensure sensitivity. Additional relevant studies were identified through reference tracking and prior research by the authors when contributing to the methodological or conceptual discussion.

2.2 Inclusion and exclusion criteria

To ensure the relevance of the selected studies, inclusion and exclusion criteria were established. Studies were included when they:

- addressed urban pavements, road surfaces, or sidewalks. Studies related to land use or urban surfaces that included pavements as part of the analysis were also considered;
- analyzed thermal behavior, surface temperature, or urban heat island effects associated with pavements or urban surfaces;
- investigated vegetation, shading, or environmental factors that influence pavement temperature;
- explored the relationship between vegetation or shading and the thermal and/or functional performance of pavements.

Studies were excluded when they:

- focused exclusively on structural or mechanical pavement performance, without any relation to surface temperature or shading;
- addressed urban heat island effects without reference to pavements, typically focusing only on buildings or urban morphology;
- were not directly related to the thermal and/or functional behavior of urban surfaces.

Studies that presented methodological approaches for analyzing surface materials or modelling the urban thermal environment were also retained when their methods could contribute to the analysis or replication of thermal assessment techniques relevant to pavements.

2.3 Screening process

The selection of articles followed a screening procedure with the following steps: (i) duplicate records from both databases were removed; (ii) the remaining studies were analysed based on their titles, keywords, and a cursory reading of the abstract, when necessary, to identify those aligned with the research scope; (iii) the inclusion and exclusion criteria presented earlier were used to accept, reject, or submit the work to a more in-depth evaluation, in which topics such as introduction and conclusion were explored.

After steps (i) and (ii), 56 articles remained (accepted and subsequently evaluated) to verify their relevance and contribution to the topic. After step (iii), 39 articles were selected, which had open access to the general public or the university. The overall screening process is summarized in Figure 1, which presents the article selection flowchart.

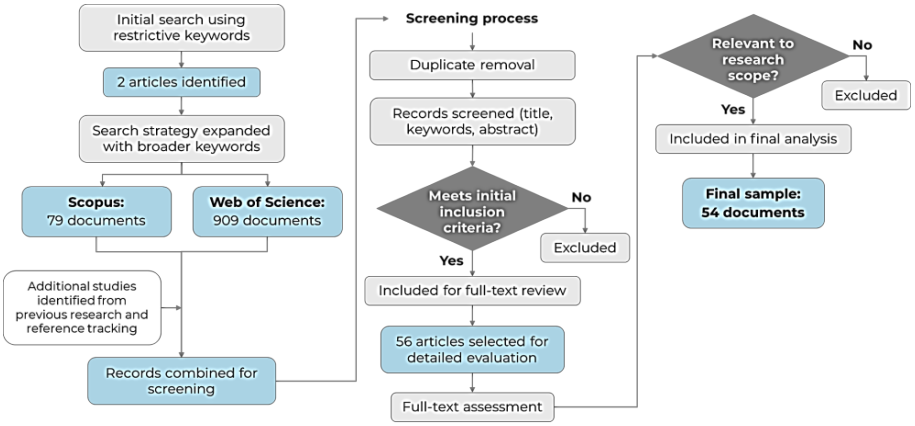

Figure 1 – Flowchart of article selection

Subsequently, 15 supplementary references that were not revealed in the search for scientific articles (including institutional reports and conceptual studies) were incorporated to support the theoretical framework and contextual discussion, resulting in a final corpus of 54 documents.

3. Summary of the systematic literature review

An initial overview of the selected literature is presented in Section 3.1, which provides a classification of the studies according to their main research focus and highlights the distribution of articles across different thematic approaches. Based on the analysis of the selected studies, the literature was organized into three main research themes:

(i) thermal behavior of pavement materials in urban environments;
(ii) the role of vegetation and shading in mitigating pavement surface temperatures and urban heat island effects;
(iii) methods used to analyze pavement temperature and urban microclimates, including spatial analysis, remote sensing techniques, and urban data integration.

The following sections present the main findings of the literature according to these thematic groups.

3.1 Overview and classification of the selected literature

The selected literature highlights a strong predominance of studies focused on thermal aspects (68.5%), while studies integrating functional and thermal performance represented only 13.0%, divided into analyses of pavement behavior (9.3%) and tree shading (3.7%). Although some studies refer to pavement "performance" or "durability", these terms are often used in a general or thermal context, without explicitly addressing the mechanical or structural behavior of pavement materials. Studies investigate the effect of tree shading on pavement surface temperature; however, only two explicitly address its implications for functional (mechanical) performance.

Figure 2 shows the temporal distribution of the analysed documents, including studies selected through the systematic review and complementary references. An increasing publication trend was observed over recent years, indicating growing interest in the topic.

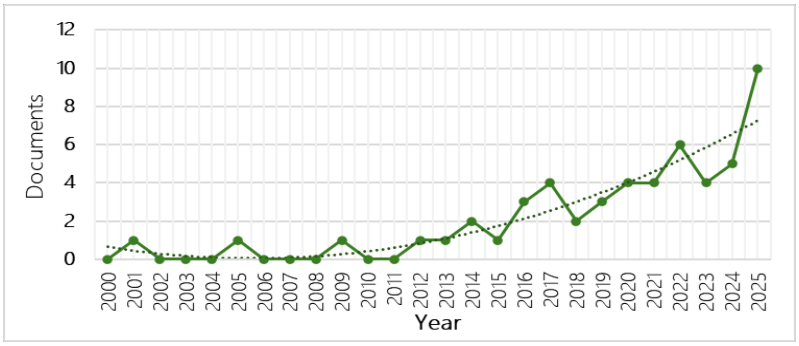

Figure 2 – Historical evolution of the number of documents published per year.

The selected studies were published across a wide range of journals, reflecting the interdisciplinary nature of the topic. Journals such as *Urban Climate* and *Sustainable Cities and Society* highlight the relevance of urban climate and sustainability, while *Building and Environment*, *Energy and Buildings*, and *Renewable & Sustainable Energy Reviews* emphasize thermal performance in the built environment. Additional publications in environmental and infrastructure-related journals further support the integration of climate, vegetation, and pavement research, consistent with the thematic structure of this review.

4. Results from literature analysis

4.1 Thermal and functional behavior of pavements for urban heat mitigation

Published literature highlights urban development characterized by the expansion of large impermeable areas occupied by artificial materials such as concrete and asphalt. The replacement of vegetated surfaces by impervious materials accounts for approximately 30% to 45% of urban areas and represents one of the main drivers of urban heat island (UHI) formation (Santamouris, 2013; Wang et al., 2021; Rouzmehr and Jamshidi, 2025).

These materials exhibit specific properties, such as high thermal absorption rates and varying levels of reflectance, making them both contributors to and affected by climatic variations due to changes in temperature and humidity, the occupation of permeable areas, the absence of surface shading, and the lack of local tree cover (Ibrahim et al., 2018; Ding et al., 2022; Chen et al., 2025; Yang et al., 2025).

Within transportation infrastructure, excessive heat acts as a degrading agent, as increased asphalt pavement temperature accelerates the oxidative aging of the binder. Thus, material characteristics such as albedo (reflectivity), emissivity, and thermal inertia represent key thermophysical properties that directly determine the magnitude of heating of both surfaces and the adjacent air layers (Santamouris, 2013; Qin et al., 2022).

Tsirigoti and Gkyrtis (2026) investigated the use of recycled materials in asphalt mixtures in Greece, which, when combined with high reflectivity properties, can reduce air temperature by up to 1.6 °C. Taleghani and Berardi (2018) specifically analysed pavements and sidewalks in urban environments, demonstrating their significant impact on pedestrian thermal comfort. Dark materials tend to retain more heat during the day and re-emit this heat at night, resulting in high surface temperatures during both periods.

Using climate modelling for California cities, Mohegh et al. (2017) observed that increases in albedo are nearly linearly associated with reductions in air temperature, contributing to urban cooling. Similarly, Qin et al. (2022) identified albedo as the most influential internal factor affecting pavement surface temperature. Due to their low albedo, asphalt pavements absorb shortwave solar radiation and reemit it as longwave radiation, resulting in higher surface temperatures (Cheela et al., 2021; Qin et al., 2022; Engel et al., 2023).

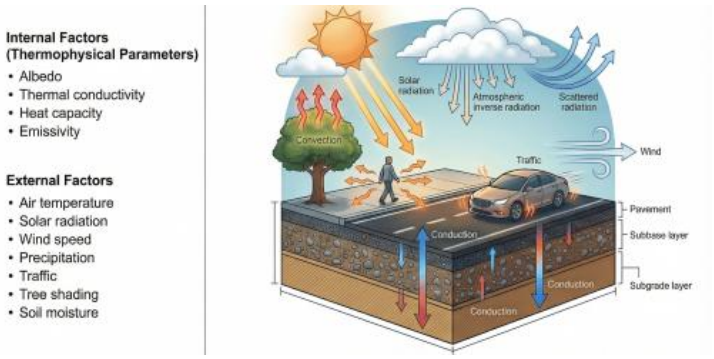

Figure 3 – Typical thermal partitioning at a pavement surface (adapted by authors from Qin et al., 2022)

Light-colored pavements or reflective coatings can reduce surface temperatures by up to 20 °C compared to conventional asphalt (Santamouris, 2013; Cheela et al., 2021; Gong et al., 2023). Thermal properties such as conductivity, albedo, and emissivity influence heat storage and release, although their effects depend on local climatic conditions, which remain difficult to control.

Extreme temperature and humidity conditions not only affect environmental quality and human well-being but also accelerate pavement deterioration, leading to reduced service life, higher maintenance costs, and significant economic impacts, with projections of up to US$ 26 billion in additional costs in the United States by 2040 (Underwood et al., 2017; Guest et al., 2019; Gulzar, Goenaga, and Underwood, 2022; Maadani, Shafiee, and Egorov, 2022).

Reducing asphalt surface temperature can significantly improve pavement performance and durability. Akbari, Pomerantz, and Harvey (2001) showed that a reduction of approximately 10 °C can prevent

permanent deformation from exceeding the failure criterion (12.5 mm), while reductions around 20 °C improve resistance to deformation (McPherson and Muchnick, 2005). Similarly, lower temperatures and thermal amplitudes minimize structural stresses and delay binder aging, reinforcing the potential benefits of shading for pavement performance, particularly in hot climates (Qin et al., 2022; Liu et al., 2025).

4.2 Methods for Evaluating Pavement Temperature and Urban Interactions

Advances in geotechnologies and the availability of urban data have expanded the possibilities for integrated analysis of transportation infrastructure, combining remote sensing, field measurements, and computational simulations (Stathopoulou et al., 2009; Wang et al., 2021; Elmagri et al., 2024).

At the regional scale, satellite data (such as Landsat, MODIS, and ASTER) enable land use characterization, land surface temperature (LST) assessment, and correlation with land cover indices such as the Normalized Difference Vegetation Index (NDVI) and the Normalized Difference Built-up Index (NDBI), revealing that highly impervious areas exhibit significantly higher temperatures (Stathopoulou et al., 2009; Ranagalage et al., 2017; Engel et al., 2023; Ahmad, Najar, and Ahmad, 2024; Façanha and Arantes, 2024).

Studies based on LST and NDVI analyses highlight vegetation as the main factor associated with lower temperatures (Engel et al., 2023; Ahmad, Najar, and Ahmad, 2024; Façanha and Arantes, 2024), whereas other works emphasize that urban materials store more heat and cool more slowly than natural surfaces, and that soil sealing, urban growth, and transport-related areas intensify thermal patterns and should be prioritized for intervention (Stathopoulou et al., 2009; Ranagalage et al., 2017).

At the microscale, unmanned aerial vehicles (UAVs) equipped with thermal cameras enable high-resolution analysis of land use and surface temperature variations, showing that artificial surfaces are major sources of sensible heat, while vegetation-related humidity contributes to cooling (Feng et al., 2020). Additionally, simulation tools such as ENVI-met and Ladybug Tools, along with machine learning approaches, are widely used to model thermal patterns and support urban planning (Choi et al., 2021; Elmagri et al., 2024; Rouzmehr and Jamshidi, 2025; Ye et al., 2025).

Several metrics and indices are used in the literature to characterize material behavior and spatially classify urban areas, including the Leaf Area Index (LAI), Mean Radiant Temperature (MRT), Universal Thermal Climate Index (UTCI), Physiological Equivalent Temperature (PET), evaporation rates, and Standard Effective Temperature (SET*), among others (Sen et al., 2019; Del Serrone et al., 2022; Peluso et al., 2022; Elmagri et al., 2024; Dalla Mora et al., 2025; Lu et al., 2025).

ENVI-met has been widely used to simulate interactions between urban variables and assess their effects on thermal behavior (Tsoka et al., 2020; Choi et al., 2021; Del Serrone et al., 2022; Peluso et al., 2022; Dalla Mora et al., 2025; Ye et al., 2025). For example, Yang et al. (2016) demonstrated that pavement thermal performance in urban canyons is strongly influenced by street geometry and that reflective materials, despite reducing surface temperatures, may increase pedestrian thermal stress. Overall, georeferenced tools support integrated assessments of vegetation, surface temperature, and urban infrastructure, contributing to shading mapping and urban heat mitigation strategies (Figure 4).

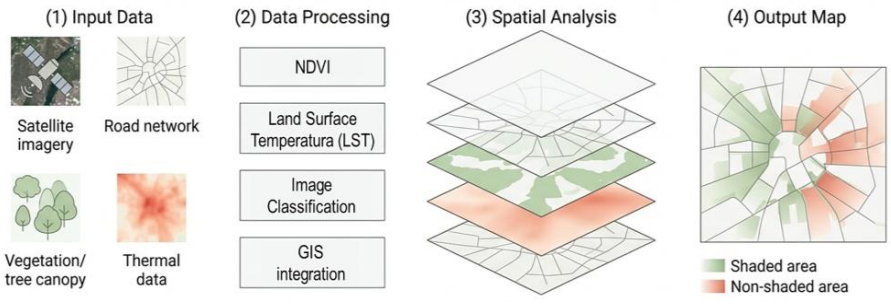

Figure 4 – Conceptual framework for mapping urban shading areas using geospatial data.

4.3 Tree shading effects on pavement thermal and functional performance

The effects of excessive heat on urban surfaces, particularly asphalt pavements, remain an underexplored topic in the literature. Although this issue is often addressed from a thermal performance perspective, it is rarely associated with the functional and mechanical performance of pavements, particularly regarding temperature-related deterioration mechanisms and pavement defects.

Thermoviscoelastic materials, such as Asphalt Concrete (AC), are highly sensitive to temperature variations, and extreme climatic conditions may compromise their mechanical properties and durability (Underwood et al., 2017; Gulzar, Goenaga and Underwood, 2022; Gong et al., 2023; Liu et al., 2025). Elevated temperatures accelerate binder aging, particularly in hot climates where asphalt surface temperatures frequently exceed 60 °C. This condition contributes to the development of pavement defects, such as fatigue cracking and permanent deformation, resulting in increased maintenance demands (Santamouris, 2013; Matlack et al., 2022; Gong et al., 2023; Dehnad et al., 2025).

Several studies address “cool pavements” as strategies to mitigate the effects of high temperatures and urban heat islands, while also contributing to extending infrastructure service life. These strategies include the use of high-reflectance materials and coatings, such as light-colored surfaces and reflective pigments, which increase albedo and reduce solar radiation absorption (Santamouris, 2013; Takebayashi et al., 2014; Wang et al., 2021; Gong et al., 2023). Another approach involves porous pavements or structures capable of retaining water, promoting moisture-based cooling and delaying surface heating (Hendel et al., 2014; Ibrahim et al., 2018; Frere et al., 2024; Dalla Mora et al., 2025). In addition, phase change materials (PCMs) have been employed to regulate pavement temperature through latent heat storage and release, reducing thermal peaks (Santamouris, 2013; Gong et al., 2023; Seifeddine et al., 2023). Most studies prioritize surface temperature reduction, with limited evaluation of long-term structural behavior. For this reason, shading is considered promising for pavement durability, given the influence of temperature on material performance (Wang et al., 2021; Gong et al., 2023).

Urban tree cover acts as an effective thermal mitigation mechanism for pavements through surface shading and evapotranspiration, significantly reducing surface temperatures and associated thermal stresses. Temperature reductions can range from 5 to 25 °C, with experimental evidence reporting reductions of up to 20.9 °C on shaded asphalt surfaces. Although results may vary depending on pavement type, climatic conditions, and tree canopy characteristics, shading stands out as an effective strategy that can provide environmental improvements through the implementation of green areas in cities (Mascaró, 2012; Napoli et al., 2016; Rahman et al., 2019; Kaluarachichi et al., 2020; Speak et al., 2020; Lu et al., 2025; Liu et al., 2025).

Matlack et al. (2022) report that shaded pavements exhibit significantly lower stress levels, from 0.7 to 1.2 MPa, compared to pavements exposed to direct solar radiation, from 1.8 to 5.3 MPa. The authors indicate that stress levels in unshaded areas fall within the range associated with cracking observed in the laboratory. Additionally, it is assumed that tensile stress increases as the pavement ages and stiffens.

Consequently, the protection provided by tree canopies may delay binder aging, potentially reducing defects such as fatigue cracks and permanent deformations, leading to lower maintenance costs and extended service life (Cheela et al., 2021; Matlack et al., 2022; Gong et al., 2023). In particular, McPherson and Muchnick (2005) estimated that shading from large trees can reduce pavement maintenance needs by up to 58% over a 30-year period, corresponding to a cost saving of $7.13 per square meter. However, more empirical evidence is needed to understand these effects on deterioration processes and defect development.

The above-mentioned effect was assessed using the Pavement Condition Index (PCI), which ranges from 0 (poor) to 100 (excellent), and the Tree Shade Index (TSI), defined as the percentage of shaded area, typically equal to or greater than 30% in commercial areas. The results indicated that shaded sections presented significantly higher PCI values, reflecting a lower incidence of cracks and deformations (McPherson and Muchnick, 2005).

Table 2 summarizes the main conclusions regarding tree shading and its thermal and performance effects on pavements. Overall, the studies analysed report substantial reductions in pavement surface temperature under tree shading, but the evidence directly linking these reductions to pavement defects, durability, and long-term performance is still relatively limited.

Table 2 – Synthesis of the literature on tree shading and pavement performance

Study	Method / Strategy	Main findings	Pavement implications	Research gaps
McPherson & Muchnick (2005); Matlack et al. (2022)	Field analysis / modeling – Tree shade	Improved pavement condition; 15–25°C reduction under canopy	Lower thermal stresses and reduced cracking potential. 58% maintenance reduction over 30 years	Limited field validation; need to isolate thermal and biological effects
Gong et al. (2023); Cheela et al. (2021)	Reviews – Shading and cool pavements	Surface temperature reductions of 5–25°C	Potential reduction in rutting, binder aging, softening, and exudation	Limited evidence on long-term mechanical performance
Mascaró (2012); Kaluarachichi et al. (2020)	Modeling + field experiments – Tree canopy	9–10°C reduction depending on canopy and 20.9°C reduction on asphalt	Reduced heat storage and potential pavement preservation benefits	Influence of canopy characteristics remains uncertain
Liu et al. (2025)	Field experiment – Tree shade	Cooling depends on surface properties	Potential urban thermal benefits	Environmental and sensor interactions

Although the thermal benefits are widely validated, authors such as Cheela et al. (2021), Gong et al. (2023), and Matlack et al. (2022) emphasize that the direct relationship between shading-induced cooling and the mechanical/functional response of asphalt still lacks long-term evidence, representing a key research gap in the field. Finally, urban green spaces and street trees are also increasingly recognized as key elements for climate adaptation and public health, contributing to reduced stress, lower incidence of cardiovascular diseases, and decreased overall mortality, while simultaneously mitigating urban heat island effects (Qin et al., 2022; Gurjão et al., 2024; Furtado et al., 2025).

5. Conclusions

This article shows that urban pavements are both contributors to and victims of urban heat, as impervious materials intensify thermal stress while their mechanical performance deteriorates under high temperatures. A second finding is that recent advances in remote sensing, thermal monitoring, simulation, and data-driven methods have significantly expanded the capacity to evaluate pavement temperature and its relationship with urban form, vegetation, and material properties across multiple scales. A third finding is that urban tree shading emerges as a particularly promising strategy because it addresses both sides of the problem at once: it mitigates heat exposure in cities and may also help preserve pavement performance by reducing thermal loading. The contribution of this paper lies in bringing these strands of research together, connecting urban heat mitigation, pavement durability, and green infrastructure within a single analytical perspective (Figure 5). By doing so, it highlights the need to move beyond treating pavements solely as engineering surfaces or urban heat solely as a climatic issue, and instead frames both as interdependent components of urban adaptation. In practical terms, this perspective can support planners, engineers, and local governments in prioritizing tree-based shading strategies, improving pavement design and maintenance decisions, and developing more integrated policies for climate resilience and urban infrastructure management.

CLASSES DE AGRESSIVIDADE DO CONCRETO NO BRASIL: INFLUÊNCIA REGIONAL, PATOLOGIAS E IMPLICAÇÕES EM PROJETO

Stefania Alexina Martins Zebral Silva

Instituto Nova Engenharia, Minas Gerais, Brasil, szengenharaia.eng@gmail.com

Resumo: A durabilidade das estruturas de concreto armado está diretamente relacionada à correta avaliação da agressividade ambiental ao longo da vida útil. No Brasil, a diversidade climática, aliada à intensa urbanização e industrialização, resulta em diferentes níveis de exposição que impactam significativamente o desempenho estrutural. Este trabalho investiga as classes de agressividade ambiental (CAA) definidas pelas normas ABNT NBR 6118:2014 (Projeto de Estruturas de Concreto) e ABNT NBR 12655:2023 (Concreto de Cimento Portland – Preparo, Controle, Recebimento e Aceitação), correlacionando-as com as condições predominantes nas cinco grandes regiões brasileiras: Norte, Nordeste, Centro-Oeste, Sudeste e Sul. A pesquisa adota abordagem qualitativa com base em revisão normativa sistemática e literatura técnico-científica consolidada, integrando análise comparativa internacional com as normas Eurocode 2 (EN 1992-1-1:2023), ACI 318-19 e BS 8500:2019. São discutidas as principais manifestações patológicas associadas a cada classe, as implicações nas fases de projeto, execução e manutenção, e é proposta uma tabela comparativa normativa inédita. Os achados evidenciam a necessidade de critérios de projeto mais rigorosos em ambientes costeiros, industrializados e de elevada umidade tropical, contribuindo para o aumento da vida útil e da confiabilidade das estruturas de concreto armado. Como limitação, a pesquisa não realizou ensaios experimentais, sendo os resultados embasados em revisão da literatura. Estudos quantitativos futuros são recomendados para validação dos padrões de classificação identificados.

Palavras-chave: durabilidade; concreto armado; agressividade ambiental; desempenho estrutural; comparação normativa internacional.

1. INTRODUÇÃO

A durabilidade das estruturas de concreto armado é condição essencial para o desempenho seguro ao longo da vida útil de projeto. Em um país de dimensões continentais como o Brasil, a diversidade climática, o processo de urbanização acelerada e a presença de polos industriais consolidados criam cenários de exposição ambiental extremamente heterogêneos, exigindo uma classificação criteriosa da agressividade ambiental desde a fase de concepção estrutural.

Estudos recentes têm demonstrado que a corrosão de armaduras induzida por carbonatação e por íons cloreto constitui o principal mecanismo de degradação do concreto armado em ambientes urbanos e costeiros (Mumberger et al., 2022; Li et al., 2024). Em áreas litorâneas, os aerossóis marinhos transportam concentrações elevadas de cloretos que penetram na matriz cimentícia, comprometendo de forma irreversível a passivação das barras de aço e reduzindo significativamente a vida útil das estruturas (Rodrigues et al., 2024). A situação é agravada pelo fato de que o Brasil possui uma costa de aproximadamente 7.500 km, com elevada concentração de infraestrutura construída em zonas de influência marinha.

A norma ABNT NBR 6118:2014 (Projeto de Estruturas de Concreto) estabelece quatro classes de agressividade ambiental (CAA I a IV), vinculando-as a parâmetros prescritivos de projeto, como cobrimento nominal das armaduras, resistência característica mínima à compressão e relação máxima água/cimento. A ABNT NBR 12655:2023 (Concreto de Cimento Portland – Preparo, Controle, Recebimento e Aceitação), complementa esses requisitos ao disciplinar o preparo, controle e recebimento do concreto de cimento Portland. Apesar da consistência técnica dessas normas, a simples consulta tabular às classes de agressividade, sem consideração das condições microambientais locais, pode conduzir a projetos insuficientemente conservadores, subestimando o risco real de deterioração.

No plano internacional, normas como o Eurocode 2 (EN 1992-1-1:2023), a ACI 318-19 e a BS 8500:2019 adotam abordagens distintas, em alguns casos baseadas em desempenho que ampliam o ferramental disponível para o projetista e explicitam cenários de exposição com maior granularidade. A comparação entre essas referências e a normatização brasileira revela lacunas e oportunidades de aperfeiçoamento, especialmente quanto à incorporação de modelos de previsão de vida útil e à definição de classes de exposição para ambientes tropicais.

Nesse contexto, o presente artigo tem como objetivo analisar criticamente as classes de agressividade ambiental do concreto armado no Brasil, correlacionando-as com os ambientes típicos das cinco grandes regiões do país, identificando as manifestações patológicas mais recorrentes, discutindo suas implicações no projeto estrutural e propondo uma tabela comparativa normativa inédita entre as principais referências nacionais e internacionais. A pesquisa contribui para a consolidação de uma abordagem regionalizada da classificação ambiental, essencial para a ampliação da confiabilidade e da vida útil das estruturas de concreto no território brasileiro.

2. FUNDAMENTAÇÃO TEÓRICA E NORMATIVA

2.1 Definição normativa das classes de agressividade ambiental

A ABNT NBR 6118:2014 (Projeto de Estruturas de Concreto) classifica a agressividade ambiental em quatro classes progressivas: Fraca (I), Moderada (II), Forte (III) e Muito Forte (IV), com base no risco de deterioração que o ambiente impõe à estrutura ao longo da sua vida útil. Essa classificação considera os principais agentes agressivos ao concreto armado: dióxido de carbono (CO_2), que promove a carbonatação; íons cloreto, transportados por aerossóis marinhos ou por soluções de degelo; sulfatos presentes em solos ou águas subterrâneas; e poluentes industriais gasosos ou líquidos. A ABNT NBR 12655:2023 (Concreto de Cimento Portland – Preparo, Controle, Recebimento e Aceitação), operacionaliza essas classes ao vincular cada nível de agressividade a requisitos mínimos de qualidade do concreto, abrangendo desde o traço e a relação água/cimento até as condições de cura e controle tecnológico da produção.

Segundo Bolina e Tutikian (2016), as normas brasileiras exigem, para estruturas enterradas com vida útil de 75 anos, parâmetros consideravelmente mais restritivos do que os valores mínimos prescritos para a classe II, evidenciando que a simples conformidade normativa básica pode ser insuficiente para garantir o desempenho a longo prazo em condições de agressividade moderada a severa. Mumberger et al. (2022) reforçam essa perspectiva ao proporem parâmetros de durabilidade para vidas úteis entre 50 e 100 anos no Brasil, concluindo que os valores prescritos pela NBR 6118 para as classes I e II são compatíveis com 50 anos de vida útil, mas demandam ajustes para projetos de maior longevidade, especialmente em ambientes costeiros e industrializados.

2.2 Parâmetros de projeto associados às classes de agressividade

Para cada classe de agressividade, as normas brasileiras definem um conjunto articulado de exigências que visam mitigar os mecanismos físico-químicos de degradação. A Tabela 2, apresentada na Seção 4, sistematiza esses parâmetros. O cobrimento nominal das armaduras constitui o principal parâmetro de proteção física do aço, e sua correta especificação depende tanto da classe de agressividade quanto da qualidade do concreto adotado. Estudos de caso conduzidos por Cascudo e colaboradores demonstram que a variabilidade do cobrimento durante a execução é uma das causas mais frequentes de deterioração prematura em estruturas inseridas em ambientes de agressividade moderada a forte.

A relação água/cimento máxima e a resistência característica mínima à compressão atuam em sinergia, reduzindo a porosidade e a permeabilidade da matriz cimentícia e, consequentemente, retardando a penetração de agentes agressivos. A qualidade e o controle tecnológico do concreto completam esse conjunto normativo, estabelecendo diferentes exigências de amostragem, ensaios e controle estatístico conforme a severidade ambiental.

2.3 Mecanismos físico-químicos de degradação

A carbonatação do concreto resulta da reação entre o CO_2 atmosférico e o hidróxido de cálcio presente na pasta de cimento hidratada, produzindo carbonato de cálcio e reduzindo o pH da solução dos poros de valores próximos a 13 para abaixo de 9. Nessa faixa de pH, a camada passivadora que protege as armaduras é destruída, iniciando o processo de corrosão. A taxa de carbonatação é governada pela concentração de CO_2, pela umidade relativa do ambiente com pico de velocidade entre 50% e 70% de UR e pela porosidade do concreto, parâmetro diretamente controlável pela relação água/cimento.

A corrosão por cloretos ocorre por um mecanismo distinto: os íons Cl^- desestabilizam localmente a camada passivadora da armadura sem necessariamente alterar o pH do concreto, deflagrando corrosão por pites altamente localizada. Esse mecanismo é particularmente severo em ambientes marinhos, onde a concentração de cloretos no aerossol pode ser ordens de magnitude superiores às encontradas em zonas continentais. Pesquisas realizadas em estruturas costeiras brasileiras com mais de 40 anos de uso registraram penetração de cloretos muito acima dos limites normativos, resultando em abertura de fissuras superiores a 30 mm e comprometimento estrutural significativo (Rodrigues et al., 2024).

O ataque por sulfatos, predominante em solos argilosos e águas subterrâneas de certas regiões, promove expansão volumétrica da pasta de cimento por formação de etringita secundária e gipsita, levando à fissuração e desagregação do concreto. Em ambientes industriais, a combinação de SO_2, NO_x e outros poluentes gasosos com a umidade superficial cria soluções ácidas que aceleram significativamente todos os mecanismos de degradação descritos.

3. METODOLOGIA

Esta pesquisa adota abordagem qualitativa, de natureza exploratória-descritiva, estruturada em quatro etapas complementares. Na primeira etapa, foi realizada a revisão normativa sistemática das normas ABNT NBR 6118:2014 (Projeto de Estruturas de Concreto) e ABNT NBR 12655:2023 (Concreto de Cimento Portland – Preparo, Controle, Recebimento e Aceitação), com foco na extração dos parâmetros prescritivos associados a cada classe de agressividade ambiental. Essa análise foi estendida às normas internacionais Eurocode 2 (EN 1992-1-1:2023), ACI 318-19, BS 8500:2019 e AS 3600:2018, permitindo a construção de um quadro comparativo inédito.

Na segunda etapa, procedeu-se ao levantamento bibliográfico em bases de dados científicas indexadas, incluindo SciELO, Scopus, Web of Science e Google Scholar, com recorte temporal prioritário entre 2016 e 2024. Os descritores utilizados combinaram termos como 'environmental aggressiveness class', 'concrete durability Brazil', 'chloride-induced corrosion', 'carbonation reinforced concrete', 'service life prediction' e seus equivalentes em português. Foram selecionadas publicações de periódicos científicos com revisão por pares, priorizando estudos com dados empíricos originais ou revisões sistemáticas com evidências robustas.

Na terceira etapa, os dados normativos e os achados da literatura foram integrados em uma análise regionalizada das cinco grandes regiões brasileiras. Para cada região, identificaram-se as condições climáticas e ambientais predominante, temperatura média anual, umidade relativa, proximidade do litoral, presença de polos industriais e agentes agressivos predominantes e correlacionaram-se essas condições com as classes de agressividade mais representativas, conforme a tipologia ambiental definida pela NBR 6118:2014 (Projeto de Estruturas de Concreto). Essa correlação foi sistematizada na Tabela 1.

Na quarta etapa, os resultados da análise regional e da comparação normativa internacional foram consolidados em discussão integradora, identificando implicações para o projeto estrutural, lacunas normativas e recomendações para estudos futuros. O artigo reconhece como limitação estrutural o fato de não ter conduzido ensaios laboratoriais nem levantamentos de campo, sendo os resultados integralmente baseados em revisão da literatura e análise documental. Essa limitação circunscreve as conclusões ao plano qualitativo e sugere a necessidade de estudos experimentais futuros que quantifiquem as taxas de degradação por região e validem os padrões de classificação ambiental propostos.

A metodologia empregada tem como contribuição original a sistematização comparativa até então ausente na literatura nacional entre o sistema normativo brasileiro e quatro referências internacionais de alta relevância técnica, aliada à proposta de uma tabela normativa integradora que pode servir de base para revisões futuras da NBR 6118 (Projeto de Estruturas de Concreto).

4. DISTRIBUIÇÃO REGIONAL DA AGRESSIVIDADE AMBIENTAL NO BRASIL

A heterogeneidade territorial brasileira impõe desafios singulares à classificação da agressividade ambiental. A análise integrada dos fatores climáticos, geográficos e de uso do solo permite identificar padrões regionais de exposição que transcendem a mera consulta tabular às normas e demandam uma leitura contextualizada do microambiente de cada obra. A Tabela 1 sintetiza a distribuição qualitativa das classes de agressividade ambiental predominantes em cada região.

Tabela 1 – Distribuição qualitativa das classes de agressividade ambiental (CAA) nas regiões brasileiras

Região	Classe I (Fraca)	Classe II (Moderada)	Classe III (Forte)	Classe IV (Muito Forte)
Norte	Ausente	Baixa	Alta	Média
Nordeste	Ausente	Baixa	Média	Alta
Centro-Oeste	Alta	Média	Média	Ausente
Sudeste	Baixa	Baixa	Alta	Média
Sul	Baixa	Média	Baixa	Ausente

Fonte: Elaboração própria, com base na ABNT NBR 6118:2014, ABNT NBR 12655:2023 e revisão da literatura.

4.1 Região Norte

Os grandes centros urbanos da Região Norte, como Manaus e Belém, apresentam condições ambientais que enquadram a maioria das estruturas externas nas classes III e IV. A umidade relativa do ar frequentemente supera 80%, as temperaturas médias anuais oscilam entre 26°C e 28°C, e a presença de águas naturais com potencial agressivo, incluindo águas ácidas de igarapés e rios de água preta com pH entre 4 e 5, cria um cenário de degradação acelerada. Esses fatores combinados favorecem a carbonatação e o ataque biogênico da matriz cimentícia, com formação de ácidos orgânicos e inorgânicos por ação microbiológica em ambientes de esgoto e drenagem. Estruturas industriais e de infraestrutura portuária estão sujeitas ainda à ação simultânea de sulfatos e cloretos, caracterizando Classe IV.

4.2 Região Nordeste

A Região Nordeste concentra o maior percentual de estruturas enquadradas na Classe IV no território nacional, em decorrência da extensa linha costeira e da ação intensa de aerossóis marinhos. Capitais como Fortaleza, Recife e Salvador apresentam concentrações de cloretos na atmosfera que chegam a ser dezenas de vezes superiores às registradas em zonas continentais. Em ambientes de até 1 km da orla marítima, o transporte de partículas de sal pelo vento carregador de brisa marinha promove a deposição de cloretos sobre superfícies de concreto, acelerando drasticamente o processo de iniciação da corrosão das armaduras. O estudo de Li et al. (2024) registrou, em edificações costeiras de países tropicais com exposição superior a 40 anos, concentrações de cloreto que excederam em mais de três vezes o limite crítico estabelecido pela norma ACI 318, resultando em fissuração severa do cobrimento. No interior do Nordeste, ambientes semiáridos e solos com elevado teor de sulfatos caracterizam predominantemente as classes II e III.

4.3 Região Centro-Oeste

A Região Centro-Oeste, marcada por regime climático de savana tropical com alternância entre estação seca e chuvosa, apresenta padrão de agressividade predominantemente situado nas classes II e III. Em Brasília, Goiânia e Cuiabá, a baixa umidade relativa na estação seca que pode cair abaixo de 20% em Brasília favorece a fissuração térmica e retração do concreto, fragilizando a barreira física de proteção das armaduras. Na estação chuvosa, os ciclos de molhagem e secagem promovem transporte de íons e carbonatação acelerada. A crescente pressão industrial em alguns polos, como o agronegócio em Mato Grosso, introduz agentes agressivos adicionais que podem elevar localmente a classificação para Classe III.

4.4 Região Sudeste

A Região Sudeste apresenta a maior variabilidade de condições ambientais do país, refletindo sua diversidade geográfica e o intenso processo de urbanização e industrialização. Em São Paulo, a combinação de elevada concentração de CO_2 e poluentes urbanos com umidade moderada resulta em taxas de carbonatação superiores às previstas para ambientes rurais de mesma classe normativa, enquadrando zonas densamente urbanizadas efetivamente na Classe III. No litoral paulista e fluminense, a influência marinha eleva sistematicamente a agressividade para a Classe IV. Belo Horizonte e o Vale do Aço concentram ambientes industriais de alta agressividade, com emissões de SO_2 e outros compostos que potencializam os mecanismos de corrosão. O estudo de Dominicini e Calmon (2017), aplicado às cidades de Vitória (ES) e Florianópolis (SC), demonstrou que a vida útil de estruturas com cobrimento mínimo normativo em ambientes de Classe III costeira pode ser inferior a 20 anos sem adoção de medidas de proteção complementares.

4.5 Região Sul

A Região Sul caracteriza-se por clima subtropical úmido, com invernos frios e verões quentes, e apresenta agressividade predominantemente nas classes II e III. O litoral gaúcho e catarinense, com destaque para Florianópolis e região dos Açores, está sujeito à ação marinha intensa, demandando a aplicação rigorosa dos critérios da Classe III ou mesmo IV em determinados microambientes costeiros. Em áreas continentais como Curitiba e Porto Alegre, os ciclos de molhagem e secagem associados a névoas ácidas em período de inversão térmica elevam localmente o risco de carbonatação. A ausência de ciclos de gelo-degelo na maior parte da região diferencia o Sul brasileiro de países de clima temperado frio, nos quais esse fenômeno constitui mecanismo adicional de degradação a ser normatizado.

5. PARÂMETROS DE PROJETO ASSOCIADOS ÀS CLASSES DE AGRESSIVIDADE

A correta tradução da classificação ambiental em requisitos de projeto é o passo decisivo para garantir a durabilidade estrutural ao longo da vida útil. A Tabela 2 consolida os parâmetros prescritivos estabelecidos pelas normas ABNT NBR 6118:2014 (Projeto de Estruturas de Concreto) e NBR 12655:2023 (Concreto de Cimento Portland – Preparo, Controle, Recebimento e Aceitação) para cada classe de agressividade ambiental, permitindo ao projetista visualizar de forma integrada as exigências que se intensificam progressivamente com o aumento do risco ambiental.

Tabela 2 – Parâmetros de projeto por classe de agressividade ambiental (CAA) segundo ABNT NBR 6118:2014 e ABNT NBR 12655:2023

Parâmetro	CAA I	CAA II	CAA III	CAA IV
fck mín. (MPa)	20	25	30	40
a/c máx.	0,65	0,60	0,55	0,45
Cobrimento nominal — laje (mm)	20	25	35	45
Cobrimento nominal — viga/pilar (mm)	25	30	40	50
Controle tecnológico	Simples	Padrão	Rigoroso	Especial

Fonte: ABNT NBR 6118:2014; ABNT NBR 12655:2023.

O cobrimento nominal é o parâmetro de maior impacto direto na durabilidade, pois representa a principal barreira física à penetração de agentes agressivos. Estudos de Cascudo e colaboradores demonstram que a variabilidade construtiva do cobrimento, frequentemente resultando em valores 20% a 30% inferiores ao especificado, é um dos principais vetores de deterioração prematura. Mumberger et al. (2022) demonstraram que, para vidas úteis de 100 anos em ambientes de Classe II, o cobrimento nominal deveria ser elevado para valores próximos aos exigidos pela norma australiana AS 3600:2018 para 60 anos, sinalizando que os requisitos da NBR 6118 estão calibrados para um horizonte temporal de 50 anos e podem ser insuficientes em projetos de maior longevidade.

A relação água/cimento atua diretamente sobre a porosidade e a permeabilidade do concreto. A redução de 0,65 (Classe I) para 0,45 (Classe IV) representa um salto qualitativo na compacidade da matriz cimentícia, com impactos significativos na resistência à penetração de cloretos e na taxa de carbonatação.

Em ambientes de Classe IV, o emprego de adições minerais como a sílica ativa, a cinza volante e a escória de alto-forno é fortemente recomendado tanto pela literatura técnica quanto pelos documentos de referência do IBRACON, pois essas adições refinam a estrutura dos poros e reduzem a permeabilidade a níveis impossíveis de alcançar apenas com o controle da relação água/cimento.

6. MANIFESTAÇÕES PATOLÓGICAS ASSOCIADAS ÀS CLASSES DE AGRESSIVIDADE

As manifestações patológicas observadas em estruturas de concreto armado apresentam correlação direta com a classe de agressividade do ambiente de exposição. Em ambientes de Classe I, a deterioração tende a ser lenta e confinada a processos de carbonatação superficial, fissuras de retração plástica e eflorescências ocasionais, em geral sem implicações estruturais relevantes nos primeiros ciclos de vida da edificação. A progressão para a Classe II introduz o risco de carbonatação progressiva com redução do pH da solução dos poros ao longo do tempo, favorecendo o início da corrosão das armaduras em elementos com cobrimento insuficiente ou de baixa qualidade.

A Classe III é caracterizada por manifestações mais severas: corrosão generalizada das armaduras com destacamento do cobrimento e manchas de ferrugem na superfície do concreto, ataque por sulfatos em fundações e estruturas enterradas em solos agressivos, e fissuração por expansão das barras corroídas. A Classe IV representa o estágio de maior vulnerabilidade, com corrosão acelerada por íons cloreto, perda de seção transversal das armaduras, desagregação do concreto e, em casos extremos, colapso localizado de elementos estruturais. Estruturas em zonas de respingo marinho classificadas na Classe IV apresentam as

taxas mais severas de deterioração, pois combinam a ação simultânea de ciclos de molhagem e secagem com alta concentração de cloretos.

A literatura internacional consolidada, referenciada por Mehta e Monteiro (2014) e Neville (2016), reforça que o modelo de Tutti, ao separar as fases de iniciação e propagação da corrosão, é essencial para compreender por que estruturas em ambientes de alta agressividade que atingem o fim da fase de iniciação em poucos anos frequentemente menos de 10 anos em zonas de respingo marinho sem proteção adicional progridem rapidamente para deterioração avançada na fase de propagação.

7. COMPARAÇÃO NORMATIVA INTERNACIONAL

A análise comparativa entre a normatização brasileira e as principais referências internacionais revela tanto alinhamentos técnicos quanto diferenças metodológicas relevantes. A Tabela 3 apresenta, de forma inédita, um quadro sinóptico comparativo entre as normas ABNT NBR 6118:2014 (Projeto de Estruturas de Concreto), Eurocode 2 (EN 1992-1-1:2023), ACI 318-19, BS 8500:2019 e AS 3600:2018, abrangendo os aspectos mais relevantes para a classificação da agressividade e o dimensionamento da durabilidade.

Tabela 3 – Comparação normativa internacional: classes de exposição e requisitos de durabilidade para concreto armado

Aspecto	NBR 6118:2014 (Brasil)	Eurocode 2 EN 1992-1-1:2023	ACI 318-19 (EUA)	BS 8500:2019 (Reino Unido)	AS 3600:2018 (Austrália)
N° de classes de exposição	4 (I a IV)	6 grupos (XC, XD, XS, XF, XA, X0)	4 categorias (F, W, S, C)	6 grupos alinhados ao Eurocode	4 (A1–A4) + subclasses
Abordagem metodológica	Prescritiva	Baseada em desempenho	Prescritiva/desempenho	Baseada em desempenho	Prescritiva/desempenho
Cobrimento nominal max. (mm)	50 (CAA IV)	55 (XS3)	75 (estruturas enterradas)	60 (XS3/RC80)	65 (A4)
a/c mínimo (ambiente marinho)	0,45	0,40–0,45 (XS3)	0,40 (C2)	0,40 (XS3)	0,40 (A4)
Vida útil de projeto prevista	50 anos (padrão)	50 ou 100 anos	Não especificado	50 ou 100 anos	50 ou 100 anos (AS)
Modelos de previsão de vida útil	Não normatizados	fib Model Code 2020	Não normatizados	Informativo (BS PD 6349)	Durability design provisions

Fontes: ABNT NBR 6118:2014; EN 1992-1-1:2023; ACI 318-19; BS 8500:2019; AS 3600:2018; Mumberger et al. (2022); Hasan et al. (2025).

A distinção metodológica mais relevante entre a normatização brasileira e as referências europeias reside na abordagem ao dimensionamento para durabilidade. Enquanto o Eurocode 2 e a BS 8500:2019 adotam uma perspectiva baseada em desempenho, articulada com os modelos probabilísticos do fib Model Code 2020, a NBR 6118:2014 (Projeto de Estruturas de Concreto) mantém uma abordagem essencialmente prescritiva. Hasan et al. (2025), em análise comparativa estatística entre ACI 318-19 e EN 1992-1-1:2023, demonstraram que o Eurocode prescreve cobrimentos nominais médios 9,6% superiores aos do ACI para

condições severas de exposição, com as maiores diferenças concentradas em ambientes marinhos, resultado que aponta para maior conservadorismo da norma europeia em ambientes de alta agressividade.

Mumberger et al. (2022) destacam que os parâmetros de durabilidade prescritos pela NBR 6118 (Projeto de Estruturas de Concreto) para as classes I e II são compatíveis com resultados obtidos pela norma australiana AS 3600 para vida útil de 60 anos, mas ficam aquém das exigências da BS 8500 para vidas úteis de 100 anos. Essa constatação é particularmente relevante para o contexto brasileiro de grandes obras de infraestrutura, pontes, túneis, portos que frequentemente demandam vidas úteis de projeto superiores a 50 anos, mas carecem de parâmetros normativos específicos para esse horizonte temporal.

A incorporação de modelos de previsão de vida útil é outro ponto de divergência significativa. O fib Model Code 2020 fornece um arcabouço probabilístico unificado para a previsão do avanço da frente de carbonatação e da penetração de cloretos, parametrizado por dados climáticos e de material. Na normatização brasileira, esses modelos não são normatizados, embora existam estudos nacionais relevantes como os de Possan (2010) e as análises de Dominicini e Calmon (2017) para Vitória e Florianópolis que demonstram a viabilidade de sua aplicação ao contexto tropical brasileiro.

8. IMPLICAÇÕES NO PROJETO ESTRUTURAL E NA GESTÃO DO CICLO DE VIDA

O impacto da classe de agressividade no projeto estrutural vai muito além da consulta às tabelas normativas de cobrimento e resistência mínima. A correta classificação ambiental deve ser entendida como uma decisão estratégica que permeia todas as fases do ciclo de vida da estrutura, desde a concepção até a manutenção preventiva e a eventual intervenção de reparo ou reforço.

Na fase de projeto, a agressividade ambiental determina a escolha do sistema estrutural, dos materiais, dos detalhes construtivos e das especificações de durabilidade. Projetos em ambientes de classes III e IV demandam o emprego de concretos de alto desempenho com adições minerais ativas, a adoção de cobrimentos nominais superiores aos mínimos normativos, o emprego de aditivos inibidores de corrosão em situações de risco extremo e o detalhamento cuidadoso de geometrias que evitem o acúmulo de água e a umidade superficial prolongada. A escolha do cimento em particular, a utilização de cimentos resistentes a sulfatos (RS) em solos agressivos e de cimentos com escória (CPIII) ou pozolânico (CPIV) em ambientes com cloretos tem impacto determinante na permeabilidade e na resistência química do concreto.

Na fase de execução, a garantia do cobrimento nominal especificado em projeto é imperativa. Estudos revisados neste trabalho indicam que desvios de cobrimento da ordem de 20% a 30% abaixo do valor especificado podem reduzir a vida útil de iniciação da corrosão à metade do previsto em projeto, comprometendo de forma irreversível a durabilidade da estrutura antes mesmo do fim da fase de construção. O controle rigoroso da relação água/cimento, a cura adequada por período mínimo de sete dias em ambientes de alta agressividade e a inspeção do cobrimento durante a concretagem são medidas indispensáveis.

Na fase de uso e manutenção, a implantação de planos de inspeção periódica baseados em risco com frequência e escopo determinados pela classe de agressividade ambiental permite a detecção precoce de manifestações patológicas e a intervenção em fase de iniciação da corrosão, quando os custos de reparo são substancialmente inferiores aos das intervenções estruturais avançadas. A relação de Sitter, popularizada por Helene, estabelece que os custos de reparo crescem na razão de 1:5:25:125 conforme se passa das fases de projeto, execução, detecção e intervenção tardia, respectivamente, argumento econômico poderoso para o investimento em classificação ambiental rigorosa desde a concepção.

9. DISCUSSÃO

Os resultados desta pesquisa evidenciam que a correta classificação da agressividade ambiental no contexto brasileiro requer uma abordagem significativamente mais refinada do que a simples consulta às tabelas normativas da NBR 6118:2014 (Projeto de Estruturas de Concreto). A análise regionalizada demonstrou que ambientes urbanos, frequentemente enquadrados na Classe II por critério genérico,

podem apresentar condições de microambiente elevada concentração de CO_2, presença de SO_2 e NO_x, ciclos intensos de molhagem e secagem que os aproximam, na prática, dos requisitos da Classe III. Essa subestimação sistemática do risco pode resultar em especificações de projeto insuficientes e em deterioração prematura de estruturas concebidas para vida útil de 50 anos.

A comparação normativa internacional revelou que o sistema brasileiro apresenta cobertura adequada para o horizonte de 50 anos em condições de agressividade moderada, mas carece de parâmetros específicos para vidas úteis prolongadas de 75 a 100 anos, e, para microambientes de alta agressividade em regiões tropicais úmidas. A introdução de classes de exposição mais granulares, alinhadas à lógica dos grupos de exposição do Eurocode 2 (XC, XD, XS, XF, XA), poderia aprimorar a capacidade do sistema normativo brasileiro de capturar a complexidade dos ambientes tropicais, nos quais a combinação simultânea de alta temperatura, alta umidade e agentes agressivos múltiplos cria sinergias não previstas pelos modelos de deterioração calibrados para climas temperados.

A incorporação de modelos probabilísticos de previsão de vida útil como os calibrados por Mumberger et al. (2022) e os desenvolvidos por Possan (2010) para o contexto brasileiro representa a principal oportunidade de evolução normativa. Esses modelos permitem ao projetista estimar, com base em dados climáticos regionais e parâmetros de material, a probabilidade de corrosão em um dado horizonte temporal, superando as limitações da abordagem prescritiva e habilitando decisões de projeto mais fundamentadas e economicamente eficientes.

Quanto às limitações desta pesquisa, registra-se que a ausência de dados experimentais próprios e de levantamentos de campo limita as conclusões ao plano qualitativo. A classificação regional proposta baseia-se em revisão da literatura e análise normativa, sem validação por meio de medições in situ de concentrações de agentes agressivos ou de taxas de carbonatação em diferentes regiões. Estudos futuros que integrem redes de monitoramento ambiental, ensaios de durabilidade em campo e análise estatística de bancos de dados de patologias estruturais poderão fornecer evidências quantitativas para embasar revisões das normas brasileiras e calibrar modelos de previsão de vida útil adaptados ao contexto tropical.

10. CONCLUSÕES

Este artigo investigou as classes de agressividade ambiental do concreto armado no Brasil, integrando revisão normativa, análise regional e comparação internacional para propor uma visão abrangente e atualizada do tema. As principais conclusões são:

A diversidade climática e ambiental brasileira exige uma abordagem regionalizada da classificação da agressividade, sendo insuficiente a aplicação genérica das classes normativas sem consideração das condições microambientais locais. Ambientes costeiros e industrializados concentram a maior incidência de estruturas em Classes III e IV, com especial criticidade nas regiões Norte e Nordeste.

Os parâmetros de projeto prescritos pelas normas ABNT NBR 6118:2014 (Projeto de Estruturas de Concreto) e NBR 12655:2023 (Concreto de Cimento Portland – Preparo, Controle, Recebimento e Aceitação) são tecnicamente consistentes para o horizonte de 50 anos, mas carecem de valores específicos para vidas úteis prolongadas, lacuna que pode ser suprida pela incorporação de modelos probabilísticos de previsão de vida útil calibrados para o clima tropical brasileiro.

A comparação normativa internacional demonstrou que o Eurocode 2, a BS 8500:2019 e a AS 3600:2018 adotam abordagens baseadas em desempenho que oferecem maior granularidade na classificação dos ambientes e maior cobertura para horizontes temporais superiores a 50 anos. A adoção parcial desses instrumentos em especial os modelos do fib Model Code 2020 pode representar uma evolução significativa na normatização brasileira de durabilidade.

Como contribuição original, este trabalho propõe a primeira tabela comparativa normativa integrando cinco referências nacionais e internacionais (NBR 6118, Eurocode 2, ACI 318, BS 8500 e AS 3600), e apresenta uma distribuição qualitativa revisada e expandida das classes de agressividade ambiental nas regiões brasileiras, incorporando a Classe I à análise e distinguindo os contextos costeiro, urbano e industrial dentro de cada região.

Estudos futuros deverão avançar na direção de validação experimental das classificações propostas, por meio de campanhas de monitoramento ambiental em múltiplas regiões, ensaios de durabilidade em estruturas existentes e desenvolvimento de mapas de agressividade ambiental de maior resolução territorial para o Brasil.

Abstract: Interlocking pavers are widely used on urban roads and in areas with light to moderate traffic due to their ease of installation, localized maintenance, and aesthetic and environmental benefits. However, over their service life, these pavements are susceptible to various defects, such as damaged pavers, rutting, heave, and pumping, which may compromise their structural performance. In this context, deflection measurements are used to evaluate the pavement's bearing capacity and its response to applied loads. Therefore, this study aims to assess whether surface defects influence the deflection values of interlocking pavements by examining the correlation between these variables. An in situ survey was conducted, including defect identification and classification using the Pavement Condition Index (PCI), along with deflection measurements collected on an experimental interlocking pavement section subdivided into five segments with distinct structural configurations. Pearson's correlation coefficient (r) was applied to evaluate the relationships between the analyzed variables. The results indicate an association between deflection values and defects such as rutting, excessive joint spacing, and loss of jointing material. A negative correlation was also observed between deflection and PCI, suggesting that poorer surface conditions are associated with increased structural deformability. These findings demonstrate that integrating functional and structural indicators enhances the understanding of interlocking pavement performance and the interaction between surface defects and load-bearing capacity.

Keywords: Defects; Deflection; Correlation; PCI; FWD.

1. Introduction

Interlocking pavements have been increasingly adopted in urban roads, residential areas, and industrial zones due to their durability and construction versatility (Di Mascio et al. 2019). This solution represents an alternative to conventional asphalt pavements, particularly in regions subjected to extreme climatic conditions and heavy traffic (Rathan & Sunitha, 2021).

Unlike asphalt pavements, interlocking pavements function as an integrated system in which load transfer occurs through the interlock between individual blocks. Their structural stability is ensured by friction within sand-filled joints, which minimizes rotation and displacement of the units. Consequently, interlocking pavements should be analyzed as multilayer systems, where mechanical behavior depends on the interaction between the surface layer, bedding sand, and underlying layers (Lin et al. 2016).

The mechanical performance of this type of pavement is influenced by the laying pattern. Among the available configurations, the herringbone pattern provides better stress distribution and greater resistance to permanent deformation compared to stretcher bond patterns (Lin et al. 2018). Additionally, block

thickness significantly affects structural behavior, influencing both service life and surface deflection control. These parameters are therefore essential for structural evaluation (Di Mascio et al. 2019).

Functional evaluation is typically performed using the Pavement Condition Index (PCI) (Hein et al., 2009), which enables standardized identification of defects such as damaged pavers, depressions, and excessive joint width, providing an overall condition rating (Zoccali et al. 2017). The systematic application of PCI supports performance prediction and decision-making regarding maintenance and rehabilitation (M&R) (Hein et al. 2009).

Despite advances in visual assessment standardization and deflection monitoring (Lin et al. 2016), there remains a need to better understand how surface defects correlate with structural response measured in the field (Singh et al. 2012). Integrating these approaches is essential for optimizing M&R strategies while ensuring user comfort and safety.

Given the above, this study aims to evaluate whether surface defects affect the deflection values of interlocking pavements, based on the correlation between these variables. The study in question was conducted on an experimental section, specifically constructed for research purposes, consisting of different sections with variations in layer materials and low traffic volume. Thus, the results obtained have limitations due to the short length evaluated, which may influence the observed structural response.

2. Literature Review

Interlocking pavements exhibit structural behavior governed by load transfer between blocks, joint friction, and lateral confinement provided by adjacent layers (Panda & Ghosh, 2002). Unlike continuous asphalt pavements, they behave as segmented systems whose equivalent stiffness depends on joint integrity, jointing material quality, and base/subbase conditions (Füssl et al. 2016).

When properly constructed, interlocking pavements can achieve structural performance comparable to asphalt pavements, with efficient stress distribution and controlled vertical deformation (García and Corte, 2021). Instrumented field tests show that stresses transmitted to lower layers depend primarily on the stiffness of the block layer and base (Khanal et al. 2013).

The geometry of paving units and laying patterns, such as the 45° herringbone, also influence resistance to horizontal displacement (Hengl et al. 2018). Furthermore, permeable interlocking pavements have demonstrated effectiveness in reducing runoff while maintaining structural stability under light to moderate traffic (Rathan et al. 2021).

Structural evaluation is essential for understanding the behavior and performance of pavement layers. The use of equipment such as the Heavy Weight Deflectometer (HWD) and the Benkelman Beam enables the measurement of surface deflections, supporting model calibration and the validation of block layer stiffness as a function of its thickness (García and Corte, 2021). In addition, strain and pressure sensors embedded within the structure can continuously monitor the effects of heavy vehicles, enabling load pulses to be correlated with the in situ mechanical response (Khanal et al. 2013; Jones et al. 2016).

One of the primary objectives of functional evaluation, combined with appropriate maintenance practices, is to maximize return on investment while ensuring safe, comfortable, and operational road conditions for users (Fernandes Júnior et al. 1996). Studies adopting integrated approaches indicate that different condition indices, such as the Pavement Condition Index (PCI) and the International Roughness Index (IRI), may yield different classifications for the same road section. In this context, the PCI has been identified as more representative for capturing the specific characteristics of defects in interlocking pavements (Sousa et al. 2024).

These differences are related to the inherent characteristics of this pavement type. The deterioration of interlocking pavements is associated with a reduced ability to transfer forces between blocks, leading to a decrease in the stiffness of the wearing course. Among the main factors contributing to this process are

joint-related defects, particularly the loss of jointing sand, which can reduce pavement service life by up to five years (Bezerra and Oliveira, 2022). In areas subjected to heavy traffic, braking and acceleration further intensify relative displacements between blocks and promote edge breakage when horizontal interlocking is insufficient (Hengl et al. 2018).

It is therefore evident that research correlating field-observed defects with in situ deflection parameters in interlocking pavements remains limited (García and Corte, 2021; Singh et al., 2012). This gap highlights the need for integrated studies that relate functional and structural conditions to better understand whether surface defects influence deflection values and, consequently, the assessment of the structural capacity of interlocking pavements.

3. Methodology

The research methodology was structured in six stages: (i) selection of the study site; (ii) application of the PCI and FWD tests; (iii) tabulation of the data collected in the field; (iv) statistical analysis of the data; (v) preparation of graphs, tables, and figures; and (vi) presentation and interpretation of the results.

The first stage consisted of defining the test section of the interlocking pavement. The section was specifically designed for research purposes, with each segment constructed using different materials in its structural layers. The total area was 175 m² (25 m long × 7 m wide), located at the Pici Campus of the Federal University of Ceará (UFC), in Fortaleza, Brazil (Figure 1).

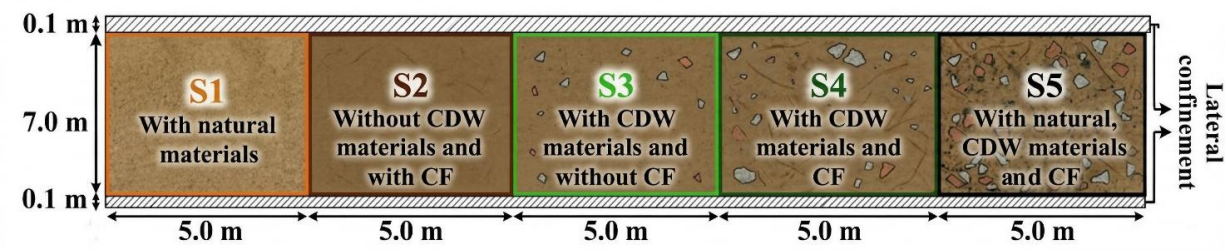

Figure 1 – Experimental concrete interlocking block pavement's sections

The section was divided into five equal experimental segments (S1 to S5), in which natural materials and by-products derived from construction and demolition waste (CDW) were used, along with the incorporation of coconut fibers (CF). The adopted layer thicknesses were 15 cm for the base and subbase, and 0.5 cm, 4.0 cm, and 8.0 cm for the jointing material, bedding layer, and paving blocks, respectively, in accordance with ABNT (2013).

In the second stage, PCI values were determined, ranging from 0 to 100, where 0 represents functional failure and 100 indicates good condition. Defect density and deduction values were also calculated in accordance with ASTM (2024). The entire experimental section was evaluated, covering all five segments, thereby eliminating the need for statistical sampling. Deflections were measured using a Falling Weight Deflectometer (FWD), in accordance with DNER (1996). In the third stage, following field data collection, the results were tabulated in a spreadsheet. In the fourth stage, the dataset was exported to R (version 4.4.0) and analyzed in RStudio. For each pavement section, FWD data were statistically analyzed using Student's t-distribution at a 95% confidence level. Subsequently, Pearson's correlation coefficient was calculated based on defect data and PCI values for each section.

In the fifth stage, graphs and figures were generated in RStudio to visually compare the results and support the interpretation of the functional condition of the interlocking pavement. Finally, in the sixth stage, the results were presented and discussed, enabling an assessment of the performance of the evaluated pavement.

4. Results and Discussions

The PCI graph by section illustrates the variability in functional performance along the evaluated stretch (Figure 2). It presents the PCI value for each sample unit.

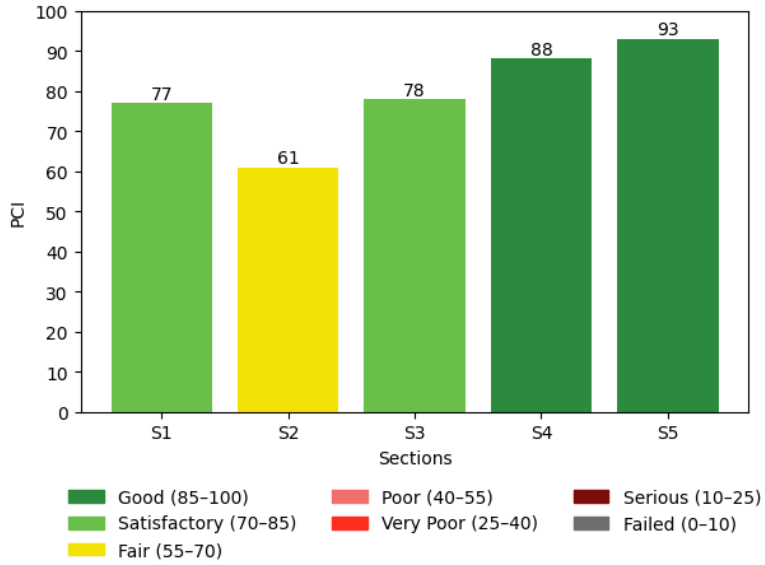

Figure 2 – PCI by Section

The PCI values range from 61 to 93, indicating a functional condition from satisfactory to good, except for Section 2, which is classified as fair. Sections 4 and 5 exhibited the highest indices, suggesting better functional integrity in these stretches. This variation in PCI reflects non-homogeneous pavement behavior, possibly due to differences in materials used across the sections (recycled materials from CDW and CF). Figure 3 relates each section to its respective deduction values and highlights the influence of defect types on the pavement's functional performance.

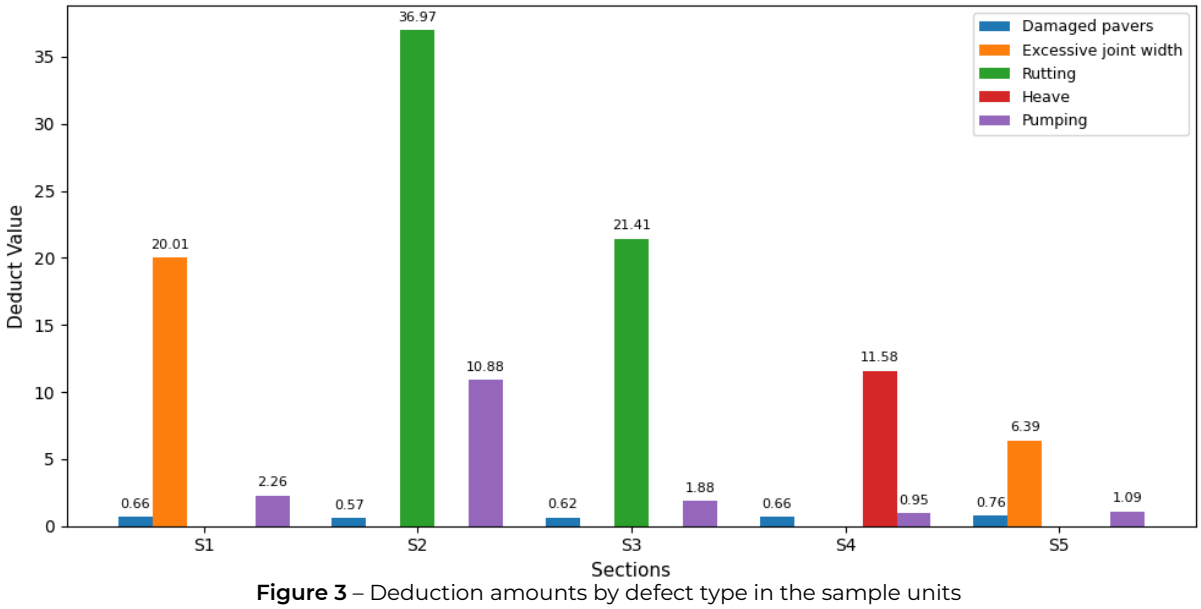

Figure 3 – Deduction amounts by defect type in the sample units

Section 2 exhibits the highest deduction values, primarily due to rutting, which explains its lower PCI compared to the other sections. In general, defects associated with structural deformations have a greater

impact, whereas surface defects, such as damaged pavers, contribute less to index reduction, according to ASTM (2024) tables. Figure 3 also shows that sections with lower deduction values correspond to better functional condition, reinforcing the inverse relationship between the severity and quantity of defects and the performance of the evaluated pavement. The deflection results obtained from the FWD are presented in Table 1.

Table 1 – Statistical Analysis (Deflections)

Round	Deflection (µm)				
	S1	S2	S3	S4	S5
1	461	449	342	445	340
2	415	398	334	396	319
3	423	406	343	406	324
4	412	393	333	394	318
5	425	403	344	399	315
6	416	392	338	388	310
Mean	425	407	339	405	321
Standard Deviation (sd)	18	21	5	21	10
Number of samples	6	6	6	6	6
Value t	2,02	2,02	2,02	2,02	2,02
Characteristic Deflection (µm)	440	424	343	422	330

The largest characteristic deflection was recorded in Section 1, with a value of 440 µm, corresponding to the section with the second-lowest PCI of 77. In contrast, the smallest characteristic deflection was observed in Sample Unit 05, at 330 µm, which had the highest PCI of 93. Thus, the deflection values varied by 110 µm across the analyzed sections. It is also noteworthy that Section 2, which exhibited the lowest PCI, had the second-highest characteristic deflection. Overall, a trend of increasing deflection with decreasing PCI is evident.

Among the analyzed parameters, rutting exhibited the lowest correlation with deflection values (Table 2), with a coefficient of -0.10. However, this result does not align with the expected theoretical behavior, since rutting accumulation is normally associated with a loss of pavement structural capacity, as reported by Bezerra and Oliveira (2022). Therefore, greater rutting would be expected to correspond to higher deflection values, as both variables indicate the progression of pavement deterioration.

Table 2 – Deflection Values vs. Rutting

Deflection × Rutting		
Section	Deflection (µm)	Density (%)
1	440	0
2	424	6
3	343	5,29
4	422	0
5	330	0

The discrepancy between the observed results and the expected behavior may be primarily attributed to the small sample size, consisting of only five observations. This limitation reduces the statistical reliability of the analyses and increases the sensitivity of the correlation coefficient to potential outliers. From a mechanical-structural perspective, rutting represents one of the most significant defects in interlocking pavements. This type of deterioration can cause block displacement and joint opening, reducing lateral friction between the blocks and compromising the interlocking mechanism responsible for proper load distribution within the pavement structure (Bezerra and Oliveira, 2022). Similarly, damaged pavers exhibited a negative correlation of -0.53 with deflections (Table 3).

Table 3 – Deflection Values vs. Damaged Pavers

Deflection × Damaged Pavers		
Section	**Deflection (µm)**	**Density (%)**
1	440	0,54
2	424	0,40
3	343	0,49
4	422	0,54
5	330	0,69

One possible explanation for this result is the low proportion of damaged pavers in the analyzed sample, which diminishes their influence on deflection values compared to other variables. In interlocking pavements, structural performance primarily depends on the transfer of forces between adjacent elements. Therefore, the isolated presence of damaged pavers may be partially offset by the collective behavior of the surrounding elements, reducing the impact of this defect when considered in isolation. Conversely, defects such as heave, excessive joint width, and pumping of jointing material exhibited a positive correlation with deflection values, with coefficients of 0.36, 0.39, and 0.37, respectively (Table 4).

Table 4 – Deflection × Heave × Excessive Joint Width × Pumping

Section	**Deflection (µm)**	**Heave**	**Excessive Joint Width**	**Pumping**
		Density (%)		
1	440	0	17,14	30,86
2	424	12,86	0	31,43
3	343	0	0	26,06
4	422	0	0	10,03
5	330	0	4,29	11,43

An increase in the density of these defects tends to compromise force transfer between panels in the joint regions, reducing the interlocking level of the pavement and increasing the deformability of the structural system, which can result in higher deflection values. However, the moderate correlation strengths indicate that, when analyzed individually, these defects are insufficient to fully explain the variation in observed deflections, suggesting the presence of interactions among multiple factors influencing the pavement's structural performance.

Regarding the PCI, a negative correlation of -0.49 was observed with deflection values (Table 5). This inverse relationship aligns with expected behavior, as lower PCI values indicate poorer pavement surface condition, which may lead to reduced structural stiffness and, consequently, higher deflection values. Furthermore, since the PCI calculation combines multiple defects into a single condition indicator, it provides a more comprehensive representation of the pavement's overall condition, simultaneously accounting for various factors that influence its performance.

Table 5 – Deflection vs. PCI

Deflection × PCI		
Section	**Deflection (μm)**	**PCI**
1	440	77
2	424	61
3	343	78
4	422	88
5	330	93

Finally, it should be noted that the results reflect the specific behavior of the analyzed section; the correlation coefficients cannot be generalized to interlocking pavements in a broader context. The small sample size also limits the precise identification of factors influencing deflection values. Despite this limitation, the analysis allowed the identification of trends between surface defects and the pavement's structural response, contributing to the understanding of this pavement type under real-world field conditions. In small samples, Pearson's correlation coefficient is sensitive to extreme values, so the behavior of a single section can affect the analysis results. Nevertheless, the observed trends provide a foundation for future studies with larger datasets, also incorporating aspects related to ride comfort and user safety.

5. Conclusions

This article analyzed the relationship between defects and the structural response of an interlocking pavement by examining the correlation between Pavement Condition Index (PCI) results and deflection values obtained from the Falling Weight Deflectometer (FWD) test. Despite the limitations presented, the results indicated that some defects, such as heave, excessive joint width, and pumping, showed a positive correlation with deflection values, suggesting that an increase in the occurrence of these defects may contribute to reduced stiffness and greater deformability of the pavement.

On the other hand, defects such as rutting and damaged pavers showed negative correlations, a behavior that may be related to the small sample size and the influence of specific characteristics of the evaluated sections. The analysis also revealed a negative correlation between PCI and deflection values, indicating that poorer pavement functional condition corresponds to greater deformations under load. The importance of functional evaluation as a complementary tool for understanding the structural performance of interlocking pavements is evident. In future studies, incorporating the International Roughness Index (IRI) into interlocking pavements could broaden the functional analysis and allow for an assessment of the relationship between ride comfort and the defects identified in the pavement.

In general, an integrated analysis of functional and structural parameters can provide a more comprehensive assessment of interlocking pavement performance. Although the correlation coefficients obtained cannot be generalized due to the limited number of observations, the identified trends offer

relevant insights into the interaction between surface defects and structural response in interlocking pavements.

Abstract: In Fortaleza, the capital of Ceará, a significant process of tourism urbanization is underway due to the state's substantial involvement and intervention through: i) ideological frameworks aimed at enhancing the city's image and integrating Fortaleza and Ceará into global economic flows, albeit in a peripheral manner; ii) public tourism policies and urban policies at the federal, state, and municipal levels; iii) and socio-spatial interventions in infrastructure and the construction of large urban projects geared toward tourism. Among these interventions, the creation of the Sabiaguaba Environmental and Gastronomic Complex stands out; it is located within a conservation area at the mouth of the Cocó River. In this context, the objective of this study is to investigate the socio-spatial impacts of the infrastructure and architecture of the Sabiaguaba Environmental and Gastronomic Complex, inaugurated in 2022, in Fortaleza, Ceará. The methodology is grounded in theoretical assumptions related to the concept of tourism urbanization, a phenomenon driven by leisure and consumption; and in practical assumptions, through the use of digital technologies. A practical reality-capture device was adopted through surveys using an Unmanned Aerial Vehicle (UAV) to obtain photos and footage, the information from which was georeferenced. Based on this data, a digital model of the complex was developed using the BIM (Building Information Modeling) platform, enabling a detailed spatial analysis of the project's integration into the local ecosystem. The results demonstrate that the infrastructure, although technically sound, promotes tourism-driven urbanization that leads to tourism gentrification, environmental degradation, and socio-spatial fragmentation and segregation. Finally, the relevance of this work lies in the importance of using digital technologies to produce and generate information on the socio-spatial impacts of tourism-driven urbanization along the Fortaleza coast, thereby contributing to the development of public policies in the areas of tourism, urban planning, and the environment.

Keywords: Tourism Gentrification, Urban Projects, Socio-spatial Fragmentation, Unequal Urbanization, Digital Modeling.

1. Introduction

The Sabiaguaba region, located at the easternmost tip of the coastline of Fortaleza, the capital of the state of Ceará, is characterized by extreme geomorphological and environmental complexity. Consequently, sensitive natural systems, such as fields of shifting and fixed dunes, mangroves, and paleodunes, coexist with the structures and infrastructure resulting from the urban expansion of the capital of Ceará. Historically, these environmental constraints established the parameters for low-impact, low-density human occupation, characterized by spontaneous settlements marked by predominantly vernacular architectural styles that were better suited to the estuary's hydrodynamics, the wind dynamics of the dunes, and the local flora and fauna, maintaining a relative conservation of the ecosystem (Souza et al., 2011). The institutionalization of Sabiaguaba's protection reached a decisive milestone in 2006 with the enactment of Municipal Decrees No. 11,986 and No. 11,987. These instruments formalized the creation of two Conservation Units (UCs): the Sabiaguaba Dunes Municipal Natural Park (PNMDS), aimed at the comprehensive preservation of fragile ecosystems, and the Sabiaguaba Environmental Protection Area (APA da Sabiaguaba), intended for the planning of sustainable land use (Figure 1). From a legal and urban planning perspective, the existence of these provisions establishes the territory as a natural sanctuary in need of preservation. In this sense, these decrees imposed essential regulatory limits for the protection of vital ecosystem functions, such as microclimatic regulation, flood control, and the protection of estuarine

biodiversity, serving as the primary legal instrument against predatory urbanization initiatives and real estate development and speculation in this coastal strip of Fortaleza.

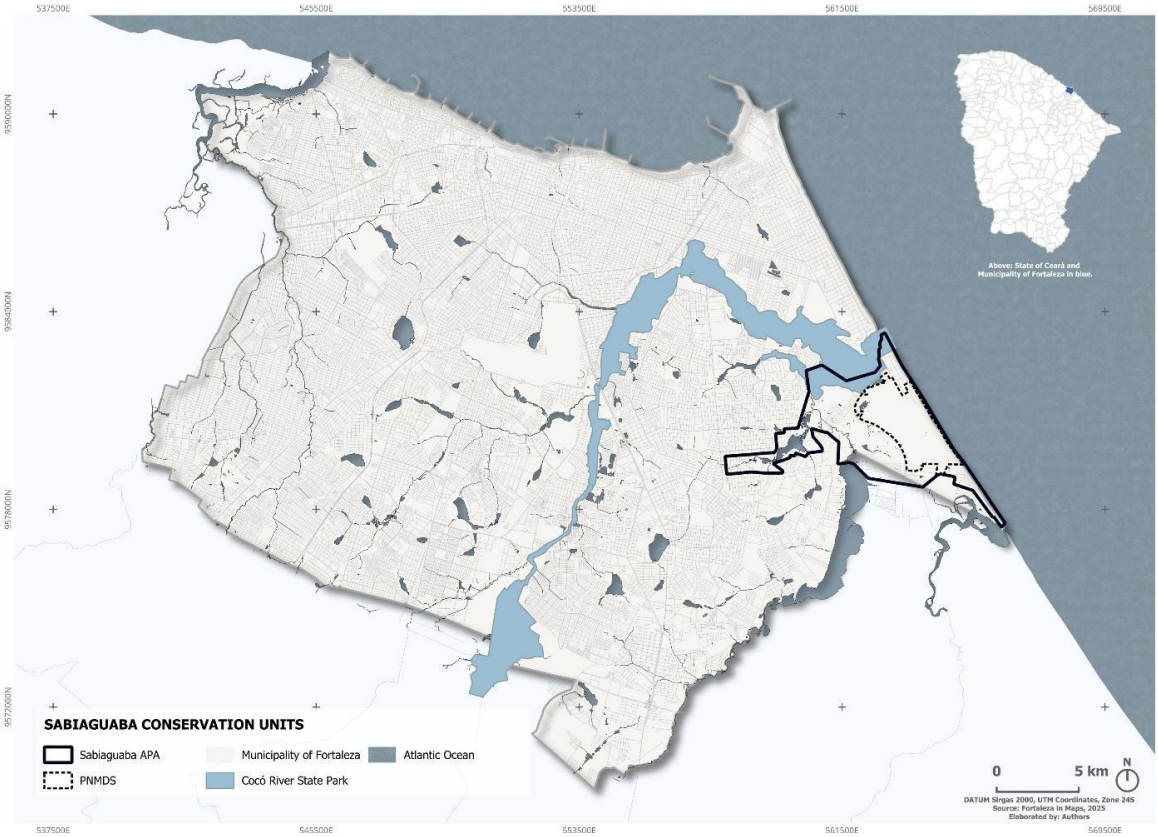

Figure 1 – Geographical location of the Sabiaguaba Conservation Units in the municipality of Fortaleza, Ceará, highlighting the boundaries of the Sabiaguaba Environmental Protection Area (APA) and the Sabiaguaba Dunes Municipal Natural Park (PNMDS). The image allows for a technical assessment of the geographic confinement and spatial friction between the capital's expanding urban fabric and the fragile estuarine ecosystems.
Source: Elaborated by the authors (2026); vectors from the SEFIN-Fortaleza IDE platform; map scale 1:120,000.

However, upon analyzing the historical process, it becomes clear that Sabiaguaba, due in part to the natural barrier of the Cocó River, has transitioned from a state of relative urban isolation to becoming a focal point for real estate and tourism interests in the process of urban spatial development in Fortaleza. As discussed by Paiva (2011), the production of coastal space in Ceará is guided by a dynamic of tourism urbanization that operates by converting the territory's "use value" into real estate "exchange value." This process does not occur naturally, but is induced by the action of the State, which, according to Harvey (2005), acts in the production of space through ideological apparatuses, public policies, and infrastructure. These forms of action materialize in the case under discussion: i) in the mobilization of ideological mechanisms aimed at promoting the urban image and positioning Fortaleza and Ceará within global economic circuits, albeit in a peripheral manner; ii) in the formulation and execution of tourism policies in coordination with urban policies at the federal, state, and municipal levels; iii) in the implementation of socio-spatial interventions manifested in infrastructure and the execution of major urban projects aimed at the enjoyment, consumption, and expansion of tourism. In Sabiaguaba, state actions took the form of large-scale infrastructure projects, notably the bridge over the Cocó River and the CE-010 highway. These transportation infrastructures not only facilitate access to the territory but also function as urban vectors that break down geographical barriers, exposing a fragile ecosystem to the pressure of real estate appreciation and speculation and to the more intense flow of tourism-related activities. It is important to note that the urbanization project for the left bank of the Cocó River, also known as the CE-251 highway project, now consolidated as CE-010, had its environmental licensing process and Environmental Impact Report (EIR)

prepared in 2013; this project constitutes the regulatory framework that anticipated and validated interventions on the left bank of the estuary.

In this regard, according to the assessment by CRZ Projetos (2013), one of the main impacts of the interventions would be a significant increase in tourism demand and the resulting pressure on the ecosystem. In response to this issue, the document highlights the need to relocate local residents and merchants, whose stalls conflicted with the new road layout and new sanitary requirements. Thus, the Sabiaguaba Environmental and Gastronomic Complex (COMAGS) emerges not only as a tourist facility but as the materialization of the relocation solution envisaged in the study, functioning as the technical-legal apparatus that called for some mitigating measures for this problem (Figure 2).

Following this line of thought, the construction of COMAGS in 2022 represented a milestone in this process of induced tourism urbanization; its implementation, within the boundaries of the Sabiaguaba APA, has been the subject of intense controversy and legal battles since its conception (Barros et al., 2024). In this context, the central point of criticism lies in the scale and nature of the intervention: the State introduced a volume of rigid construction (concrete and masonry) into a territory with environmental vulnerabilities. Furthermore, the typological replacement was radical; previously, the area was characterized by the presence of beach huts and thatched huts, ephemeral structures that, although technically simple, were part of the landscape and the communities' ways of appropriating the space. These huts served as subsistence points where the community sold local fish, creating a transitional space where the morphology of the sandy trails dictated land use. By removing these traditional structures to make way for the formal COMAGS project, the intervention severed these socio-spatial ties, creating new ones oriented toward the logic of leisure and tourism consumption (Figure 3).

Figure 2 – A multi-temporal analysis of the Cocó River estuary landscape in 2010, illustrating the pre-intervention scenario before the construction of the CE-010 highway. The image serves as a reference to demonstrate the original morphology, characterized by low-density vernacular beach huts and traditional, spontaneous settlements integrated into the trails.

Based on the project description for the Sabiaguaba Environmental and Gastronomic Complex, prepared by the firm Architectus S/S and published on ArchDaily using material submitted by the project team itself, we observe the construction of a narrative that seeks to legitimize the intervention through the interplay of landscape, community memory, environmental preservation, and tourism promotion. It is, therefore, a situated argument, formulated from the perspective of the project's authors, in which architecture is presented as a sensitive and conciliatory response to the demands of the site. In this narrative, the scenic uniqueness of the confluence of the Cocó River and the sea at Sabiaguaba repeatedly emerges as a structuring element of the design concept, transforming the landscape into the project's primary symbolic asset and the foundation for its integration into Fortaleza's leisure, gastronomy, and tourism circuits. By emphasizing the site's visual uniqueness, the discourse shifts the notion of landscape from its role as an ecological and territorial foundation to its instrumentalization as a resource for enhancing value and tourist appeal.

The description also links the development's origins to the historical struggle of Sabiaguaba's traditional families, presenting the complex as a response to local demands for job creation, cultural appreciation, and the harnessing of the region's tourism potential. Although this formulation invokes the idea of community agency and recognition of the so-called "natives," it also produces an effect of consensus-building around the intervention process, obscuring the asymmetries between traditional forms of territorial appropriation and their incorporation into a broader logic of tourist consumption and landscape enjoyment. In other words, the project's discourse tends to frame the community as the legitimizing agent of the operation, while simultaneously reintegrating it into a territorial economy driven by external visitor flows. These changes in the socio-spatial dynamics of the place result in socio-environmental impacts that are not necessarily treated here as positive or negative, but are conditioned by the specific interests of the agents involved, even though the environmental implications point toward the "commodification of the landscape" for the purposes of leisure and tourism consumption (Meneses, 2002).

From an architectural perspective, the narrative emphasizes strategies such as semi-underground construction, the preservation of views, the observation plaza, the suspended platform, and the pier, elements that reinforce the contemplative and experiential dimension of the place. More than just technical resources, such devices highlight an operation in which architecture and infrastructure organize the landscape as a setting for visual, gastronomic, and recreational consumption, aligning with contemporary processes of tourism urbanization that transform environmental and cultural attributes into inputs for

intangible consumption experiences (Paiva, 2013). In this sense, more than a simple gastronomic facility, the complex can be interpreted as infrastructure for the touristification of the landscape and local culture, albeit in a contradictory manner.

2. Methodology

The methodology of this study is based on an analytical and critical approach, structured around the concept of a digital inventory of contemporary architecture, as proposed by Paiva and Medeiros (2024) for the documentation and analysis of significant works in Ceará. The methodological approach utilizes high-precision capture and modeling tools to investigate the dissonance between the space conceived by the State and the impacts of COMAGS on the Sabiaguaba ecosystem. The methodological procedures were organized into three sequential stages: data collection, data processing, and socio-spatial analysis.

The first stage consisted of environmental diagnosis and temporal monitoring, based on the guidelines of Grenier et al. (1993). The authors highlight the need for ongoing research in ecotourism zones to mitigate the phenomenon of "cosmetic greening," a term that defines the use of "green aesthetics" and the language of sustainability merely as a superficial "cosmetic" layer to validate projects that, at their core, ignore the deep ecological and social dynamics of the place. To conduct this monitoring, a DJI Mini 2 Unmanned Aerial Vehicle (UAV) was used. The choice of this sub-250g class equipment is justified by its portability and ability to operate with minimal intrusion in areas of socio-environmental conflict, ensuring that the georeferencing of the information was carried out discreetly. The UAV aerial photography survey was conducted using a pre-programmed flight plan at an altitude of 40 meters, utilizing the 1/2.3" CMOS sensor of the device's native camera to capture oblique and vertical views of the complex and its surroundings. The captured images and georeferenced data were processed and integrated into a GIS (Geographic Information System) environment using QGIS software, referenced to the SIRGAS 2000 / UTM Zone 24S coordinate system, where historical orthophotos from the SEFIN platform were also incorporated.

The integrated use of remote sensors and geographic platforms supports the approach of Rontani et al. 2024, who advocate the use of UAVs and aerial photogrammetry to enrich spatial databases and manage complex territories. In this environment, historical orthophotos from the SEFIN-Fortaleza IDE platform were incorporated, allowing for the observation, with cartographic precision, of vegetation clearance and topographic changes at the mouth of the Cocó River, as well as the verification of the removal of old shacks replaced by the current infrastructure (Figure 4).

Figure 4 – Aerial view of COMAGS obtained by UAV (Unmanned Aerial Vehicle). The image allows us to observe the scale of the architectural intervention at the mouth of the Cocó River and the pressure exerted by the infrastructure on the environmental dynamics.
Source: Elaborated by the authors (2025); Aerial photographic survey using a DJI Mini 2 UAV; date of capture: 2025.

The second phase of the research focused on parametric digital modeling using ArchiCAD 28 software, developed by the Hungarian company Graphisoft. The model was developed based on the original floor plans and technical details provided by the architectural firm in charge. This digital reconstruction enabled the creation of a parametric digital model developed at level of detail 300 (LOD 300), whose informational and geometric density made it possible to reproduce a tridimensional analytical "digital twin" of COMAGS and its immediate surroundings based on its exact metric attributes. This structure served as the fundamental basis for the application of the "think-feel" approach by Carvalho and Ponciano (2021). By transferring COMAGS to the BIM environment, it became possible to compare the project's geometry with reports of technical failures published in local newspapers and media outlets. The modeling served to document and spatialize the reported functional pathologies, such as the complete replacement of the wooden floor in January 2025, just three years after the building's inauguration (SEMA, 2025). The error in material specification given the extremely high salinity reflects a prioritization of immediate visual appeal at the expense of the building's life cycle. Similarly, the critical analysis of the project in the software revealed the absence of exhaust systems in the kitchens and the thermal inadequacy of the awnings, which ultimately create "heat islands" that are hostile to users (Brisa, 2025).

Finally, the socio-spatial dimension was analyzed using the Social Vulnerability Index (IVS), developed in 2015 by the Institute of Applied Economic Research (IPEA). Methodologically, the SVI operates as the inverse of the Human Development Index (HDI): while the HDI measures individual achievements, the SVI maps the deficiencies and absence of services that should be guaranteed by the government. The index consists of 16 indicators structured across three dimensions: Urban Infrastructure, Human Capital, and Income and Work. In Sabiaguaba, the analysis focused on the Urban Infrastructure dimension, which assesses access to basic sanitation and waste collection. This reality, as mapped by the IVS, was compared with the objectives and guidelines outlined in the Management Plan for the Sabiaguaba Conservation Units, approved in 2010, which already anticipated the need to reconcile environmental preservation with social infrastructure for the traditional population. The comparison of these indicators with the high investment in infrastructure for promoting tourism highlights a historical neglect of essential services for the indigenous community in favor of enhancing the urban image for external tourism consumption, revealing social exclusion in the territory.

3. Results and discussion

The results obtained through digital documentation, BIM modeling, and critical analysis of the complex reveal contradictions between the image of landscape enhancement proposed by COMAGS and the actual impacts on the Sabiaguaba area.

Regarding territoriality, the sense of belonging and the identity of the local community were dimensions deeply explored and highlighted by Maciel (2011), who demonstrated how existence in Sabiaguaba is inseparable from daily practices of direct interaction with the ecosystem. For the author, the territory is not merely a physical substrate but a field of meanings, constructed through labor and ancestry. However, this territoriality, based on artisanal fishing and gathering in mangrove areas, is now under threat. Following this line of thought, the urban design and architecture of COMAGS ignore the subjectivity of the place in favor of a space that prioritizes the flow of visitors. By allocating large areas to parking lots and contemplative zones, the project imposes symbolic and physical barriers that disrupt residents' daily lives. The connection of the locals to the sea, the mangroves, and the dunes, explored by Maciel (2011), is sanitized and turned into a "showcase," becoming an institutionalized tourist attraction. This process of "spectacularization" of the urban image, as defined by Paiva (2011), uses architecture as an ideological apparatus to insert Fortaleza into global consumption flows, often at the expense of the decharacterization of local identities (Figure 5).

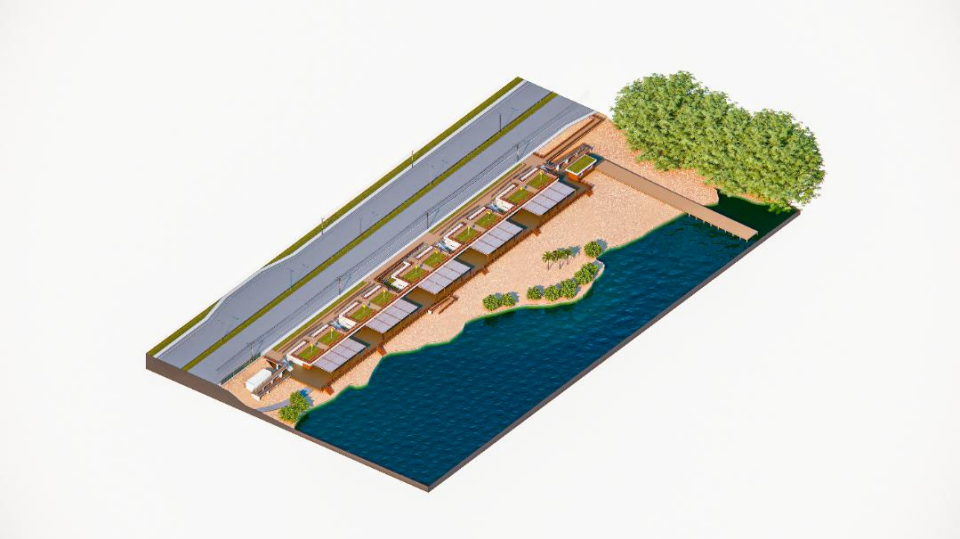

Figure 5 – Spatial relationship between the complex and the Cocó River estuary. The perspective exposes the implementation of the built environment, illustrating the strategies of physical-environmental integration, serving as a basis for analyzing the impact of the infrastructure on the surrounding environment.
Source: Elaborated by the authors (2026); based on the parametric digital twin modeled in ArchiCAD 28 (LOD 300).

From a critical analysis perspective, it is evident that COMAGS exhibits early signs of specification errors that reveal a disconnect between the design and the environment. A striking example occurred in January 2025, just three years after the inauguration, when the complex's wooden flooring required complete replacement (Figure 6). As reported by the local press, the work took place in the middle of the high season, raising serious questions from merchants and highlighting the socioeconomic damage caused by flawed planning. In this context, in an area of extremely high salinity, intense solar radiation, and heavy foot traffic, the choice of a material incapable of withstanding the aggressiveness of the marine environment reveals that the project prioritized immediate visual appeal at the expense of technical performance and the materials' lifecycle. Officially, the Secretariat of the Environment and Climate Change confirmed the completion of this replacement in April 2025. This approach directly conflicts with what Carvalho and Ponciano (2021) advocate, namely that architecture should be a sensitive response to the natural forces of the site, rather than an imposed object that requires immediate corrective maintenance.

Figure 6 – Detail of early pathologies in the COMAGS wooden deck. The accelerated deterioration, manifested in just three years of use, highlights the error in specifying a material with poor performance for the very high salinity, heavy traffic, and high solar radiation conditions of the estuary.
Source: Photographic record of Brisa (2025); date taken: January 2025; detailed close-up photograph.

The modeling performed in ArchiCAD 28 revealed serious deficiencies in environmental comfort that make the space inhospitable. The COMAGS kitchens, which are essential to the operations of local vendors, were designed without adequate exhaust and cross-ventilation, resulting in excessively hot environments that hinder food preparation and degrade work quality (Figure 7). Furthermore, the inappropriate specification of the awning material had an adverse effect: instead of providing shade and coolness, these surfaces create small "heat islands" that, depending on the time of day, make it impossible for visitors and workers to remain in outdoor areas. These functional flaws prove that the intervention ignored local characteristics, requiring constant maintenance funded by the government. The use of UAVs and GIS-based processing, in accordance with the methodology validated by Rontani, Dionizio, and Dezen-Kempter (2024), made it possible to document that such design choices not only fail technically but also generate spatial impacts.

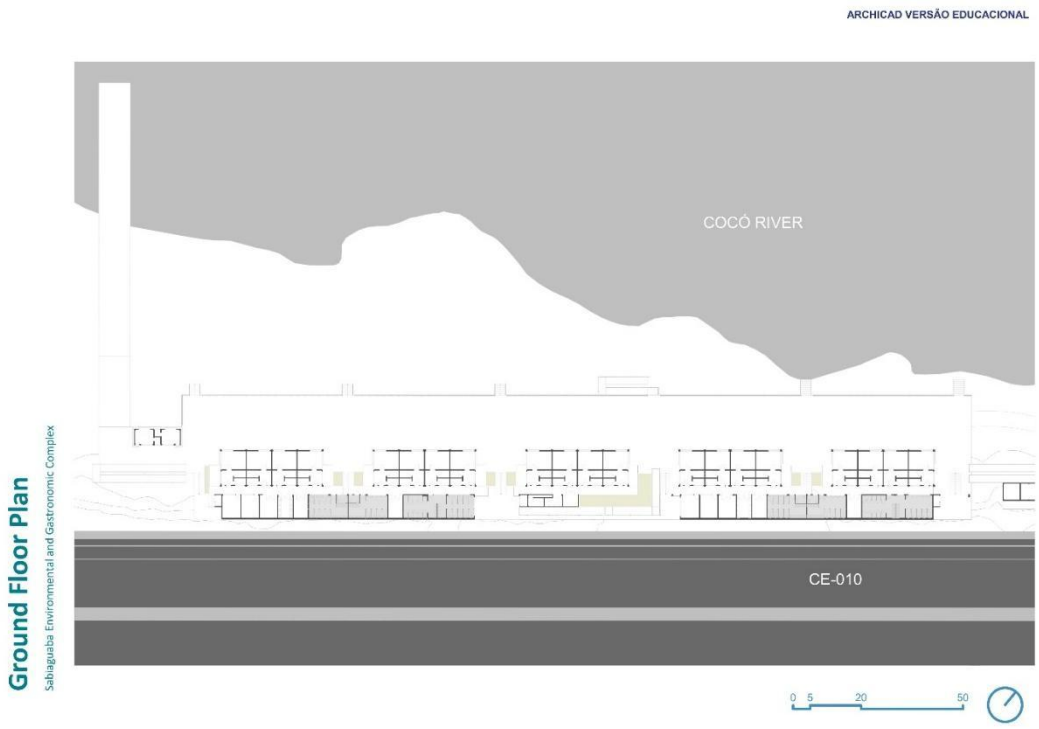

Figure 7 – Floor plan of COMAGS. The project reveals critical deficiencies in natural ventilation strategies, where some kiosks lack effective cross-ventilation and exhaust systems, compromising thermal comfort and the functionality of the kitchen and service areas.
Source: Elaborated by the authors (2026); based on a parametric digital twin modeled in ArchiCAD 28 (LOD 300); scale 1:500.

Thus, this process of aestheticizing the coastline masks severe socio-spatial exclusion: while COMAGS receives investments in scenic lighting, street furniture, and finishing materials, the immediate surroundings, where community life persists, and bonds of identity are formed, remain neglected by urban planning, lacking even basic sanitation and housing infrastructure. From this perspective, the results of this urbanization model become evident when we compare COMAGS' infrastructure with the region's social vulnerability indicators. In this regard, the Social Vulnerability Index (IVS), which in some areas is classified as "high" (Figure 8), reveals that Sabiaguaba is affected by a historical neglect that defies the guidelines established by the Conservation Units Management Plan itself.

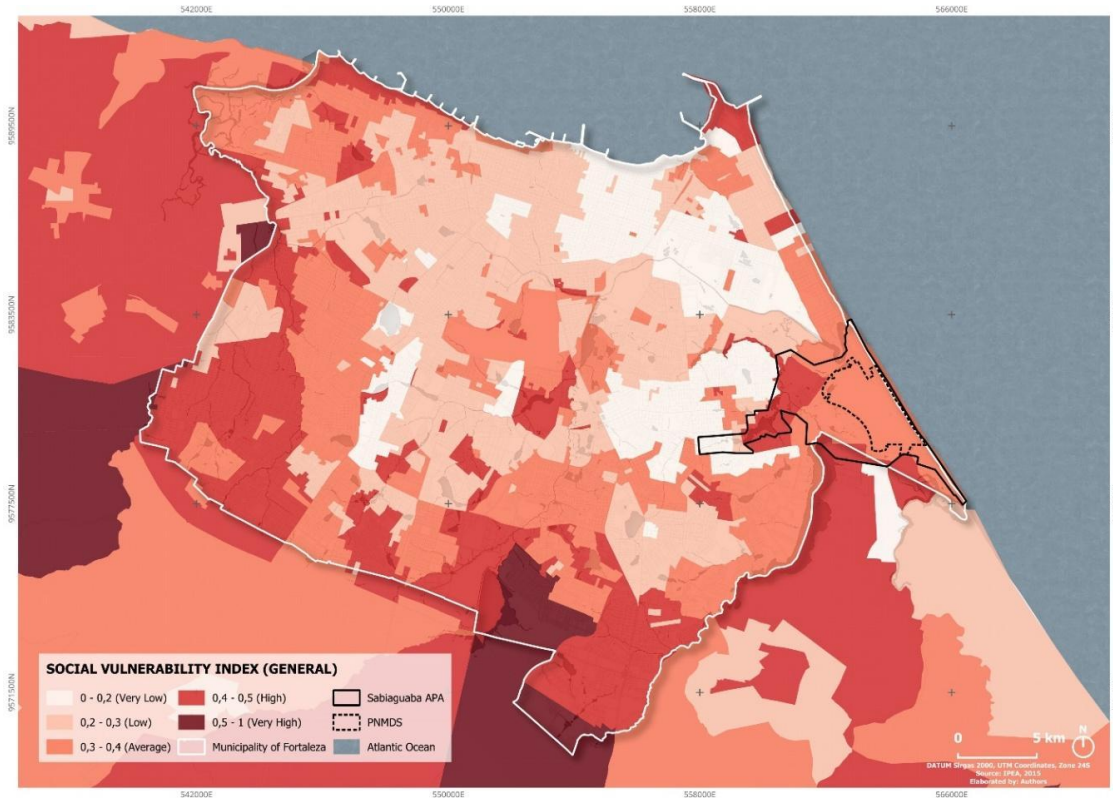

Figure 8 – Map showing the spatial distribution of the Social Vulnerability Index (SVI) in the Sabiaguaba Conservation Units region. The map reveals a serious socio-spatial paradox, demonstrating that areas with "High" social vulnerability directly border the highly commercialized tourist enclave.
Source: Elaborated by the authors using data from IPEA (2015); georeferenced on municipal vectors in QGIS; data processing date: 2026; map scale 1:120,000.

While the technical document clearly outlined the urgent need to assist vulnerable populations through the implementation of ecological sanitation, adequate drainage, and land regularization, what we see today is the opposite. By allocating large investments to raise the construction standards of an area, with leisure and tourism consumption as its sole justification, the state ignores the social welfare goals that the Management Plan designated as priorities. In this sense, this duality creates a "fragment of a city" well-equipped with tourism infrastructure, yet isolated from a periphery where the lack of basic sanitation and waste collection remains neglected.

The chronic ineffectiveness of public authorities in implementing the drainage and sanitation solutions proposed by the Management Plan to mitigate the risks of groundwater contamination and minimize flooding (Figure 9), which is so frequent in the region, leaves the community at the mercy of exclusion and vulnerability. Thus, current public investment does not aim to fulfill the land-use planning and social sustainability advocated by the Management Plan studies, but rather to enhance the city's image for tourism consumption, primarily from abroad. From this perspective, what is witnessed in Sabiaguaba is the conversion of socio-environmental heritage into a real estate asset.

Figure 9 – Photographic record of urban flooding and the lack of basic drainage infrastructure in the residential areas surrounding COMAGS. The image provides evidence of historical socio-spatial fragmentation, confirming that public funds were allocated primarily to improve the region's image as a tourist destination, while vital ecological sanitation solutions guaranteed by the 2010 Conservation Area Management Plan for the indigenous population were neglected.
Source: Photograph by Vieira (2025); date taken: March 2025.

4. Conclusions

The discussion developed in this study does not seek to disqualify the ideas embedded in the project, materialized in a work that, within its own objectives, effectively fulfills the role of producing an urban intervention aimed at enhancing Fortaleza's tourist image, while also providing architectural and tourism-support infrastructure. In fact, the complex has been widely appropriated by the tourism dynamics of Sabiaguaba, contributing to increased visitation of the area. The critiques advanced here, however, are situated within an expanded and broader interpretative framework, aimed at understanding the implications of contemporary architecture and urbanism on pre-existing cultural, territorial, and environmental conditions.

Research on the Sabiaguaba Environmental and Gastronomic Complex reveals that, although state intervention is presented under the guise of promoting the landscape and local culture, its implementation results in a process of exclusionary and technically problematic tourism urbanization. The transition from a low-impact settlement area to a tourist destination has resulted in the replacement of vernacular building types and traditional ties with a logic of "spectacularized" leisure consumption, which prioritizes external visitors at the expense of the local community. The digital modeling methodology and the use of UAVs highlighted the dissonance between the designed space and the environmental reality of the Cocó River estuary. The identified functional pathologies, such as the mis-specification of materials in a high-salinity environment and thermal inadequacy, confirm that the project prioritized immediate aesthetics at the expense of technical sustainability and the project's life cycle.

Furthermore, the contrast between the high investment in tourism infrastructure and the region's high rates of social vulnerability points to a historical neglect of essential services for local residents. It is therefore concluded that COMAGS functions as a tourism infrastructure that promotes tourist gentrification and socio-spatial fragmentation.

Pathological Manifestations in Building Structures: Evaluation of Causes, Impacts on Durability, and Intervention Costs

Bruna Sell[1], Marilia Araújo[2]

[1] Instituto Nova Engenharia, São Paulo, Brazil, brubesell98@gmail.com
[1] Instituto Nova Engenharia, São Paulo, Brazil, marilia_carla10@hotmail.com

Abstract: The presence of pathological manifestations in buildings compromises their durability, safety, and performance over time, in addition to resulting in high costs when proper maintenance becomes necessary. This study aims to analyze, diagnose, and estimate the costs of the main anomalies identified in three buildings located in the city of Joinville, Santa Catarina, Brazil. Among the observed manifestations, infiltration leading to reinforcement corrosion, detachment of coatings, and foundation settlement stand out. The causes of these pathologies were investigated through building inspections and classified using the GUT Matrix methodology, which allowed the prioritization of issues according to their severity, urgency, and tendency to worsen. In Case 1, efflorescence and infiltration were identified as the most critical symptoms, resulting in reinforcement corrosion and requiring immediate corrective actions. In Case 2, the improper application of materials and lack of maintenance obtained high scores in the GUT analysis, indicating compromised façade integrity. In Case 3, the absence of maintenance in hydraulic systems led to soil leaching, resulting in foundation settlement. The cost analysis establishes a relationship between the lack of preventive maintenance and the high costs of corrective interventions. The estimated results reinforce the need for preventive measures and regular inspections to minimize financial impacts and extend the service life of buildings, highlighting the importance of proper structural execution and adequate planning from the design phase.

Keywords: Pathological manifestations. GUT Matrix. Estimate costs.

1. Introduction

Pathological manifestations in buildings constitute a highly relevant topic in civil engineering and are understood as structural and/or functional alterations that result in material degradation and loss of performance of building systems. According to Iantas, such manifestations may be compared to “diseases” of buildings, appearing through cracks, fissures, stains, detachments, deformations, ruptures, corrosion, oxidation, among other anomalies. In general, these occurrences are directly associated with reduced building performance, affecting aspects such as stability, functionality, aesthetics, and, above all, durability under conditions of use and environmental exposure.

In this context, the service life of a building, as defined by ASTM (1982), corresponds to the period during which materials, components, and systems maintain their properties above minimum acceptable performance levels. An element is considered to have reached the end of its service life when its degradation renders it unsafe or economically unfeasible to maintain in operation. Therefore, structural durability may be understood as a function of the performance-versus-time relationship, making it essential that clear criteria regarding expected service life, environmental exposure conditions, and maintenance strategies be established during the design phase in order to ensure the integrity of the building over time.

Several factors contribute to the emergence and progression of pathological manifestations. According to Thomaz (2001), in addition to the natural aging of buildings, major causes include design flaws, execution deficiencies, inappropriate use of materials, and lack of preventive maintenance. Furthermore, the increasing pressure for reduced construction schedules, combined with the use of lighter building systems,

insufficient project detailing, lack of coordination among disciplines, and inadequate construction supervision, directly impacts the final quality of buildings, intensifying the occurrence of anomalies.

Failures resulting from construction defects, lack of maintenance, or improper use of buildings are recurrent and lead to reduced system performance and durability, compromising structural, functional, and economic aspects (Helene; Terzian, 1992). In this regard, Andrade (2012) highlights that approximately 40% of resources invested in the construction sector in developed countries are allocated to structural maintenance, emphasizing the importance of efficient management and conservation strategies throughout the service life of buildings, as can be observed in Figure 1. According to Farias (2023), the most frequent types of degradation are those caused by inadequate operation and maintenance management, and building inspection plays a crucial role in verifying maintenance conditions and usage patterns as a means of ensuring safety, durability, and proper performance.

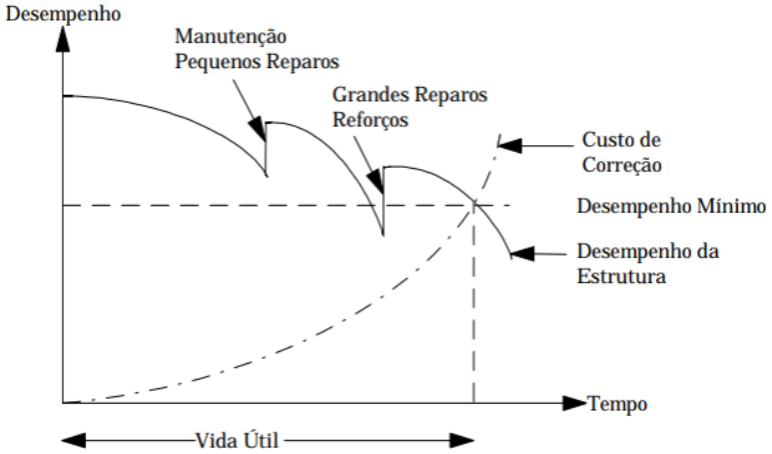

Figure 1 – Performance phases of a structure throughout its service life (adapted from CEB (1992) and Helene (1992))

According to Deutsch (2016), any problem identified at an early stage is easier and significantly less costly to solve. Learning to recognize the symptoms of structural or finishing deterioration makes it possible to avoid or minimize future problems. Ideally, routine inspections should be carried out in order to monitor pathological manifestations affecting the various components of the building under analysis.

The lack of inspections, and consequently the absence of maintenance, leads to severe problems in buildings, which progressively become obsolete and develop construction deficiencies. Negligence and lack of awareness regarding the importance of building inspections make identified repairs more complex and costly (DEUTSCH, 2016). Maintenance of any building aims not only at preserving the asset, but also at preventing performance levels from deteriorating to the point of impairing usability or causing discomfort to occupants. Through proper maintenance, the service life of the building can be extended. Therefore, inspection and maintenance are essential to ensure the safety and service life of the development, in addition to preventing unnecessary repair costs (SARTOR, 2020).

Additionally, climatic conditions and regional characteristics significantly influence building performance. Brazil's climatic diversity, characterized by temperature variations, solar radiation levels, and high rainfall indices in certain regions, requires specific technical knowledge for the proper specification of materials and construction systems. Disregarding these factors — combined with recent climate changes — may intensify degradation processes and compromise building habitability, which should encompass not only aesthetic and functional criteria, but also adequate sanitary and comfort conditions.

Concern regarding building durability gained greater prominence with the publication of the performance standard ABNT NBR 15575 (2013), which establishes parameters for the service life of building systems and reinforces the importance of periodic maintenance. According to Costa (2015), the absence of preventive maintenance can significantly reduce the designed service life of a structural system, potentially resulting in reductions of up to 50%, thereby increasing safety risks and repair costs. Conversely, regular

maintenance associated with small repairs over time contributes to extending service life and maintaining structural performance, as illustrated in Figure 1. Marinho and Mesquita (2020) state that problems arising from pathological manifestations range from minor damage to severe compromise of building safety, potentially leading to structural collapse. According to Sartor (2020), pathological manifestations are increasingly present in buildings, generating risks, occupant discomfort, high repair costs, and property devaluation.

Given this context, the present study aims to analyze three case studies of pathological manifestations in buildings located in Southern Brazil, a region characterized by high humidity and elevated rainfall rates. For this purpose, the Gravity, Urgency, and Tendency (GUT) Prioritization Matrix methodology is applied, enabling the ranking of problems based on qualitative criteria, complemented by failure mode and effects analysis methods, which classify occurrences according to their criticality. In Case 1, efflorescence and infiltration were identified as the predominant manifestations, resulting in reinforcement corrosion processes and requiring immediate intervention. In Case 2, improper material application and lack of maintenance were identified as critical factors, compromising façade integrity and resulting in high repair costs, in disagreement with the guidelines established by ABNT NBR 15575. In Case 3, the lack of maintenance of hydraulic systems caused soil leaching and foundation settlement, aggravated by inadequate palliative interventions. Overall, the analysis demonstrates the direct relationship between the absence of preventive maintenance and the significant increase in corrective intervention costs throughout the service life of buildings.

2. Methodology

The methodology adopted in this study was based on a case study approach, chosen for its ability to thoroughly explore pathological manifestations in real buildings, as well as to analyze solutions applicable to the identified problems. Additionally, a comparison was established between the costs of corrective interventions and those associated with preventive maintenance, highlighting the economic impacts resulting from the lack of proper management throughout the service life of buildings.

For the development of the fieldwork, methodological procedures were defined and structured into six stages, which are schematically presented in Figure 2.

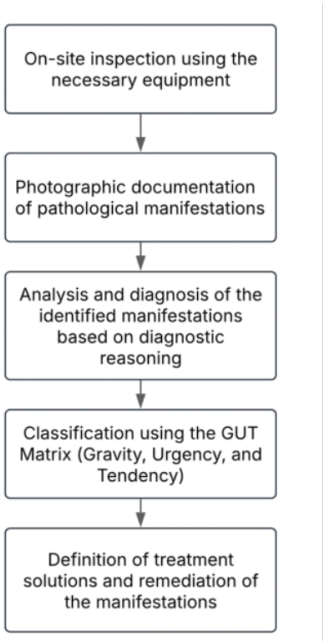

Figure 2 - Flowchart of activities (Author)

These stages ranged from initial data collection to the analysis and interpretation of the obtained results. The surveys carried out provided technical support for understanding the pathological manifestations,

enabling not only the identification of their symptoms but also a more in-depth analysis of their possible causes. This approach contributes to supporting rehabilitation interventions and maintenance strategies, as well as enhancing the understanding of the different stages involved in the construction process, enabling the adoption of more effective preventive measures.

The building inspection was conducted based on the identification and classification of pathological manifestations observed in situ. To prioritize interventions, the GUT Matrix methodology (Gravity, Urgency, and Tendency) was employed, which consists of assigning scores from 1 to 5 for each of these criteria, allowing the ranking of problems according to their level of criticality. According to Kepner and Tregoe (1981), the GUT matrix is a decision-support tool that enables the rational definition of priorities. In this context, as also discussed by Sotille (2014), its application promotes efficient resource allocation and strategic planning of corrective actions.

Each parameter of the GUT matrix was considered as follows: (i) Gravity (G), related to the intensity and extent of potential damage resulting from non-intervention; (ii) Urgency (U), associated with the time available to take action before undesirable consequences occur; and (iii) Tendency (T), which evaluates the progression of the problem over time in the absence of corrective measures. The combination of these factors allowed the establishment of a priority order for the interventions required in each case study.

It is important to note that some limitations were identified in the development of this study, particularly regarding the lack of detailed information on the design and construction stages of the analyzed buildings, as well as the unavailability of formal maintenance records. Furthermore, it was not possible to perform destructive testing or collect material samples, which restricted the analysis primarily to visual and non-destructive methods.

It is also emphasized that this study did not aim to evaluate the qualifications or performance of the professionals and companies involved in the analyzed projects, focusing exclusively on the identification and analysis of pathological manifestations from a symptom-based perspective.

Finally, after conducting the inspections and classifying risks using the GUT matrix, cost estimates were carried out for the repair of the identified pathologies, along with the development of comparative scenarios involving preventive maintenance costs that could have mitigated or prevented the progression of these manifestations. This analysis objectively demonstrated the technical and economic benefits associated with the adoption of systematic maintenance practices throughout the service life of buildings.

3. Headings and Subheadings

The city of Joinville has a humid subtropical climate, characterized by hot summers with high levels of thermal discomfort, mild winters, and high precipitation throughout the year. Average annual temperatures range between 13 °C and 30 °C, with perceived temperatures exceeding 35 °C during the summer due to high relative humidity. Rainfall is significant, with annual averages typically ranging from 1,700 mm to 2,700 mm, according to data provided by the municipal government. These climatic conditions have a direct influence on building performance, particularly with regard to material durability and the occurrence of moisture-related pathological manifestations.

Each case study analyzed refers to a distinct building, with specific construction characteristics, ages, and usage conditions.

3.1 Case 1 - Efflorescence and infiltration

Case 1 corresponds to a public building with more than 26 years of service, comprising several exposed slabs without roofing, such as floor slabs and ramps. In these areas, no effective waterproofing systems were

identified, which favors the occurrence of infiltration due to the porosity of the concrete, allowing water penetration into internal environments, as illustrated in the presented figures. These infiltrations are associated with the failure or absence of waterproofing, resulting in the initiation of reinforcement corrosion processes, as well as incidents such as the detachment of gypsum ceiling panels.

The occurrence of the spalling phenomenon was also observed, characterized by the detachment of concrete due to the expansion of corroded reinforcement. Additionally, the presence of a rainwater drainage system attached to the underside of the beams was identified, lacking proper waterproofing protection, which contributes to the intensification of deterioration processes. This condition is further aggravated by the porosity of the concrete and capillary action, facilitating the ingress of water and aggressive agents.

Based on the application of the GUT Matrix, the analyzed case presents high levels of gravity, urgency, and tendency, as continuous exposure to moisture accelerates the progression of deterioration processes, particularly reinforcement corrosion. The evolution of this condition may compromise the load-bearing capacity of structural elements and, in more critical scenarios, may lead to localized collapse. It is also important to emphasize that, due to the high flow of people in the area, the associated safety risk is significantly increased, requiring priority intervention.be used.

Figure 3 - Exposed reinforcement and attached drainage gutter (Author, 2025)

Figure 4 - Exposed reinforcement and attached drainage gutter (Author, 2025)

Given the current stage of degradation, the recommended corrective measure is the implementation of a complete waterproofing system for all exposed areas, including slabs and ramps, combined with the installation of an efficient drainage system. This system should be composed of appropriate materials, such as properly sized PVC pipes connected to the building's drainage network, ensuring the adequate discharge of rainwater and preventing moisture accumulation in structural elements.

It is important to emphasize that the observed pathological manifestations could have been avoided through the adoption of proper waterproofing and drainage solutions during the design and construction phases. Additionally, the implementation of preventive maintenance and early corrective interventions throughout the building's service life would have contributed to mitigating the progression of reinforcement corrosion processes, significantly reducing the costs and risks associated with the current interventions

3.2 Case 2 - improper material application

Case 2 refers to a building with approximately 8 years of service life, in which pathological manifestations were identified on the façade, notably the detachment of coatings and the significant presence of biological colonization, especially reddish algae. These manifestations indicate unfavorable environmental conditions, characterized by high humidity, insufficient ventilation, and low solar exposure on the analyzed surfaces.

Prolonged exposure to these conditions contributed to the development of efflorescence, resulting from the migration and subsequent crystallization of salts present in cementitious materials. This process promotes substrate degradation, reducing its cohesion and mechanical strength, which in turn leads to coating detachment at various points. Additionally, areas with intense biological colonization and detachment of the finishing layer were observed, as evidenced in the corresponding figures.

Figure 5 - Coating detachment and reddish mold (Author, 2025)

Based on adhesion tests of the coating system, a reduction in the bond strength between the coating and the substrate was identified, indicating weakening of the cementitious material, possibly associated with premature degradation and continuous exposure to moisture.

According to the application of the GUT Matrix, the analyzed case presents high levels of gravity, urgency, and tendency, as the persistence of moisture conditions accelerates façade deterioration mechanisms. The progression of this condition may compromise the integrity of the coating system and, in more critical scenarios, may result in the detachment of fragments, posing risks of material damage and hazards to user safety. It is important to note that, as this is an area with pedestrian circulation, the associated risk level is increased, requiring priority intervention.

As a corrective measure, the complete removal of compromised coating areas is recommended, followed by the restoration of the system using materials suitable and compatible with the exposure conditions. Additionally, the application of water-repellent coatings is suggested to reduce water absorption and enhance system durability. Furthermore, periodic maintenance actions should be implemented, including façade cleaning at intervals of approximately three years and repainting according to manufacturer specifications, in order to mitigate the recurrence of pathological manifestations and ensure adequate performance over time.

3.3 Case 3 - Pipeline failure causing soil leaching and settlement

Case 3 is related to the lack of maintenance of old metallic pipelines, whose oxidation process resulted in sewage leakage into the soil. Over time, these leaks promoted the leaching of fine particles and the consequent erosion of the soil in the foundation support region. As a result, differential settlement was observed, evidenced by inclined cracks at approximately 45° in masonry walls, as well as cracking in structural elements such as columns and beams, as shown in the presented images. This condition highlights the direct relationship between inadequate maintenance of building systems and the impairment of structural performance and stability.

Figure 6 - Diagonal cracks in Masonry Partition Walls (Author, 2025)

Figure 5 - Longitudinal Crack in a Structural Element (Column) (Author, 2025)

From a preventive standpoint, such manifestations could have been avoided through periodic maintenance of the pipelines, including annual inspections and cleaning, as well as the early replacement of compromised sections at the initial stages of leakage. These measures would significantly reduce the risk of soil infiltration and, consequently, the occurrence of leaching and erosion processes responsible for foundation settlement.

At the current stage, the adopted solution required more complex corrective interventions, including foundation reinforcement through the execution of “mega” footings, combined with soil improvement using soil-cement. These measures aim to restore the load-bearing capacity of the ground, mitigate the progression of settlement, and ensure the long-term stability of the structure.

4. Results and Discussions

The analysis of the three case studies clearly demonstrates the direct relationship between the lack of preventive maintenance and the significant increase in the costs of corrective interventions throughout the service life of buildings. In general, it was observed that the costs associated with correcting pathological manifestations can be up to five times higher than those required for implementing preventive measures and proper maintenance.

In Case 1, related to a public building with deficiencies in waterproofing and drainage systems, the estimated cost for corrective interventions—including the removal of the existing pavement and the execution of an adequate waterproofing system using asphalt membrane, as recommended by NBR 9575—is approximately R$ 600,000.00. In contrast, if the waterproofing system had been properly executed during the construction phase, without subsequent interventions compromising its integrity, the estimated cost would have been around R$ 120,000.00. This scenario highlights an increase of approximately five times due to delayed corrective intervention.

In Case 2, associated with the lack of maintenance in hydraulic systems, it was observed that simple preventive measures, such as cleaning and localized replacement of pipes, would have cost approximately

R$ 20,000.00. However, due to the progression of the problem and the occurrence of differential foundation settlement, the initial cost for structural correction reached approximately R$ 95,000.00, in addition to further expenses related to floor replacement and the repair of internal structural elements damaged by the settlement. This case illustrates how seemingly minor issues can evolve into complex pathologies with high repair costs.

In Case 3, it was found that the improper specification of finishing materials—particularly the use of a coating incompatible with the exposure conditions—resulted in the need for complete removal of plaster and façade finishes. The total cost of this intervention exceeded R$ 750,000.00. In contrast, adopting an appropriate solution during the construction phase would have represented an estimated additional cost of only R$ 100,000.00, clearly demonstrating the economic impact of inadequate material selection and lack of technical criteria in the construction process.

Overall, the results indicate that neglecting preventive maintenance practices, as well as deficiencies in design and construction stages, not only reduces the performance and durability of buildings but also leads to significantly higher costs over time. The adoption of preventive measures, combined with proper technical supervision during construction and the implementation of systematic maintenance plans, proves to be substantially more cost-effective and efficient.

Therefore, the importance of an integrated approach is reinforced, encompassing proper specification of materials and construction systems, adequate execution, and continuous monitoring of buildings. Such an approach contributes not only to mitigating pathological manifestations but also to optimizing costs throughout the building life cycle, ensuring greater safety, performance, and durability.

5. Conclusions

This study demonstrated that pathological manifestations in buildings are directly related to deficiencies in the design, construction, and, especially, the lack of preventive maintenance throughout the service life of structures. The analysis of the three case studies showed that factors such as inadequate waterproofing, improper material specification, and neglect in the maintenance of building systems significantly contribute to premature structural degradation and reduced performance.

The application of the GUT Matrix proved to be an effective tool for prioritizing interventions, allowing a systematic evaluation of problems based on their severity, urgency, and tendency to worsen. In all analyzed cases, high levels were identified for these parameters, highlighting the need for immediate corrective actions, particularly in situations involving risks to user safety.

From an economic perspective, the results clearly indicate that the absence of preventive maintenance can significantly increase intervention costs, reaching values up to five times higher than those required during the initial phase or for preventive actions. The analyzed case studies reinforce that simple and low-cost interventions, when carried out early, have the potential to prevent more severe, complex, and costly damages.

Therefore, it is concluded that the adoption of appropriate practices from the design phase—such as proper specification of materials and construction systems—combined with rigorous execution and the implementation of systematic maintenance plans, is essential to ensure the durability, performance, and safety of buildings. Furthermore, the importance of continuous technical supervision and the awareness of managers and users regarding the necessity of preventive maintenance is emphasized.

Finally, this study highlights that investing in construction quality and maintenance should not be seen as an additional cost, but rather as a fundamental strategy to reduce expenses throughout the building life cycle, contributing to the technical, economic, and functional sustainability of the built environment.

Abstract: This study is based on a case study involving a public school building funded by the Federal Government, located in the municipality of Itaperuna, in the state of Rio de Janeiro, Brazil, whose construction cycle was interrupted for approximately four years. During the period of suspension, the reinforced concrete superstructure of the educational facility remained exposed to continuous weathering cycles, without the protection of roofing or enclosure systems. The methodology adopted is grounded in the principles of building pathology and diagnostic engineering, through systematic visual inspection and photographic surveying, with the objective of correlating prolonged environmental exposure with material degradation. The research analyzes the technical consequences resulting from the interruption of the school construction project, demonstrating that the execution of the final finishing layers is technically dependent on the prior treatment of the accumulated pathological manifestations. The study shows that substrate degradation compromises the compatibility and adhesion of finishing systems, requiring restorative interventions to ensure the building's performance and durability requirements.

Keywords: Pathological Manifestations; Diagnostic Engineering; Resumption of Works; Durability of Structures.

1- Introduction

Educational infrastructure plays a fundamental role in ensuring adequate conditions for the teaching and learning process, and the execution of public works aimed at the construction, expansion, and requalification of school units is an essential element to ensure the efficient functioning of these spaces. In this context, the quality and continuity of the works assume direct relevance to the performance and durability of the buildings.

In the social and economic sphere, the high rate of paralysis of educational works directly compromises the expansion of the public education network and the provision of adequate environments for the development of pedagogical activities. The non-completion of these projects implies a waste of public resources, delays in the delivery of essential equipment to the population, and damage to the effectiveness of educational policies. In this context, the data presented reinforce the need for greater technical rigor in the planning, control, and supervision of public works, especially in the educational sector, due to the structural, financial, and social impacts resulting from construction discontinuity.

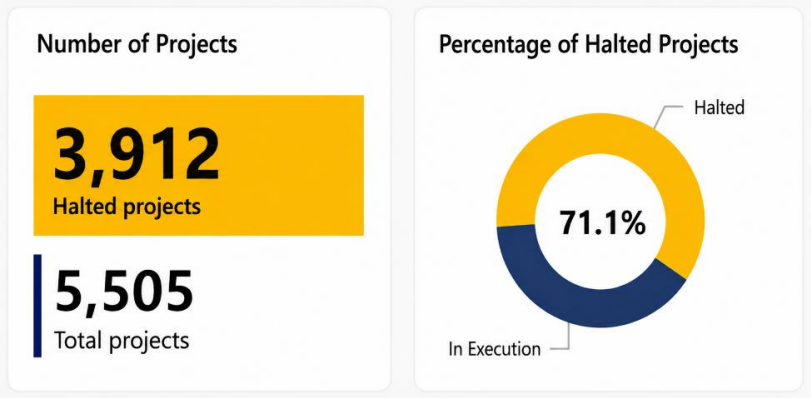

Figure 1: Scenario of Execution and Stoppage of Federal Public Educational Works.
Source: Adapted from the Federal Court of Accounts of Brazil (TCU, 2025).

As shown in Figure 1, it can be observed that, of the 5,505 public educational works monitored by the Federal Court of Accounts (TCU), 3,912 are paralyzed, corresponding to approximately 71.1% of the total projects. The data highlight a critical scenario of construction discontinuity in the education sector, revealing that more than two-thirds of educational works financed with federal public funds are not under construction.

From an engineering perspective, the high rate of paralysis of public educational works represents a technical problem of significant complexity, since the prolonged interruption of executive activities compromises the performance and integrity of the construction systems. In school buildings, the lack of construction continuity exposes structural elements, sealing components, and construction surfaces to weathering actions without proper technical protection, favoring the accelerated development of deterioration processes.

The continuous exposure of materials to climatic variations, associated with the absence of adequate roofing, waterproofing, and rainwater drainage systems, subjects the building components to successive cycles of wetting and drying, intensifying surface degradation and reducing the lifespan of the materials used (SOUZA; RIPPER, 1998). In addition, the stoppage of works interrupts essential executive stages for the proper performance of the building, such as concrete curing, waterproofing procedures, and the application of surface protection mechanisms.

This discontinuity in execution creates favorable conditions for the emergence and spread of pathological manifestations, such as cracking, infiltration, corrosion of the reinforcement, and premature degradation of the building systems. The inadequate interruption of the wet curing of concrete, for example, contributes to the increase in the porosity of the cementitious matrix, facilitating the penetration of aggressive agents and significantly reducing the period of initiation of corrosion of the exposed reinforcement (HELENE, 1993). As a consequence, there is a direct compromise to the structural performance, durability, and safety of buildings, in addition to a significant increase in recovery costs and technical difficulties related to resuming projects.

In this context, the stalled construction ceases to represent merely an unfinished undertaking and becomes a constructive system in continuous physical and functional deterioration (LICHTENSTEIN, 1986). Therefore, it becomes fundamental to understand the relationship between the stoppage of public educational works and the development of pathological manifestations, in order to support more precise technical analyses and contribute to the formulation of strategies aimed at mitigating the damage resulting from construction discontinuity.

Therefore, this research is characterized as an applied study, with a qualitative approach, developed through the case study method, focused on the analysis of pathological manifestations resulting from the prolonged stoppage of the construction of a public daycare center financed by the Federal Government, located in the municipality of Itaperuna, in the state of Rio de Janeiro. It is a larger architectural model within the program, designed to meet the demand for early childhood education in daycare centers and preschools, with a functional structure composed of pedagogical, administrative, and service blocks.

During this period, the reinforced concrete superstructure remained directly subjected to the action of physical, chemical, and biological degradation agents, potentiating the emergence of pathological manifestations and compromising the durability and performance conditions of the construction systems. Given this scenario, the theoretical framework addresses the main pathological manifestations observed in reinforced concrete structures exposed to adverse conditions, highlighting their characteristics, mechanisms of occurrence, and consequences for the building's performance.

2- Theoretical Framework

Prolonged interruptions in public works are a critical factor for the durability and performance of buildings, especially when partially completed structures remain exposed to environmental actions without the adoption of adequate protection measures. From a civil engineering perspective, the halt in the construction cycle involves essential execution stages, such as concrete curing, waterproofing, and surface protection of structural elements, favoring the development and intensification of pathological manifestations over time.

According to the Brazilian Association of Technical Standards, through ABNT NBR 6118:2023, the durability of reinforced concrete structures is directly related to environmental exposure conditions, the quality of materials used, and the correct execution of structural protection systems. The standard highlights that the lack of control of aggressive agents compromises the service life of buildings and accelerates manipulation mechanisms, especially in environments continuously exposed to moisture and weather.In this context, the interruption of construction activities can significantly compromise the concrete curing process. According to ABNT NBR 14931:2023, proper curing is essential to ensure cement hydration, the development of mechanical resistance, and the reduction of concrete permeability. Deficiencies in this process favor the occurrence of plastic and hydraulic shrinkage, resulting in the appearance of surface cracks and reduced structural performance. As highlighted by Thomaz (1989), cracking is one of the most recurrent pathological manifestations in buildings subjected to construction failures or premature exposure to weathering, acting as a preferential pathway for the entry of aggressive agents.

Another relevant mechanism refers to the corrosion of reinforcement bars in reinforced concrete structures. According to Helene (1993), the ingress of moisture, carbon dioxide, and aggressive ions into the pores of the concrete causes the depassivation of the steel, initiating corrosive processes that directly compromise the structural safety and durability of the building. Corrosion promotes volumetric expansion of the steel bars, generating internal stresses capable of causing cracking, detachment of the concrete cover, and reduction of the resistant section of columns, beams, and slabs.

Additionally, prolonged exposure of unfinished structures to wetting, drying, and thermal variations intensifies the physical-chemical deterioration mechanisms of reinforced concrete. According to Helene and Pereira (2007), high surface porosity associated with the absence of structural protection favors the ingress of aggressive agents, such as carbon dioxide, chlorides, and moisture, accelerating the carbonation and corrosion processes of the reinforcement bars.

Carbonation of concrete consists of the reaction between carbon dioxide present in the atmosphere and the alkaline compounds of the cement paste, reducing the hydrogen ion potential (pH) of the concrete and

compromising the passivating layer responsible for protecting the steel. According to Cascudo (1997), the reduction of concrete alkalinity is one of the main factors initiating corrosion in reinforced concrete structures subjected to prolonged environmental exposure.

The persistence of the structure without definitive covering and sealing systems further favors the increase in concrete permeability, intensifying capillary absorption and moisture retention in the structural elements. This phenomenon contributes to the leaching of hydrated cement compounds, loss of surface cohesion, and progressive reduction in the durability of the structure. According to Bauer (2019), the continuous action of water on cementitious materials is one of the main agents of degradation in exposed buildings without adequate protection.

From the perspective of building performance, ABNT NBR 15575:2021 establishes that constructions must meet minimum requirements related to structural safety, watertightness, durability, and design service life. However, in interrupted construction projects, the absence of preventive maintenance and adequate conservation directly compromises these normative parameters, significantly reducing the building's expected service life and increasing future structural recovery costs.

In this scenario, diagnostic engineering plays a fundamental role in evaluating the conditions of stalled buildings. According to Gomide, Pujadas, and Fagundes Neto (2015), the technical diagnosis should consider not only the apparent symptoms of pathological manifestations but also the active mechanisms responsible for the evolution of structural degradation, allowing for more precise, economically viable interventions compatible with the existing state of deterioration.

From this perspective, a stalled construction project ceases to represent merely an unfinished building, becoming a system subjected to continuous processes of physical, chemical, and mechanical degradation. As Souza and Ripper (1998) point out, the evolution of pathological manifestations is directly related to the exposure time and the absence of preventive interventions, significantly increasing rehabilitation costs and compromising the technical viability of resuming the project.

Therefore, understanding the impacts of prolonged interruption on construction systems becomes essential to support more precise technical diagnoses and define appropriate structural recovery strategies. Analyzing pathological manifestations in public educational buildings makes it possible not only to identify the active mechanisms of deterioration, but also to understand how construction discontinuity compromises the performance, safety, durability, and lifespan of buildings over time.

3- Methodology

The study is based on the principles of diagnostic engineering, an area focused on the technical investigation of the performance, durability, and integrity conditions of buildings, with a focus on the identification, characterization, and interpretation of the constructive anomalies present in the analyzed structure. The research concentrated especially on evaluating the effects caused by the continuous exposure of the reinforced concrete superstructure to the elements, considering factors such as humidity, solar incidence, thermal variations, biological agents, and the absence of sealing and roofing systems.

The methodology adopted initially comprised the documentary and historical survey of the work, including information regarding the period of stoppage, the conditions of resumption, and the executive stage of the building. Subsequently, on-site technical inspections were carried out, with systematic procedures of visual observation and photographic recording of the existing constructive conditions.

Figure 2 shows the state of the building at the time of the resumption of work, which occurred in 2023, highlighting the advanced level of exposure of the structural elements and the absence of finishes and protection systems for the construction.

Figure 2: Status of the work at the time of resumption in 2023. Source: Author's own elaboration (2023)

Figure 3: Status of the work at the time of resumption in 2026. Source: Author's own elaboration (2026)

The assessment of pathological manifestations was carried out through a visual technical inspection conducted during the resumption phase of the work, when the building was undergoing the application of

the coatings. The analysis was based on the direct inspection of the constructive elements, with photographic recording and identification of the anomalies observed.

It is noteworthy that the authors had prior knowledge of the building's conditions during the period in which the work remained paralyzed, at which time signs of degradation were already perceptible, characterized mainly by points of superficial darkening, stains associated with the presence of moisture, and initial signs of deterioration in elements exposed to the elements. This knowledge allowed for a comparative analysis between the conditions observed during the stoppage and those verified after the resumption of services.

The records and assessments of the building's conditions were carried out at two distinct times. The first inspection took place in 2023, when construction activities resumed after the period of work stoppage, when the pathological manifestations present in the exposed structure were identified and recorded. The second inspection was carried out in 2026, a period in which the building was in the finishing phase, making it possible to verify the evolution of the conditions observed previously and to evaluate the effects of the interventions carried out during the continuity of the project.

The analysis was based on on-site visual inspections, complemented by photographic records obtained in both stages of evaluation. The comparison between the surveys carried out made it possible to identify the persistence, mitigation or emergence of new pathological manifestations, providing subsidies for the discussion of the impacts resulting from the prolonged stoppage of the work and the measures adopted during its resumption.

4- Analysis and Discussion

Visual inspections carried out on the building allowed the identification of several pathological manifestations associated with the period of work stoppage and the consequent prolonged exposure of the building elements to environmental conditions. The observed anomalies were recorded through photographic documentation and analyzed in light of the degradation mechanisms described in the technical literature and the principles of diagnostic engineering.

In general, occurrences related to the action of moisture, the development of biological agents, the superficial alteration of materials, and deterioration processes resulting from the lack of adequate protection during the interruption of construction activities were observed. The analysis of these manifestations makes it possible to understand the impacts of the prolonged stoppage on the performance and durability of the building, as well as to evaluate the technical implications for the resumption and completion of the work.

The photographic records obtained during the inspections are presented below, accompanied by a description of the identified pathological manifestations, a discussion of their possible causes, and their potential effects on the evaluated construction systems.

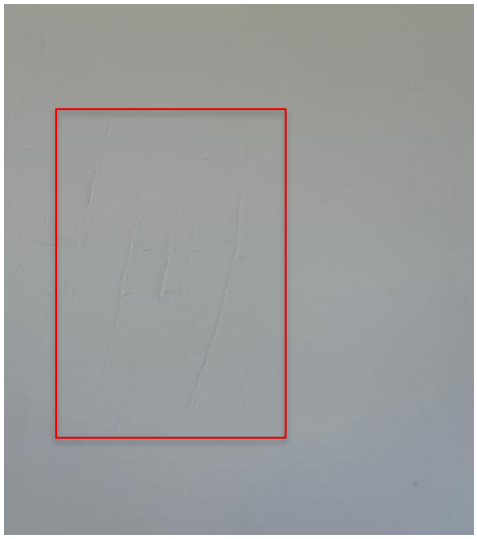

Figure 4 – pathologies found in the walls of the building. Source: Authors' field inspection (2023).

In Figure 4, the severity of the situation is accentuated by prolonged exposure to the elements without the protection of roofs or efficient drainage systems. The continuous dark stain at the base of the walls indicates water saturation of the components, which favors biological colonization (mold and algae), visible by the grayish darkening of the plaster. As pointed out by Santos and Araújo (2022), such pathologies not only compromise aesthetics but also degrade the cohesion of the mortars and reduce the long-term structural and economic performance of the construction.

Figure 5- Dried corrugated conduit. Source: Authors' field inspection (2023).

Figure 5 shows that prolonged pre-exposure degradation of the corrugated conduit results in the phenomenon of polymer drying. Under the action of the sun, the molecular chains of the plastic break, which removes the material's flexibility and makes it extremely brittle.

Figures 6 and 7: Pathological manifestation in the plaster. Source: Authors' field inspection (2026).

The pathological manifestations observed in Figures 6 and 7 comprise mapped cracks in the coating associated, simultaneously, with runoff marks resulting from the action of moisture. These occurrences may be directly related to the set of conditions to which the building was subjected during the period of work stoppage, in which there was prolonged exposure to climatic agents without the proper protection of the construction system.

The mapped cracks are predominantly linked to the mortar shrinkage mechanisms, intensified by inadequate execution and curing conditions. The action of the weather, especially the incidence of solar radiation and ventilation, promoted the accelerated evaporation of the mixing water, generating differential shrinkages and the consequent development of internal stresses in the coating. This scenario favors the emergence of randomly distributed cracks, typical of the mapped pattern.

In parallel, the presence of vertical runoff marks evidences the action of moisture on the surface, indicating possible infiltration or absorption of water by the exposed coating. This process contributes to the surface leaching of mortar and paint components, altering the texture and appearance of the finish, as well as potentially increasing the degradation of the system.

In addition, factors related to the composition and application of the coating such as high fines content, excess cement, multi-layer application, and possible adhesion failures to the substrate act synergistically in intensifying internal stresses and reducing the coating's performance against hygrothermal variations.

Therefore, it is concluded that the identified pathologies do not result from a single isolated agent, but rather from the interaction between material characteristics, execution deficiencies, and adverse environmental conditions, with prolonged exposure to weathering being a determining and aggravating factor for both the development of the mapped cracks and the appearance of the observed signs of moisture.

Figure 8: manifestation of dampness. Source: Authors' field inspection (2026).

In Figure 8, the observed pathological manifestation is characterized by the presence of mold on the surface of the coating, evidenced by greenish stains concentrated at the base of the walls. This type of pathology is directly associated with the continuous presence of moisture, which creates favorable conditions for the proliferation of fungi and microorganisms.

In the case analyzed, the pattern of occurrence indicates a strong relationship with rising damp by capillarity, in which water from the soil is absorbed by porous materials and transported along the masonry. The absence or inefficiency of waterproofing systems at the interface between the soil and the structure contributes significantly to this process.

In addition, the prolonged exposure of the building to the elements during the period of work stoppage acted as an aggravating factor, intensifying the moisture in the building elements. Conditions such as low ventilation and high relative humidity also favor the development of mold, enhancing the degradation of the coating.

Although this manifestation does not directly compromise structural stability, it indicates inadequate building performance conditions, potentially affecting the durability of materials and the healthiness of the environment. Therefore, its occurrence reinforces the need for corrective measures aimed at controlling humidity and adequately protecting building elements.

5- Conclusions

It is concluded that the prolonged exposure of the building during the period of work stoppage is a determining factor for the emergence and intensification of the observed pathological manifestations. The absence of adequate protection allowed the direct action of climatic agents, such as solar radiation, precipitation, and thermal variations, compromising the performance of materials still in the curing process and favoring mechanisms of premature degradation.

In this scenario, not only was the development of mapped cracks and signs of moisture infiltration observed, but also the occurrence of surface disintegration of the coating, evidenced by the powdery ("crumbling") appearance of the wall. This condition stems mainly from the loss of cohesion of the mortar due to inadequate curing, leaching of components, and continuous exposure to moisture, resulting in a weakened substrate.

This degradation significantly compromises the adhesion of new finishing materials, making it difficult to apply fillers, sealers, and paints, in addition to reducing the durability of the system as a whole. Thus, merely superficial interventions become ineffective, making it essential to remove the compromised layers and properly restore the coating.

In this way, it is evident that neglecting the protection of the work not only favors the emergence of pathologies, but also aggravates their complexity and increases recovery costs, directly impacting the final quality of the building. It is therefore reinforced that the adoption of preventive measures during shutdowns, such as surface protection, control of curing conditions, and mitigation of exposure to the elements, is technically indispensable and economically more efficient than subsequent correction.

Abstract: A expansão da infraestrutura urbana no Trevo de Triagem Norte (TTN) configura-se como um marco para as estratégias de manutenção do patrimônio da capital federal. A preservação desse acervo moderno exige uma revisão documental rigorosa, que considere desde as diretrizes do projeto original até as intervenções acumuladas ao longo do tempo. Tais transformações culminaram na necessidade de ampliar a capacidade de carga de pontes e viadutos por meio de reforços estruturais, uma vez que o complexo representa uma das principais artérias viárias de Brasília, com alto volume de tráfego no eixo Sul-Norte (MACHADO et al., 2024). O projeto de reabilitação deve garantir segurança, durabilidade e sustentabilidade, integrando a manutenção periódica ao respeito ambiental. O objetivo central é otimizar o desempenho e a vida útil do conjunto estrutural, visando à melhoria da qualidade das construções (Possan & Demoliner, 2013). Ademais, a preservação do patrimônio cultural demanda uma análise das características construtivas originais, das alterações físicas e das patologias decorrentes do envelhecimento dos materiais e da ação antrópica (Formisano & Milani, 2019). Embora o Brasil careça de uma norma específica para essa prática, a ABNT NBR 15575:2013 a define como uma atualização tecnológica voltada à longevidade do bem (Negreiros, 2019). Diante disso, este trabalho utiliza pesquisas históricas e investigações experimentais no TTN para definir um modelo de interpretação qualitativa, visando à intervenção mais adequada à salvaguarda do patrimônio moderno.

Keywords: A maximum of five keywords should be provided. These should accurately describe the content of the paper.

1. Introdução

O patrimônio cultural incorpora a historiografia e a identidade de uma sociedade, detendo um expressivo potencial econômico e social capaz de subsidiar o enfrentamento dos desafios contemporâneos no âmbito das cidades (Matos et al., 2024). Sob essa ótica, torna-se imperativo reposicionar as políticas patrimoniais, integrando-as ao planejamento urbano com ênfase na conservação, manutenção e proteção da infraestrutura urbana moderna. No contexto das infraestruturas rodoviárias, observa-se que as intervenções em Obras de Arte Especiais (OAEs), como pontes e viadutos, têm sido motivadas predominantemente pela obsolescência decorrente da escassez de manutenção preventiva, o que culmina na precarização dos espaços urbanos adjacentes (Galimi et al., 2025).

Essa urgência demanda estudos aprofundados acerca da degradação de elementos estruturais e da avaliação sistêmica do estado de conservação dessas unidades (Lima et al., 2019) A preservação do acervo edificado exige, portanto, uma abordagem multidisciplinar que examine o bem em sua totalidade, harmonizando critérios históricos e estéticos à manutenção do valor patrimonial e à salvaguarda da autenticidade (Peixoto et al., 2022). Nesse cenário, a reabilitação urbana qualifica-se como instrumento de

revitalização capaz de promover melhorias socioestruturais, fundamentando a reutilização de estruturas históricas como centros de renovação cultural e indutores de capital social.

A intervenção em infraestruturas rodoviárias transcende a mera recuperação física; configura-se como uma estratégia de valorização de territórios que, malgrado o estado de degradação, preservam um conteúdo simbólico e histórico relevante. A revitalização busca, portanto, perpetuar a memória e os valores culturais, ressignificando o uso de ativos degradados para reintegrá-los ao tecido social e urbano (Galimi et al., 2025). Tais ações, ao superarem a dimensão estritamente funcional, estabelecem vínculos entre territórios e atividades, otimizando a qualidade do ambiente construído.

Em Brasília, a expansão da infraestrutura urbana e a consequente necessidade de intervenção nas OAEs confrontam-se com as diretrizes de preservação do Conjunto Urbanístico de Brasília (CUB). A reabilitação sustentável surge como o caminho para viabilizar a conservação do patrimônio moderno, onde a intervenção não se limita à recuperação estrutural, mas abrange a refuncionalização e a extensão da vida útil das obras (Negreiros, 2019). O presente trabalho analisa, especificamente, o caso do Trevo de Triagem Norte (TTN), compreendendo o projeto de reabilitação como uma iniciativa de requalificação urbana que visa à reintegração de espaços segregados à malha viária principal, aplicando princípios de reconversão aplicáveis às infraestruturas de transporte (Costa, 2015).

2. Brasília, Patrimônio e Tombamento

A capital brasileira, reconhecida como Patrimônio Cultural da Humanidade pela UNESCO, apresenta desafios ímpares para a preservação de sua infraestrutura modernista. Tal cenário é particularmente crítico em Obras de Arte Especiais (OAEs), que demandam intervenções que conciliem as exigências funcionais contemporâneas à salvaguarda de seu valor histórico-arquitetônico (Galimi et al., 2021). O tombamento de Brasília, enquanto mecanismo de proteção legal, impõe diretrizes rigorosas que visam à preservação da coexistência das quatro escalas urbanísticas concebidas por Lúcio Costa: a monumental, a residencial, a gregária e a bucólica. Qualquer alteração no sistema viário deve, portanto, respeitar a hierarquia dessas escalas, evitando que a expansão da infraestrutura segregue o tecido urbano ou comprometa a visibilidade da linha do horizonte — elemento central da escala bucólica e da concepção de "cidade-parque" (Farret, 2018).

Nesse contexto, a aplicação dos conceitos de autenticidade e integridade às OAEs de Brasília transcende a conservação da matéria original. A integridade refere-se à manutenção da unidade do conjunto urbanístico e da funcionalidade dos eixos, enquanto a autenticidade está vinculada à permanência do espírito do projeto e das soluções estruturais inovadoras que caracterizam a escola carioca de Oscar Niemeyer e Joaquim Cardozo (Peixoto et al., 2022). Intervenções de reabilitação no Trevo de Triagem Norte (TTN) devem, assim, garantir que os reforços estruturais e as ampliações de carga não descaracterizem a leveza e o protagonismo da estrutura, elementos fundamentais da identidade tectônica da capital (Inojosa, 2019)

Os instrumentos normativos decorrentes do tombamento conferem um caráter inalienável à preservação do sítio urbano, estabelecendo que intervenções no sistema viário respeitem uma abordagem integrada dos fenômenos sociais, culturais e ambientais. Nesse sentido, dispositivos como o Decreto n.º 10.829/1987 e a Portaria n.º 314/1992 do IPHAN definem áreas de preservação que englobam não apenas a volumetria edificada, mas o entorno e as infraestruturas que estruturam as quatro escalas de Brasília (Galimi et al., 2021). No caso específico do Trevo de Triagem Norte (TTN), a intervenção exige uma análise aprofundada de seu valor patrimonial, uma vez que a estrutura se insere na zona de amortecimento e visibilidade do Plano Piloto.

Contudo, observa-se que a percepção pública acerca do tombamento muitas vezes restringe-se aos monumentos isolados, em detrimento da compreensão da cidade como um sistema de infraestrutura contínuo. A composição urbanística configura a área de proteção que articula edifícios, espaços livres e vias, constituindo uma totalidade indissociável. Essa complexidade normativa demanda um exame minucioso

das legislações pertinentes para garantir que as intervenções rodoviárias estejam em conformidade com as exigências de proteção (Ficher, 2019).

Embora o tombamento seja ocasionalmente interpretado como um óbice ao desenvolvimento urbano, ele deve ser compreendido como um instrumento de controle e planejamento estratégico. Sua função primordial é balizar o crescimento da metrópole, assegurando que a evolução da infraestrutura não comprometa os valores culturais e históricos que fundamentam a excepcionalidade de Brasília (Farret, 2018

3. Brasília, Infraestrutura Urbana

A capital federal, caracterizada pelo rigor de seu planejamento modernista, apresenta uma infraestrutura urbana complexa e interligada, cuja manutenção e adequação às demandas contemporâneas exigem abordagens metodológicas inovadoras (Alwehab & Juvara, 2018). A gênese morfológica de Brasília fundamenta-se na articulação de dois eixos ortogonais: o Eixo Rodoviário (curvo) e o Eixo Monumental (retilíneo). Esta configuração em "cruz" não apenas organiza o espaço urbano e a mobilidade, mas estabelece a espinha dorsal sobre a qual se assenta a setorização da cidade (Pereira & Avena, 2018).

Nesse sistema, as Obras de Arte Especiais (OAEs) — pontes, viadutos e passagens inferiores — atuam como conectores urbanos essenciais. Elas viabilizam a segregação de fluxos e a continuidade dos eixos sem interrupções por cruzamentos em nível, consolidando a visão de uma cidade planejada para a funcionalidade e para o tráfego de alta fluidez (Oliveira & Sobrinho, 2022). O projeto original (Figura 1) já previa estruturas estratégicas para a conexão das escalas, como exemplificado na Ponte do Braghetto, concebida ainda nos primórdios da construção para viabilizar a saída norte da capital.

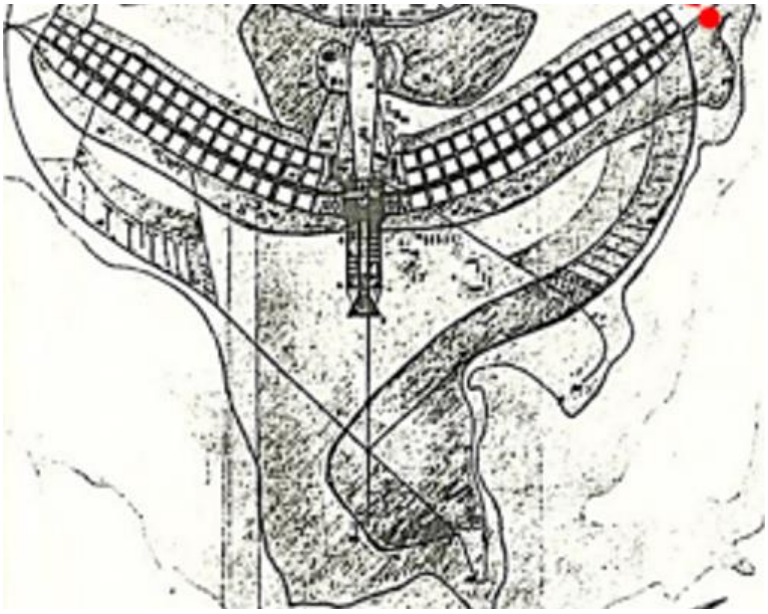

Figura 1 – Esboço do Plano Piloto, com indicação da Ponte do Braghetto em 1956. Fonte: (MACHADO et al., 2024)

Entretanto, após mais de seis décadas de operação, a infraestrutura rodoviária de Brasília enfrenta o desafio do envelhecimento natural dos materiais e da obsolescência tecnológica. O aumento exponencial do volume de tráfego e das cargas rodoviárias, que superam consideravelmente as previsões de cálculo da década de 1960, impõe uma severa degradação às estruturas de concreto armado). Esse cenário exige intervenções de reforço e atualização que equilibrem a necessidade de modernização e segurança estrutural com o respeito absoluto às diretrizes de preservação do patrimônio arquitetônico e urbanístico

(Galimi et al., 2020). A reabilitação destas OAEs, portanto, não é apenas uma demanda de engenharia, mas uma condição para a sustentabilidade da mobilidade urbana no Distrito Federal (Moraes, 2021).

4. O Trevo de Triagem Norte (TTN)

A intervenção no Trevo de Triagem Norte (TTN), que compreende a ampliação e reestruturação do sistema viário na saída norte do Distrito Federal, insere-se num contexto complexo de gestão urbana. O projeto (Figura 2) constitui uma das mais ambiciosas iniciativas de requalificação de infraestrutura rodoviária no Distrito Federal, enfrentando o desafio de expandir a capacidade logística em uma área de sensibilidade patrimonial. O complexo situa-se na extremidade norte do Plano Piloto, articulando o fluxo entre a Asa Norte, a Estrada Parque Indústria e Abastecimento (EPIA) e a Estrada Parque Contorno (EPCT). O projeto foi concebido para mitigar o estrangulamento viário na "Saída Norte", onde a convergência de fluxos das regiões de Sobradinho, Planaltina e condomínios adjacentes gerava congestionamentos crônicos e acelerava a degradação das estruturas pré-existentes (Galimi, 2021). A reabilitação e a modernização desse complexo viário representam, assim, uma resposta fundamental às crescentes demandas de mobilidade e ao desgaste decorrente da intensificação do tráfego, elementos que sobrecarregam as infraestruturas projetadas para um cenário urbano distinto (MACHADO et al., 2024).

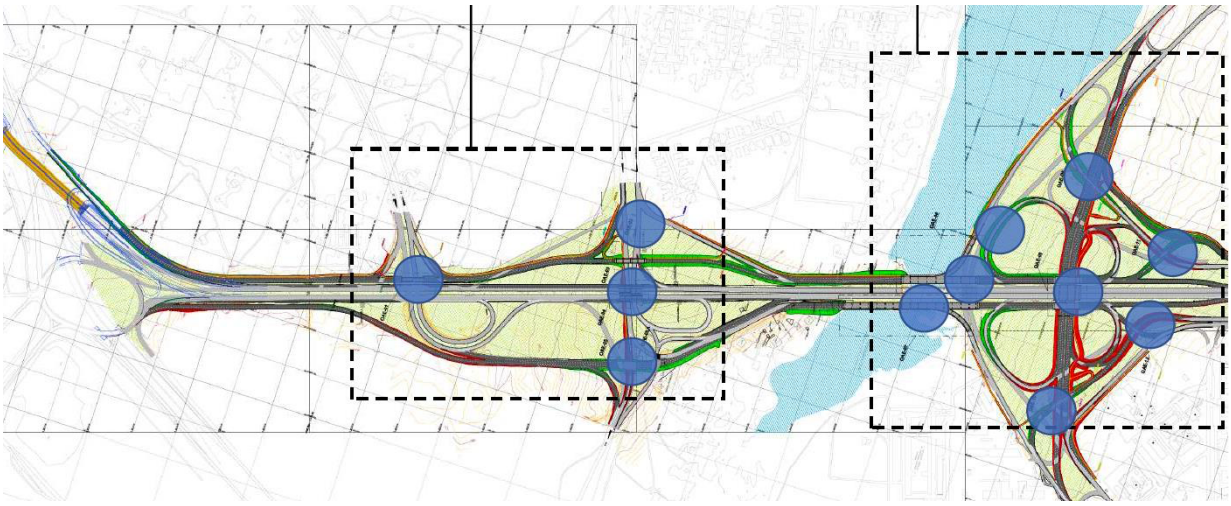

Figura 2 – Conjunto Infraestrutural TTN – Trevo de Triagem Norte. Fonte: (Galimi, 2021)

O Trevo de Triagem Norte é composto por um conjunto de 15 Obras de Arte Especiais, incluindo 13 viadutos e 2 pontes, o retrofit estrutural da Ponte do Braghetto, OEA já existente, além de 9 km de ciclovias, sistemas de drenagem, entre outras adequações como sinalizações e recuperação ambiental. A intervenção, de grande magnitude, visou separar os fluxos locais dos expressos, por meio do conceito de vias marginais para organizar o tráfego que adentra a malha urbana da Asa Norte. A execução, realizada em 2018 pelo DER-DF, adotou padrões modernos de concreto armado e protendido, com vistas a uma vida útil estendida e à redução de custos de manutenção futura por meio de um modelo de retrofit sistêmico (MACHADO et al., 2024).

4.1 A continuidade dos eixos rodoviários principais preservando as vias originais.

A abordagem adotada no TTN priorizou a minimização dos impactos sobre o traçado original, mantendo a coerência com o projeto urbanístico de Lúcio Costa. Brasília foi concebida sob o paradigma modernista, onde a estrutura detém o protagonismo formal e a arquitetura nasce integrada à solução de engenharia (Inojosa, 2019). No entanto, a Ponte do Braghetto, principal componente desse sistema, enfrentava um

cenário de saturação crítica. Antes da intervenção, o volume de tráfego atingia cerca de 100 mil veículos diários, operando muito além da capacidade projetada na década de 1960 (MACHADO et al., 2024).

O desenvolvimento de Brasília foi marcado por um estilo arquitetônico modernista, centrado na expressão artística e na forma. Seu planejamento urbano e paisagístico avançado enfatizava as qualidades espaciais, por meio de abordagens estruturais inovadoras e tecnologias de ponta. Isso impulsionou avanços significativos na construção civil, especialmente em arquitetura e engenharia estrutural, resultando em soluções originais para uma execução eficiente (Inojosa, 2019).

Sendo a primeira ponte construída sobre o Lago Paranoá e figurando nos esboços originais da capital, a Ponte do Braghetto (com 180 m de extensão e 32 m de largura) exigiu um processo de reabilitação que preservasse sua importância simbólica enquanto expandia sua capacidade operacional. O projeto de reabilitação incluiu o retrofit estrutural da obra pré-existente, que apresentava manifestações patológicas decorrentes do envelhecimento natural e da sobrecarga de tráfego. A intervenção não se limitou à estrutura em si, mas reconfigurou toda a região circundante para absorver o fluxo proveniente do Complexo Viário de Torto-Colorado, transformando a antiga passagem em um sofisticado complexo viário, influenciando toda a região circundante (MACHADO et al., 2024). As imagens comparativas de satélite da Figura 3 registram as intervenções entre 2008 e 2020.

Figura 3 – Imagens comparativas de satélite entre 2008 e 2020. Fonte: (MACHADO et al., 2024)

De acordo com Galimi (2021), a complexidade do TTN reside na necessidade de conciliar a preservação do patrimônio moderno com a obsolescência funcional das estruturas originais. A análise das intervenções entre 2008 e 2020 demonstra que, apesar da inserção de novas alças e viadutos, o Eixo Rodoviário manteve sua diretriz original, preservando a leitura das escalas urbanas (Le, 2011). Esta estratégia ratifica a viabilidade de modelos de requalificação que harmonizam a atualização tecnológica — como o uso de concreto de alto desempenho e novas técnicas de reforço — com a salvaguarda do conceito urbanístico original da cidade.

4.2 A adoção de viadutos construídos em trincheiras com preservação da paisagem urbana.

Tal estratégia converge com os princípios de permeabilidade visual e integração ao entorno, característicos do planejamento de Brasília, promovendo a harmonia entre a funcionalidade da infraestrutura e a estética paisagística. Essa metodologia, portanto, reforça o compromisso com a preservação do patrimônio cultural edificado, ao mesmo tempo em que permite a modernização e a otimização da capacidade de fluxo viário em áreas urbanas de alta sensibilidade patrimonial (MACHADO et al., 2024).

A preservação de elementos paisagísticos e o mobiliário urbano, como o uso de calhas para atenuar o impacto visual e ambiental do tráfego, são exemplos de como essas intervenções podem ser integradas ao planejamento urbano, expandindo o uso seguro e esteticamente enriquecedor das infraestruturas (Aflalo, 2020). Adicionalmente, a implementação de transposições e o rebaixamento de certas seções viárias contribuem para mitigar a interferência no tecido urbano e na percepção visual da cidade, alinhando-se com a lógica projetual de transversalidade entre a via e o solo urbano (Moraes, 2021).

No caso específico do TTN, a opção pelas trincheiras em substituição aos elevados convencionais permitiu que o sistema de alças de acesso fosse "ocultado" sob a topografia natural, evitando a fragmentação do horizonte — um dos valores fundamentais do tombamento de Brasília. Essa solução de engenharia responde ao conceito de "cidade-parque", onde a infraestrutura não deve competir com a massa arbórea e os espaços livres, mas sim subordinar-se a eles para manter a fluidez da percepção espacial (Bispo, 2020).

Além disso, o rebaixamento das pistas no TTN favorece o controle da poluição sonora nas áreas residenciais adjacentes da Asa Norte. As paredes das trincheiras, quando tratadas com materiais de absorção e integradas a barreiras vegetais, atuam como atenuadores acústicos, resolvendo um dos maiores desafios de inserir uma via expressa de alta densidade em um contexto urbano consolidado. Essa abordagem transforma a via rodoviária em um componente infraestrutural menos agressivo ao cotidiano da cidade (Moraes, 2022). Além disso, como visto na Figura 4, essa solução preserva o visual do horizonte para o Plano Piloto, mantendo o platô original e a paisagem urbana.

Figura 4 – Perspectiva dos Viadutos 2 ao 5 em nível, preservando o platô original e a paisagem urbana. Fonte: (Galimi 2024)

Por fim, a utilização de passagens inferiores viabiliza a continuidade da rede cicloviária e de pedestres em nível, sem a necessidade de passarelas elevadas que frequentemente descaracterizam a paisagem modernista (Le, 2011,). Ao manter os fluxos de mobilidade ativa na superfície e deslocar o tráfego pesado para o subsolo, o TTN reafirma a premissa de que a modernização da infraestrutura não precisa sacrificar a escala humana e a integridade visual do Plano Piloto.

4.3 Reabilitação das estruturas existentes.

Outra importante intervenção foi a reabilitação estrutural da Ponte do Braghetto, cuja demolição completa constava no projeto original licitado para a obra . Após reunião de equipe técnica, buscou-se a preservação desse patrimônio com a recuperação de sua estrutura e ampliação da capacidade de uso (MACHADO et al. 2024). Na Figura 5, mostra-se a intervenção na Ponte do Braghetto com a recuperação estrutural.

Figura 5 – Vista da recuperação estrutural da Ponte do Braghetto. Fonte: (Machado 2024)

A Ponte do Braghetto, uma das infraestruturas mais conhecidas da capital brasileira, cujo projeto estrutural foi elaborado pelo engenheiro Aderson Moreira da Rocha, foi construída em 1960, pouco antes da inauguração de Brasília. Seu sistema estrutural e construtivo empregou concreto armado protendido por protensão parcial de aderência posterior, com bainhas metálicas, injeção de calda de cimento e ancoragens do tipo Freyssinet, refletindo as tecnologias construtivas da época. Esse tipo de protensão aplica-se a um elemento estrutural de concreto já endurecido, processando a aderência posteriormente.

Em 2018, foram realizadas análises estruturais com o intuito de avaliar o estado de conservação da estrutura e as intervenções necessárias à sua recuperação. As práticas de retrofit estrutural aplicadas na Ponte do Braghetto consistiram na adoção de uma laje de transição com extensão de 6,0 m nas extremidades dos balanços da ponte, na construção de consoles de apoio dessa laje em concreto armado nas extremidades dos balanços, na disposição de armadura de reforço nos apoios para absorver os esforços devidos à laje de transição sobre a face superior do tabuleiro após remoção do capeamento, na adição de armadura de reforço para absorver esforços transversais nos apoios centrais, no tratamento de anomalias como áreas de concreto segregado, armaduras expostas e com baixo cobrimento, além do aumento da seção dos pilares por encapsulamento. Tais intervenções visaram não apenas a recuperação da integridade estrutural, mas também a adaptação da ponte às novas demandas de tráfego, garantindo a longevidade e a segurança da infraestrutura.

4.4Visão crítica do uso atual do Trevo de Triagem Norte.

Apesar das intervenções realizadas para otimização da capacidade de tráfego, observa-se que o Trevo de Triagem Norte, como complexo infraestrutural, ainda apresenta desafios no que tange à integração plena com o tecido urbano circundante. Em uma análise crítica, o TTN ainda não logrou consolidar-se como um "nó-plataforma" (Moraes, 2022) — conceito que define a infraestrutura não apenas como canal de passagem, mas como um espaço de articulação que conecta diferentes modais (transporte coletivo, ciclovias e pedestres) e diversos usos urbanos. Embora a fluidez para o automóvel individual tenha sido priorizada, a barreira física imposta pelas alças de alta velocidade ainda dificulta a permeabilidade para o pedestre e a fruição da orla do Lago Paranoá.

Ademais, a expansão urbana contínua nas regiões adjacentes (Freitas & Anjos, 2016), como o Trecho 2 da Etapa 1 do Setor Habitacional Taquari (Conserva et al., 2019), intensifica uma pressão constante e crescente sobre esta infraestrutura. Esse fenômeno de espraiamento urbano gera um ciclo de demanda que pode, em médio prazo, tornar obsoleta a ampliação recém-concluída, exigindo uma reavaliação permanente de sua capacidade de absorção. A infraestrutura, portanto, deve ser compreendida dentro de uma visão sistêmica de planejamento territorial estratégico do Distrito Federal, e não apenas como uma solução isolada para um gargalo viário específico (Silva & Saboia, 2016).

Outro ponto sensível reside na manutenção do caráter de "cidade-parque". A magnitude do TTN, com sua vasta área de pavimentação e taludes, desafia a escala bucólica projetada por Lúcio Costa. Galimi (2021) pondera que o sucesso do retrofit no patrimônio moderno depende da capacidade da intervenção de regenerar o entorno degradado, transformando "vazios residuais" sob viadutos em espaços públicos qualificados. No estado atual, o TTN ainda carece de uma estratégia de ocupação humana que mitigue a segregação espacial causada pelo sistema de trevos, garantindo que a infraestrutura cumpra sua função social de aproximar, e não apenas de deslocar, os cidadãos (MACHADO et al., 2024).

5. Conclusão

Este artigo analisou a intervenção no Trevo de Triagem Norte, destacando a complexidade envolvida na modernização de infraestruturas rodoviárias em contextos de alto valor patrimonial, como Brasília, e sublinhando a necessidade de se considerar a requalificação urbana sob uma perspectiva multicritério (Galimi et al., 2022).

A análise das intervenções no Trevo de Triagem Norte (TTN) e a reabilitação da Ponte do Braghetto permitem concluir que a reabilitação estrutural se consolida como a alternativa mais sustentável e técnica frente à substituição total das estruturas, a partir do conhecimento detalhado das manifestações patológicas nas estruturas existentes, cruciais para a proposição de diretrizes eficazes de preservação e intervenção, especialmente em obras que constituem patrimônio moderno (Inojosa et al., 2022). Além disso, a requalificação de infraestruturas urbanas, como a proposta para a Ponte do Bragheto, transcende a mera solução de problemas estruturais, abarcando parâmetros ambientais, espaciais e patrimoniais, para uma abordagem holística (Galimi, 2021).

No contexto de Brasília, onde a infraestrutura é parte integrante do valor excepcional do patrimônio, a demolição e substituição de Obras de Arte Especiais (OAEs) representariam uma perda irreparável da autenticidade técnica e histórica da capital. O retrofit, portanto, não apenas estende a vida útil do sistema viário, mas preserva a memória do saber-fazer da engenharia modernista brasileira.

Um fator determinante para o sucesso dessas intervenções é o rigoroso papel da revisão documental e da investigação experimental. Conforme preconizado por Formisano & Milani (2019), a definição de qualquer estratégia de intervenção em estruturas históricas deve ser precedida por um diagnóstico profundo, que combine a análise de projetos originais com ensaios in loco e monitoramento. No TTN, essa investigação permitiu identificar que, embora a Ponte do Braghetto apresentasse sinais de fadiga, sua reserva estrutural e a qualidade do concreto original viabilizavam o reforço em vez da reconstrução, otimizando recursos públicos e tempo de execução.

Para intervenções futuras em OAEs inseridas no patrimônio moderno, as diretrizes, sintetizadas neste estudo apontam para a necessidade de compatibilidade tecnológica, com o uso de materiais e técnicas que respeitem as propriedades físico-químicas do concreto original; mínima intervenção visual, pela adoção de soluções como trincheiras e reforços internos para preservar a silhueta e a linha do horizonte; e abordagem multicritério, com avaliação que considere simultaneamente o desempenho estrutural, o impacto ambiental e a integração espacial.

A complexidade reside em equilibrar a necessidade de adaptação funcional com a preservação da integridade estética e histórica de elementos arquitetônicos e de engenharia que definem a identidade

urbanística da capital (Lima, 2017). A abordagem de requalificação, conforme evidenciado nesse estudo, demonstra a viabilidade de preservar o patrimônio moderno por meio de intervenções que consideram aspectos sociais, culturais, ambientais e econômicos.

O Trevo de Triagem Norte oferece contribuições valiosas para o modelo de gestão de infraestrutura em Brasília. Ele demonstra que é possível modernizar nós logísticos de alta densidade sem descaracterizar o traçado de Lúcio Costa. O TTN serve como um laboratório vivo de como a engenharia diagnóstica pode atuar em favor da preservação, transformando "gargalos" viários em conectores urbanos que respeitam a escala bucólica e monumental da cidade. O desafio remanescente, contudo, é evoluir para uma gestão que transcenda o fluxo automotivo, integrando plenamente a infraestrutura reabilitada ao cotidiano social e aos modais sustentáveis da capital.

Agradecimentos

Os autores agradecem o Programa de Pós-Graduação em Arquitetura e Urbanismo da Faculdade de Arquitetura e Urbanismo da Universidade de Brasília – PPGFAU-UnB.

Resumo: A segurança sísmica dos edifícios escolares constitui uma preocupação central em Lisboa, devido ao seu significativo risco sísmico e elevada densidade populacional. Uma parte considerável do edificado foi construída anteriormente à implementação de regulamentos sísmicos modernos, o que acentua a vulnerabilidade do parque escolar. Neste contexto, a aplicação de metodologias simplificadas à macroescala revela-se fundamental para o apoio à tomada de decisão e à definição de prioridades de intervenção.

Neste âmbito, a pedido da Câmara Municipal de Lisboa, o Laboratório Nacional de Engenharia Civil (LNEC) procedeu à avaliação do parque escolar com base em indicadores de risco, incluindo o estado de conservação e uma estimativa simplificada da resistência sísmica. Posteriormente, no âmbito de trabalhos de investigação do NCREP, foi aplicada uma abordagem alternativa, igualmente à macroescala, baseada em tipologias estruturais, integrando a construção de uma base de dados, a classificação tipológica e a aplicação de métodos de Rapid Visual Screening. Estas metodologias permitem uma priorização preliminar dos edifícios, embora apresentem limitações na caracterização detalhada do seu comportamento estrutural.

No âmbito de intervenções promovidas pela Lisboa SRU, e com base na priorização definida, o NCREP realizou uma análise detalhada de dois edifícios representativos de escolas técnicas construídas entre 1947 e 1962: a Escola Básica Paula Vicente e a Escola Secundária D. Luísa de Gusmão. Para o efeito, foi conduzida uma campanha de inspeção e diagnóstico estrutural, incluindo a caracterização estrutural, a avaliação do estado de conservação e a análise das condições geotécnicas. Com base nesta informação, foram desenvolvidos modelos numéricos detalhados e realizadas análises não lineares, com o objetivo de avaliar o desempenho sísmico e identificar potenciais vulnerabilidades estruturais.

A comparação entre os resultados das abordagens simplificadas e da análise detalhada permite discutir a complementaridade de cada nível de detalhe e as diferenças e limitações associadas a cada metodologia, contribuindo para uma melhor compreensão da sua aplicabilidade na avaliação da vulnerabilidade sísmica de edifícios escolares.

Palavras-chave: Inspeção e diagnóstico estrutural; Vulnerabilidade Sísmica; Escolas Técnicas; Estruturas mistas betão armado e alvenaria.

1. Introdução

A segurança sísmica do parque escolar de Lisboa apresenta-se como um problema simultaneamente técnico, social e político: técnico, porque uma fração significativa do edificado foi construída antes da entrada em vigor da regulamentação sismo-resistente atualmente em vigor e aceite como referência; social, porque a ocupação destes edifícios é elevada e concentrada em horários definidos; político, porque a

definição de prioridades tem implicações orçamentais relevantes e exige sustentação em metodologias de avaliação reprodutíveis e defensáveis.

A fase de maior produção do parque escolar decorreu sob o RBA-1935 e o RSCCS-1958, sem disposições específicas de pormenorização sísmica. O RSA/REBAP (1983) introduziu as primeiras regras explícitas para a ação sísmica; os Eurocódigos estruturais (NP EN 1998-1 e NP EN 1998-3), em vigor desde 2019, constituem o quadro atual de avaliação e reforço de edifícios existentes.

Cerca de 80% das 137 escolas do município de Lisboa foram construídas antes de 1983, das quais um conjunto significativo nunca foi alvo de qualquer intervenção estrutural posterior. Este universo, onde coexistem estruturas de alvenaria, betão armado e estruturas mistas de betão armado e alvenaria, dimensionado de acordo com práticas anteriores à NP EN 1998-1, constitui a população-alvo do processo de avaliação e priorização descrito neste artigo.

O ponto de partida foi o estudo de vulnerabilidade sísmica encomendado pela Câmara Municipal de Lisboa ao LNEC (Carvalho et al., 2021), que avaliou 32 escolas com recurso a metodologia analítica simplificada à macro-escala, permitindo hierarquizar o parque e identificar um conjunto de edifícios prioritários para intervenção estrutural. Com base nessa hierarquização técnica das escolas e nas necessidades particulares de cada escola, a Lisboa SRU identificou escolas prioritárias para intervenção estrutural. Entre as diferentes escolas selecionadas, o NCREP ficou responsável pela análise detalhada de dois edifícios representativos da tipologia das Escolas Técnicas (1947–1962), com estruturas mistas de betão armado e alvenaria, em particular a Escola Básica Paula Vicente (EBPV), em Belém, e a Escola Secundária D. Luísa de Gusmão (ESDLG), na Penha de França.

Paralelamente, no âmbito de uma dissertação de mestrado orientada pelo NCREP (Lezaack, 2025), foi desenvolvido um exercício de triagem por Rapid Visual Screening (RVS) aplicado ao parque escolar de Lisboa, com o objetivo de verificar se este método mais expedito, baseado em tipologias estruturais e inspeção visual exterior, consegue replicar as prioridades identificadas pelo estudo do LNEC para um conjunto de 58 escolas antigas. Este exercício não precedeu nem condicionou a decisão de intervenção; foi antes uma investigação metodológica posterior, orientada para avaliar a rastreabilidade do RVS face a uma avaliação analítica de referência.

O presente artigo compara os resultados das três abordagens aplicadas às mesmas duas escolas: o estudo analítico simplificado do LNEC, que fundamentou a priorização; a análise detalhada do NCREP, que a sustenta tecnicamente e fornece a base para o projeto de reforço; e o exercício RVS, que testa a capacidade de um método de triagem mais expedito em identificar os edifícios de maior risco. O objetivo não é hierarquizar as três abordagens em termos de qualidade absoluta, mas caracterizar a sua função específica, as suas limitações e o grau de convergência ou divergência dos respetivos resultados para um mesmo edifício.

2. Estado da arte

A avaliação da vulnerabilidade sísmica de edifícios existentes recorre a uma hierarquia de métodos de complexidade crescente. No nível mais expedito, os métodos de Rapid Visual Screening, de que o FEMA P-154 (FEMA, 2015) será a referência internacional mais difundida, atribuem a cada edifício uma pontuação a partir da inspeção visual exterior, baseada na tipologia estrutural e em modificadores associados a irregularidades, idade e tipo de solo. Metodologias como o RISK-UE LM1 (Mouroux & Le Brun, 2006) partilham o mesmo princípio com um trade-off entre rapidez de aplicação e profundidade do diagnóstico.

Num nível intermédio, os métodos analíticos simplificados, como o RISK-UE LM2 ou as variantes usadas pelo LNEC (Carvalho et al., 2017), recorrem a modelos de complexidade reduzida e análises não lineares estáticas para estimar curvas de capacidade por tipologia. A Capacity Spectrum Method (CSM) prescrita na NP EN 1998-3:2017 e o método N2 (Fajfar, 2000) constituem o quadro analítico de referência.

No nível mais detalhado, exigido pela NP EN 1998-3 para avaliação individual de edifícios existentes, o desempenho sísmico é avaliado em modelos tridimensionais não lineares com leis constitutivas calibradas com ensaios materiais. A aplicação destes métodos a estruturas mistas de betão armado e alvenaria de meados do século XX coloca dificuldades específicas: armaduras em varão liso, ausência de cintagem nas zonas críticas, presença frequente de pilares curtos e heterogeneidade construtiva entre projeto e execução. Em particular, a representação das paredes de alvenaria, desde modelos de bielas equivalentes até elementos sólidos, é determinante para a previsão dos modos de rotura (Magenes & Penna, 2011; pVanin et al., 2017).

3. Avaliação RVS à escala do parque escolar: validação metodológica

3.1 Enquadramento

A avaliação usando RVS descrita nesta secção foi desenvolvida em (Lezaack, 2025), com o objetivo de verificar se um método de Rapid Visual Screening adaptado ao contexto português, aplicado por tipologias estruturais, consegue replicar as prioridades de intervenção identificadas pelo estudo LNEC (Carvalho et al., 2021) para o conjunto das 58 escolas antigas de Lisboa. Trata-se de um exercício de validação retrospetiva, útil para triagens de parques escolares onde a aplicação do método analítico não é viável para a totalidade dos edifícios.

3.2 Caracterização do parque escolar

O parque escolar gerido pelo município de Lisboa é composto por 137 estabelecimentos públicos, . Não existindo um repositório consolidado da informação relativa a estes edifícios, a sua caracterização foi realizada a partir de diversas fontes municipais (Lisboa Interativa), inventários arquitetónicos (Alegre & Heitor 2019) e arquivos de projeto. Adotando 1985 como ponto de corte regulamentar e 2000 como a data limite de renovações estruturais, o parque divide-se em três grupos: 58 escolas antigas (anteriores a 1985 e sem renovação posterior a 2000), 51 escolas renovadas após 2000 e 28 escolas recentes (posteriores a 1985). As 58 escolas antigas constituem o universo de risco potencial mais elevado e forma a população de partida para a triagem descrita nesta secção.

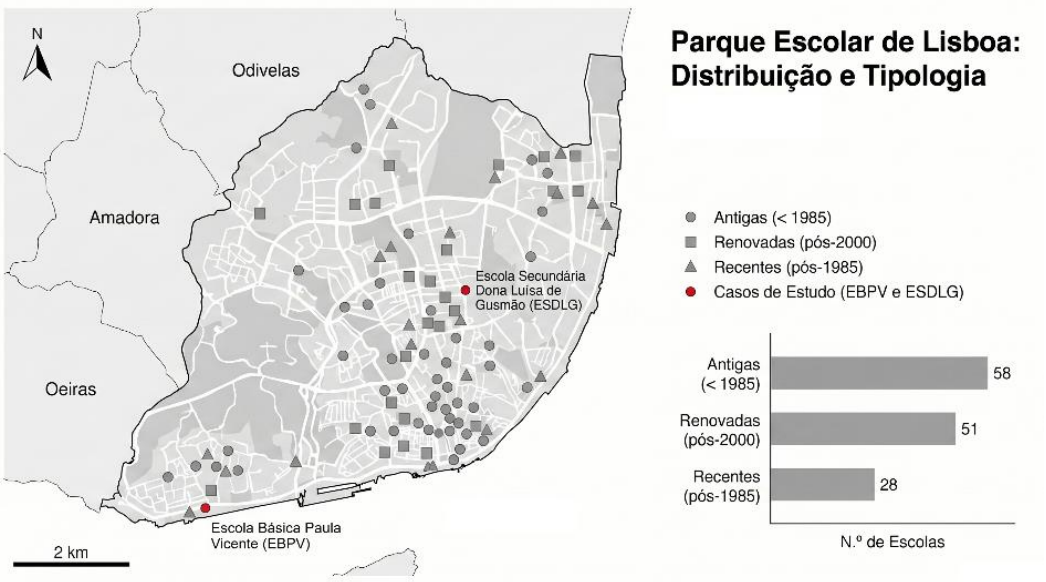

Figura 1 – Mapa de Lisboa com localização das 137 escolas, com identificação da caracterização do parque escolar incluindo EBPV e ESDLG.

3.3 Classificação tipológica e avaliação por RVS

3.3.1 Classificação por tipologia

As 58 escolas antigas foram classificadas em sete tipologias arquitetónicas, Figura 2, com base na aparência exterior, configuração geométrica e contexto histórico-construtivo: Antiga (anterior a 1920, em alvenaria resistente sem normalização), Centenários (1940–1960, do Plano dos Centenários do ensino primário), Técnica (1947–1962, dos planos de ensino técnico), Porticada (1968–1990, em pórticos de betão armado), Bloco 70 - 3×3 (a partir de 1970), Bloco 80 - 3×3 (a partir de 1980) e Outra. A tipologia Técnica - onde se integram a EBPV e a ESDLG - subdivide-se em duas subcategorias: Placa (alvenaria resistente, layout padronizado de 19×62 m) e Porticada-Mista (pórticos de betão armado com paredes de alvenaria de enchimento ou contraventamento). Ambas as escolas alvo do estudo detalhado pertencem a esta segunda subcategoria.

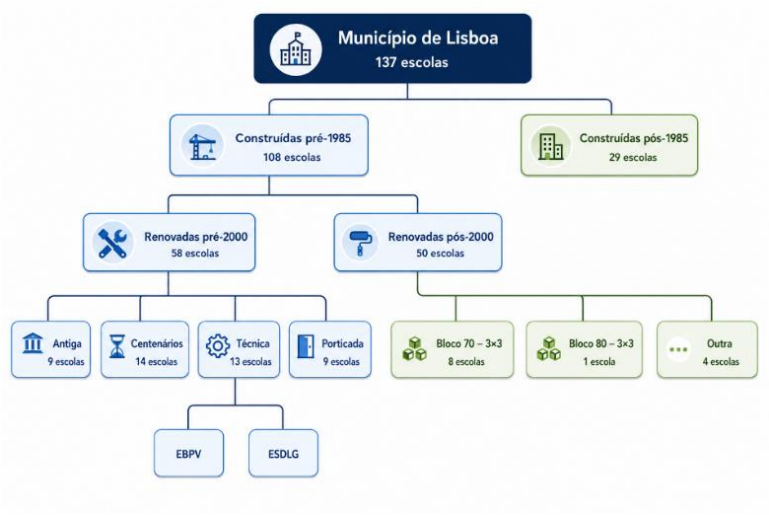

Figura 2 – Classificação das escolas por tipologia.

3.3.2 Avaliação por RVS (Lezaack 2025)

A avaliação RVS aplicou o FEMA P-154 (FEMA 2015), com adaptação ao contexto português. A categoria de sismicidade foi determinada pela aceleração espectral correspondente ao MCE_r, calculada de forma agregada sobre os sismos Tipo 1 (afastado) e Tipo 2 (próximo) da NP EN 1998-1, com fatores corretivos para o período de retorno equivalente. Os valores obtidos ($S_s \approx 1{,}0$ g) colocam Lisboa no limiar entre as classes *High* e *Very High*, optando-se conservadoramente por *High Seismicity*. As escolas técnicas foram classificadas como tipo URM do FEMA (alvenaria não reforçada) por serem as paredes longitudinais de alvenaria a comandar a resposta sísmica, apesar da presença de pórticos de betão armado.

A Figura 3 apresenta a soma média dos modificadores RVS (FEMA P-154) por tipologia estrutural. Valores negativos indicam que os modificadores penalizadores predominam sobre os favoráveis; valores positivos indicam o inverso.

A tipologia Técnica (a vermelho) regista uma soma média de -0.5, coerente com os modificadores negativos na EBPV e na ESDLG. As tipologias Bloco 70-3x3 e Bloco 80-3x3 apresentam os valores mais elevados, refletindo características estruturais mais regulares.

Para a EBPV, foram assinalados sete modificadores penalizadores, dos quais se destacam a presença de *pilotis* e *soft-storey* no piso de cantina, o *plan setback* induzido pela compartimentação por corpos com fundações em socalco e a presença de pilares curtos. Para a ESDLG, foram assinalados seis modificadores, dos quais se destacam o desenvolvimento em encosta, o canto reentrante associado à planta em "L" e a presença de pilares curtos.

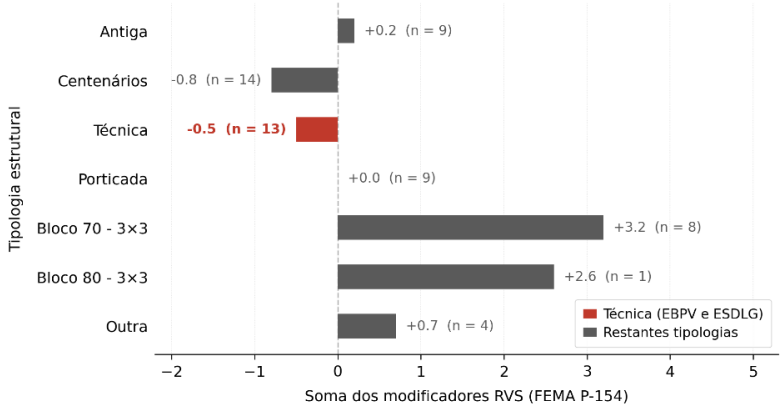

Figura 3 – Resultados da análise RVS por tipologia estrutural: identificação dos grupos prioritários, (Lezaack 2025)

4. Avaliação simplificada: estudo LNEC

4.1 Metodologia

O estudo do LNEC, encomendado pela Câmara Municipal de Lisboa, constitui o instrumento que fundamentou a hierarquização do parque escolar e a identificação das escolas prioritárias para intervenção estrutural. A sua aplicação a 32 escolas de 2.º e 3.º ciclos e secundárias do município (Carvalho et al., 2021) permitiu estimar, para cada edifício, indicadores de risco relativo que sustentaram as decisões de priorização por parte da Câmara Municipal e, subsequentemente, da Lisboa SRU. A EBPV e a ESDLG integram o conjunto de escolas identificadas como prioritárias por este estudo; a decisão de avançar para análise detalhada nestas duas escolas, no âmbito da tipologia Técnica, resultou diretamente dessa priorização.

A metodologia organiza-se em seis passos: (i) tipificação em tipologias estruturais; (ii) caracterização da ação sísmica por cruzamento com o mapa regional de colunas de solo da AML (Campos Costa et al., 2010), sem ensaios geotécnicos específicos; (iii) análise não linear estática (CSM); (iv) avaliação do desempenho face a quatro estados limite; (v) cálculo de perdas esperadas; e (vi) elaboração de ficha individual por escola.

A análise estrutural é realizada em *SeismoStruct*, com elementos de barra de plasticidade distribuída e leis constitutivas de Mander para o betão e Menegotto-Pinto para o aço. Para edifícios mistos, o LNEC adota o modelo do pórtico plano transversal, no qual as paredes de alvenaria são representadas por bielas biarticuladas com módulo de elasticidade de 2,0 GPa, sob o pressuposto de manterem a integridade durante o sismo.

4.2 Resultados para a EBPV e ESDLG

A EBPV é classificada na tipologia “Mista BA” e enquadrada em solo tipo A (rocha sem amplificação, com base no mapa regional do LNEC). Os períodos de retorno globais para os quatro estados limite são, respetivamente, 6 anos (EL1), 14 anos (EL2), 4085 anos (EL3) e 8415 anos (EL4) - sendo os mais baixos para EL1 e EL2 entre as 32 escolas analisadas. O LNEC atribui o desempenho desfavorável ao mecanismo transversal, em que as paredes de alvenaria descarregam apenas verticalmente sobre os pórticos.

A ESDLG é classificada na mesma tipologia, mas em solo tipo H, com amplificação calculada ao nível do substrato rochoso. Os períodos de retorno globais são 88 anos (EL1), 181 anos (EL2), 3110 anos (EL3) e superiores a 10 000 anos (EL4); a perda anual esperada é de 0,09 % e a perda em 50 anos é de 4,06 %, com 18,8 dias de interdição e 621 alunos×mês deslocados. O LNEC sinaliza como vulnerabilidade dominante a ausência de vigas transversais que assegurem o funcionamento em pórtico nessa direção, com os pilares a responder praticamente como consolas, e recomenda reforço focado no aumento de resistência transversal.

4.3 Limitações da abordagem simplificada

A abordagem LNEC é adequada para a hierarquização à escala do parque, mas apresenta limitações que apenas se tornam visíveis face a uma análise de detalhe: (1) a classificação cartográfica atribuiu solo tipo A à EBPV, quando a campanha SPT do NCREP demonstrou tipo C — espetros significativamente mais exigentes; (2) o modelo plano assume alvenaria íntegra, contrariamente ao mecanismo crítico de rotura por corte identificado; (3) materiais genéricos (C16/20, A250) divergem dos experimentais. Os ensaios *in situ* e laboratoriais obtiveram valores distintos em ambas as escolas.

Estas limitações não desqualificam o estudo LNEC no contexto para que foi concebido: hierarquizar o parque à escala municipal e fundamentar decisões de priorização. Indicam, porém, que os resultados não devem ser interpretados como avaliações absolutas de segurança individual.

5. Análise detalhada das escolas EBPV e ESDLG

5.1 Caracterização construtiva das escolas

A EBPV, Figura 4a, na Rua Gonçalves Zarco, em Belém, organiza-se em três corpos interligados: Corpo A - Edifício de Aulas; Corpo B - Ginásio; Corpo C - Intermédio. A estrutura é mista, com pórticos de betão armado, elementos pontuais em betão simples nas fachadas, paredes de alvenaria de pedra calcária e de tijolo cerâmico, e lajes aligeiradas com elementos cerâmicos.

A ESDLG, Figura 4b, com projeto de 1955 e inauguração em 1958, na Rua da Penha de França, organiza-se também em três corpos interligados: Corpo A - Edifício Principal, com planta em "L" e cinco pisos incluindo o desvão da cobertura; Corpo B - Ginásio, com planta retangular e três pisos; Corpo C - Ligação, com formato trapezoidal e dois pisos. A estrutura dos Corpos A, B e C é mista, com pilares de betão armado e simples nas fachadas, paredes de alvenaria de pedra calcária e de tijolo cerâmico, e lajes maioritariamente aligeiradas.

Corpo A e C | Corpo B | Corpo C

(a) Escola EBPV

(b) Escola ESDLG

Figura 4 – Resultados da análise RVS por tipologia estrutural: identificação dos grupos prioritários, (Lezaack 2025)

5.2 Inspeção e diagnóstico

A campanha de inspeção e diagnóstico estrutural foi a primeira fase do trabalho em ambas as escolas, abrangendo: a confrontação dos elementos de arquivo com o edificado existente; a inspeção visual com registo de anomalias e danos; a abertura de janelas de sondagem para caracterização de elementos ocultos; e a realização de ensaios in situ e laboratoriais.

Figura 5 – Ensaios e sondagens de caracterização da estrutura.

A confrontação com os elementos de arquivo da EBPV revelou correspondência global de ~38 %: apenas 16,7 % das secções de pilares correspondem ao projeto, e 50 a 64 % dos elementos horizontais. As discordâncias críticas foram: (i) fundações em alvenaria de pedra, previstas como sapatas de BA; (ii) cobertura em lajes aligeiradas, prevista em madeira.

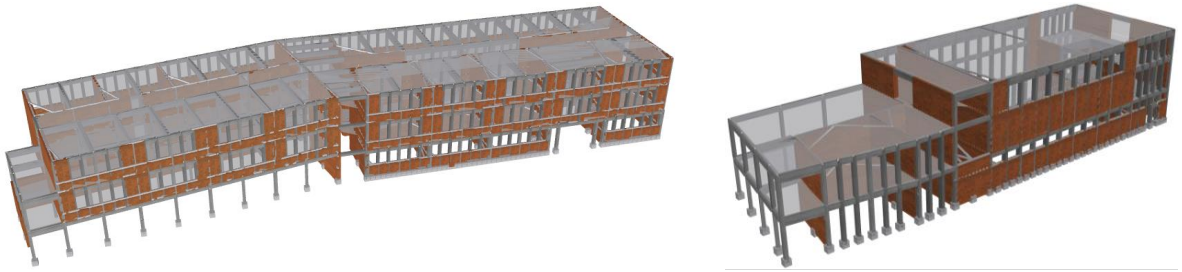
Em termos gerais, ambas as estruturas apresentam bom estado de conservação, com danos pontuais que não comprometem a estabilidade global. Na EBPV, destacam-se: corrosão de armaduras nos varandins e cornijas; manchas de humidade; e deformação das lajes de cobertura. Na ESDLG, os danos de maior relevância são as manchas de humidade nas coberturas e o ataque por fungos xilófagos na estrutura de madeira.

5.2.1 Caracterização material

A campanha experimental abrangeu, em ambas as escolas, ensaios de compressão em carotes de betão, ensaios de tração em armaduras, ensaios esclerométricos com esclerómetro de Schmidt, ensaios de compressão em provetes de pedra calcária e determinação de densidade e porosidade aberta. A Tabela 1 sintetiza os resultados, com confronto com os valores de referência do RBA-1935 (17.7 MPa para o betão; 363.0 MPa para o aço).

A resistência do betão é próxima do valor regulamentar em ambos os edifícios (EBPV: 18,3 MPa; ESDLG: 16,8 MPa). A resistência das armaduras coloca a EBPV acima da referência (411,0 MPa) e a ESDLG na vizinhança desta (362,5 MPa). A pedra calcária da ESDLG apresenta resistência substancialmente superior à da EBPV, refletindo origens petrográficas distintas, Tabela 1.

Tabela 1 - Caracterização material: EBPV e ESDLG (valores médios).

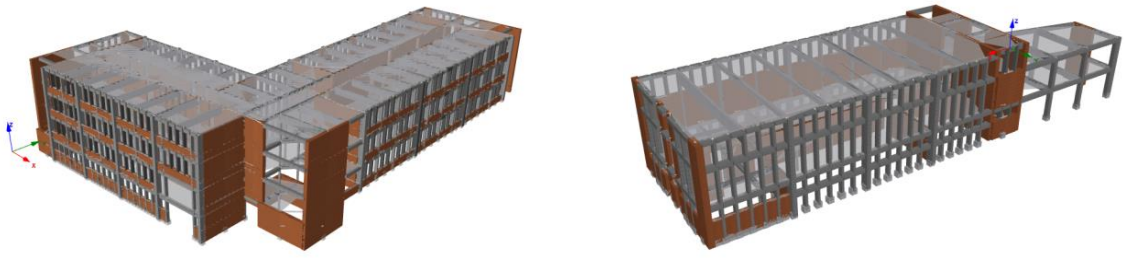


Material	Propriedade	Referência (RBA-1935)	EBPV	ESDLG
Betão armado				
Betão	f_{cm} – resist. compressão [MPa]	17.7	18.3	16.8
Aço (armadura)	f_y – resist. tração [MPa]	363.0	411.0	362.5
Alvenaria de pedra calcária				
Pedra calcária	f_c – resist. compressão [MPa]	-	37.9	62.1
	ρ – densidade aparente [kg/m^3]	-	2348	2239-2557

5.3 Modelação numérica e análise não linear

Ambas as escolas foram analisadas adotando análises estáticas não lineares (*pushover*) integradas com o método N2/CSM da NP EN 1998-3. A ação sísmica foi quantificada para Lisboa (Tipo 1, zona 1.3; Tipo 2, zona 2.3) em solo tipo C, classe de importância III, coeficiente de redução 0.90 (Portaria n.º 302/2019; foi adotado nível de conhecimento normal (KL2) com fator de confiança CF = 1.20). Foram verificados os três estados limite (DL, SD, NC) com duas distribuições de cargas horizontais e excentricidades acidentais.

As escolas foram modeladas no *software SeismoStruct*. Os pilares e vigas em betão armado foram representados por elementos de barra de fibras com modelos de Mander et al. para o betão e Menegotto-Pinto para o aço. As paredes resistentes de alvenaria foram modeladas através elementos de barra (*frame*) que simulam o comportamento no plano de paredes, nembos e lintéis de alvenaria quando sujeitos a forças horizontais (como é o caso dos sismos).

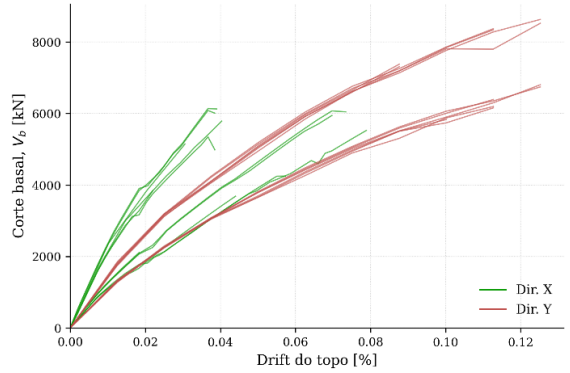


Na escola EBPV, o Corpo B foi modelado isoladamente, enquanto os corpos A e C foram modelados de forma conjunta, Figura 6.

Corpo A e Corpo C Corpo B

Figura 6 – Modelos numéricos para análise da EBPV.

Já na escola ESDLG, o Corpo A foi modelado isoladamente, enquanto os Corpos B e C foram modelados de forma conjunta, Figura 7. As simplificações de ligação de corpos foram assumidas devido à fraca ligação nas zonas de transição entre os corpos.



Corpo A Corpo B e Corpo C

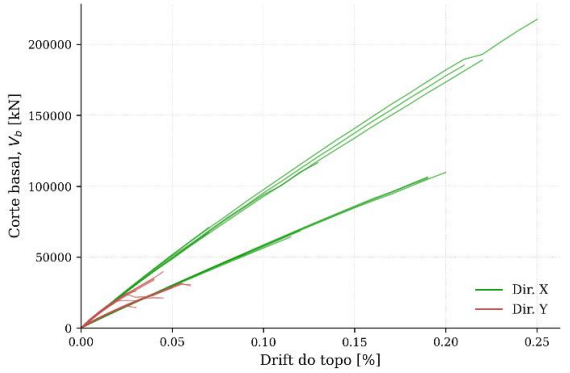


Figura 7 – Modelos numéricos para análise da ESDLG.

Os modelos das escolas anteriormente apresentados permitiram obter as curvas de capacidade das escolas, as quais se apresentam na Figura 8, que posteriormente serviram para a verificação de segurança das estruturas.

EBPV

ESDLG

(c) Corpo A (direção X e Y)

(d) Corpo B e Corpo C (direção X e Y)

Figura 8 – Curvas de capacidade das escolas.

5.4 Resultados da análise não linear

Em ambas as escolas, a Ação Sísmica Tipo 1 revelou-se condicionante. A Tabela 2 apresenta os *drifts* de capacidade e os *drifts-alvo* para os três estados limite, em cada corpo e direção analisada. O único caso de verificação positiva é o Corpo B - Ginásio da EBPV, quando analisado na direção Y para o estado SD; em todos os restantes casos, a capacidade é significativamente inferior ao alvo regulamentar.

Tabela 2 – Drifts no topo (%): capacidade vs alvo AST1, (estados limite DL, SD e NC).

Corpo	Direção	DL		SD		NC	
		Cap.	Alvo	Cap.	Alvo	Cap.	Alvo
EBPV							
Corpo B	X	0.008	0.042	0.060	0.143	0.080	0.232
Corpo B	Y	0.013	0.019	0.075 ✓	0.065	0.100	0.105
Corpos A + C	X	0.005	0.016	0.086	0.057	0.115	0.092
Corpos A + C	Y	0.005	0.015	0.023	0.138	0.030	0.257

EBPV							
Corpo A	X	0.010	0.068	0.045	0.277	0.060	0.460
Corpo A	Y	0.010	0.056	0.045	0.260	0.060	0.443
Corpos B + C	X	0.020	0.046	0.105	0.165	0.140	0.198
Corpos B + C	Y	0.010	0.051	0.083	0.187	0.110	0.218

✓Estado limite verificado; todos os restantes casos não verificados.

ESDLG - mecanismos de rotura

No Corpo A, o comportamento é predominantemente frágil em ambas as direções, com *drifts* de capacidade (NC) de apenas 0,060%. A planta em `L` introduz excentricidades que mobilizam danos nos elementos transversais à ação, concentrando as roturas por corte nas paredes de alvenaria de maior rigidez e nos pilares das fachadas.

EBPV - mecanismos de rotura

No Corpo B - Ginásio, a direção X é condicionante: a análise regista rotura simultânea por corte em paredes de alvenaria e em pilares de betão armado logo ao nível do estado DL, com *drifts* de capacidade (0,008 %) muito inferiores ao alvo regulamentar (0,042 %). Na direção transversal (Y), este é o único corpo que verifica o estado SD (capacidade 0,075 % vs. alvo 0,065 %), sendo a rotura dominada pelas paredes de alvenaria.

No edifício principal (Corpo A e C) a direção Y é a mais condicionante, os *drifts* de capacidade são de 0,005 % (DL), 0,023 % (SD) e 0,030 % (NC), face a alvos de 0,015 %, 0,138% e 0,257%. Na **Figura 9**, apresenta-se um exemplo dos danos em elementos estruturais que compõem esta escola.

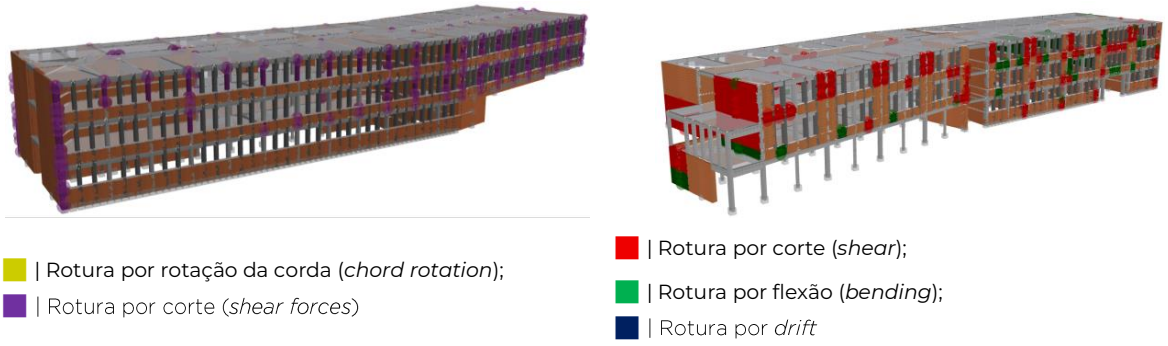

Figura 9 – Danos nos elementos estruturais do Corpo A e C (EBPV) no final da análise pushover (último step antes da rotura) na direção transversal (Y) - AST1.

6. Perspetiva do dono de obra: SRU Lisboa

A Lisboa SRU é uma empresa pública municipal da CML com a missão de promover a reabilitação urbana de equipamentos, habitação e espaço público na Área de Reabilitação Urbana (ARU) de Lisboa.

A intervenção visa adequar as escolas aos padrões de segurança, conforto e funcionalidade definidos pela Carta Educativa da CML e pelo Ministério da Educação.

No âmbito do 5.º Contrato de Mandato – Programa Escolas e Creches, a CML mandatou a Lisboa SRU para intervir em sete escolas do concelho, incluindo a ESDLG e a EBPV. Para cada escola foram elaborados os Relatórios de Inspeção e Diagnóstico Estrutural e de Avaliação da Vulnerabilidade Sísmica (Portaria n.º 302/2019).

Paralelamente, foram lançados concursos de conceção para ambas as escolas. Os projetos, em fase de Estudo Prévio, serão desenvolvidos em BIM; as estratégias de reforço sísmico estão em definição, Figura 10.

(a) EBPV (b) ESDLG

Figura 10 – Projetos em fase de Estudo Prévio.

7. Conclusões

O artigo documentou a avaliação sísmica de duas escolas técnicas de Lisboa (EBPV e ESDLG) com três abordagens: a avaliação simplificada do LNEC (Carvalho et al., 2021), que hierarquizou o parque e fundamentou a seleção para intervenção pela Lisboa SRU; a análise detalhada do NCREP (NCREP, 2025a, 2025b) segundo a NP EN 1998-3 para o projeto de reforço; e RVS por tipologias (Lezaack, 2025) como investigação metodológica.

A comparação principal confronta o estudo simplificado do LNEC com a análise detalhada. Qualitativamente, ambas identificam as escolas como vulneráveis e urgentes; quantitativamente, divergem em três fatores: solo tipo A (cartografia) vs. tipo C (SPT), alvenaria íntegra vs. mecanismo de corte, e pórtico plano sem efeitos torsionais. O LNEC reporta TR(EL3) de 4085 e 3110 anos; o NCREP evidencia rácios capacidade/exigência de 1:5 a 1:10.

O modelo macroescala é adequado para estimar indicadores relativos de vulnerabilidade, mas os seus resultados absolutos não podem fundamentar avaliações individuais de segurança; para os edifícios priorizados, a análise de detalhe é necessária antes de qualquer decisão de intervenção.

A comparação com o LNEC demonstra que o RVS por tipologia identifica os mesmos edifícios prioritários, sugerindo potencial de aplicação a parques mais vastos, sem eliminar a necessidade da análise de detalhe.

Agradecimentos

Os autores agradecem à Lisboa SRU - Sociedade de Reabilitação Urbana E.M., promotora dos estudos de inspeção e diagnóstico estrutural e dos relatórios de avaliação da vulnerabilidade sísmica das duas escolas, pela colaboração ao longo do desenvolvimento dos trabalhos. Agradecem ainda à Câmara Municipal de Lisboa e ao Laboratório Nacional de Engenharia Civil pelo acesso aos resultados do estudo de avaliação da vulnerabilidade sísmica do parque escolar de Lisboa. A contribuição da Eng.ª Alice Lezaack, no âmbito da sua dissertação de mestrado, é igualmente reconhecida.

Abstract: The climate emergency has repositioned the construction sector at the center of global mitigation strategies, since the built environment accounts for a substantial share of energy consumption and greenhouse gas emissions. Historic buildings, although essential to urban memory, often present limitations in energy performance, requiring solutions that reconcile efficiency, conservation, and reductions in embodied carbon. In this context, retrofit stands out as an environmentally preferable alternative to replacing the existing building stock. This article analyzes the Bernardo Mascarenhas Cultural Center (BMCC), in Juiz de Fora, Minas Gerais, through a technical and heritage diagnosis, intrinsic and extrinsic inspections, and a qualitative matrix of indicators. The adopted approach is technical-qualitative and integrated, rather than a quantitative experimental validation. The results indicate potential for environmental and functional improvement associated with the preservation of the existing structure, the use of reversible solutions, and the maintenance of lower-impact components. The study concludes that retrofit can support the ecological transition of built heritage, provided it is guided by compatibility, reversibility, minimal intervention, and, in future stages, by measurements and simulations capable of quantifying energy and environmental gains.

Keywords: Sustainable retrofit. Case study. Historic buildings. Built heritage. Urban regeneration.

1. Introduction

The climate emergency and the transition toward sustainable cities require the construction sector to contribute effectively to the mitigation of environmental impacts and to the decarbonization of the built environment (IPCC (2022), OECD (2022)). This demand is related to the sector's high energy consumption and greenhouse gas emissions, which represent a substantial share of global energy-related CO_2 emissions (IEA (2023), UNEP (2023)). It is therefore necessary to connect energy efficiency, reductions in embodied carbon, and the preservation of the existing building stock.

Historic buildings, although essential to urban memory, often present energy performance levels below contemporary requirements (Webb (2017), Broström et al. (2022)), forming a relevant field for scientific and technical intervention (Ma et al. (2023)).

In this context, retrofit - understood as the upgrading and modernization of existing buildings through sustainability-oriented interventions - emerges as one of the most responsible strategies for supporting carbon neutrality goals, especially when compared with demolition and new construction (De Wolf et al. (2017), Crawford et al. (2019); Liu et al. (2023)).

The World Economic Forum (WEF, 2023) indicates that adapting an existing building can generate 50% to 75% less carbon than constructing an equivalent building from scratch. This perspective reinforces the idea that the adaptive conservation of existing stock tends to be environmentally preferable to disposal and replacement. Accordingly, studies on embodied carbon argue that existing buildings should be treated as carbon reservoirs whose potential should be preserved whenever possible (Pomponi and Moncaster (2016)).

It must be emphasized, however, that inappropriate interventions can cause irreversible losses to built heritage, both in its material and symbolic dimensions. The main international guidelines recommend that any alteration should observe criteria of compatibility, reversibility, and minimal intervention (McCaig et al. (2018); Luo et al. (2024)), in order to reduce energy demand and improve indoor environmental conditions without compromising the historical integrity of buildings (ICOMOS (2021)).

Lucchi (2022) shows that the combination of non-intrusive monitoring and integrated performance models contributes to safer interventions in heritage buildings. In this field, the systemic reading of the building, or integrated approach, has become consolidated through the Energy Retrofit Hierarchy, which prioritizes the reduction of loads before interventions in the envelope and the adoption of active systems.

Decision-support methods have also expanded in retrofit processes, including multi-criteria assessments (MCDA/MCDM), AHP, TOPSIS, ELECTRE, and SAW, which enable alternatives to be compared according to energy, environmental, heritage, and economic criteria (Zavadskas et al. (2015); UN-HABITAT (2022); Saad et al. (2023)). Although this article does not apply multi-criteria modelling or energy simulations, these references support the organization of indicators and the integrated reading of the case study.

Within this framework, retrofit should be understood as a central strategy for sustainable rehabilitation, capable of articulating technological innovation, energy efficiency, and cultural preservation. In the Brazilian context, this discussion becomes particularly relevant when focused on symbolic buildings such as the Bernardo Mascarenhas Cultural Center (BMCC), located in Juiz de Fora, Minas Gerais, which is the object of this study.

The objective of this paper is to analyze, through a technical-qualitative case study, the potential of retrofit as an instrument for ecological transition in the built environment, relating heritage conservation, environmental performance, and urban sustainability. The analysis seeks to identify opportunities and limitations in the existing interventions, without generalizing the results beyond the evidence observed in the BMCC case.

2. Bernardo Mascarenhas Cultural Center (BMCC)

The Bernardo Mascarenhas Cultural Center (Figure 1) is part of a built complex of high historical, architectural, and symbolic relevance to the city of Juiz de Fora, in Minas Gerais, Brazil. Its origin dates back to the Bernardo Mascarenhas Textile Company, inaugurated on May 7, 1888. The company played a central role in regional industrialization and in the urban consolidation of the municipality at the end of the nineteenth century (Barbosa et al. (2016)).

Figure 1 - Bernardo Mascarenhas Cultural Center (Barbosa et al. (2016)).

Croce (2021) observes that the installation of the factory was decisive for the modernization of Juiz de Fora and enabled the construction of the Marmelos Hydroelectric Power Plant, designed in 1889 and considered the first hydroelectric power plant in Latin America, revealing the connection between industry, technological innovation, and urban expansion.

The BMCC therefore constitutes a heritage asset with expressive historical, architectural, and social materiality. The institutional recognition of the heritage value of the complex occurred in the 1980s through Decree-Law No. 2,866/1983 (JFCH (1983)). In 1984, after the end of industrial activities, the complex underwent several interventions and was protected by municipal listing, which requires the preservation of the façades and original volumetry while allowing internal adaptations compatible with new uses (Barbosa et al. (2016)).

The architectural complex has an approximate area of 12,498 m², in addition to spaces intended for open circulation, civic squares, and urban support areas. It is currently composed of four main buildings (Figure 2): the BMCC (1); the Municipal Market (MM) (2); the Municipal Department of Education, including the library (MDE) (3); and the Youth and Adult Education Center (EC) (4) (JFCH (1983)).

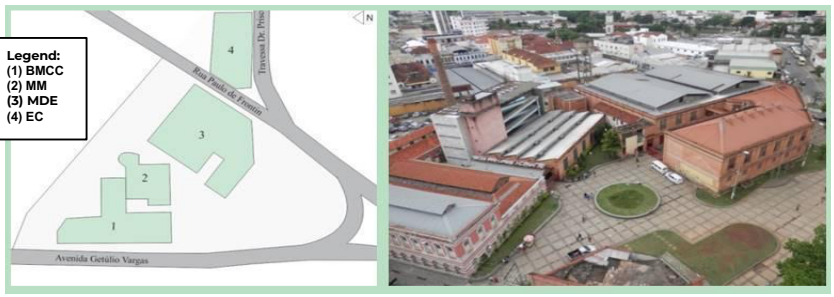

Figure 2 - BMCC sketch (Barbosa et al. (2016)).

The transformation of the former factory complex into a cultural center and public facilities reveals a paradigmatic shift in the understanding of industrial heritage, now recognized not only as a historical remnant but also as active support for contemporary social, educational, and cultural uses. Nevertheless, the intervention stages occurred heterogeneously, resulting in different levels of compliance with sustainability guidelines, environmental comfort, and energy efficiency (Barbosa et al. (2016)).

3. Methodological procedure

Webb (2017) emphasizes that interventions in historic buildings require a holistic reading, because such buildings behave as complex systems in which changes to one element can significantly affect the others. Broström et al. (2022) state that energy-efficiency strategies in historic buildings must balance technical performance and preservation, avoiding risks related to moisture and material degradation.

In this context, the methodological procedure was organized into four stages:

1 - Technical and heritage diagnosis: technical and historical survey of the BMCC architectural project.

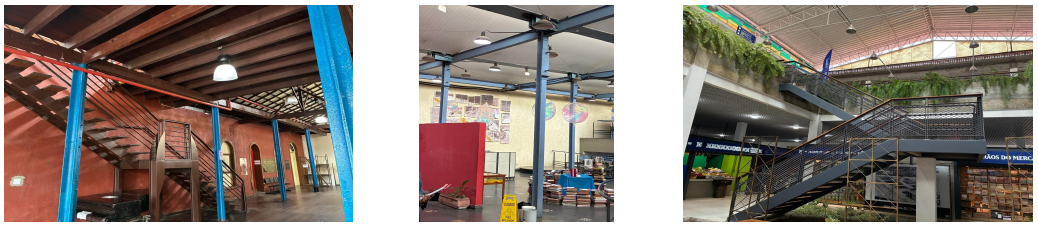
2 - Characterization of construction materials and components: carried out in loco through intrinsic inspection (habitability, safety, sustainability, and social responsibility) and extrinsic inspection (anomalies and maintenance services).

3 - Evaluation and prioritization of retrofit: identification of sustainability indicators, including energy efficiency, potential for CO_2 emission reduction, management and maintenance, and the performance of reversible solutions already adopted.

4 - Discussion of the data obtained and indication of more appropriate solutions to strengthen the sustainability of the complex.

The data analysis for stages 1 and 2 was conducted as a technical-qualitative assessment based on building inspection and objective verification of the items evaluated. For the profiles of intrinsic inspection, extrinsic inspection, energy efficiency, potential CO_2 reduction, maintenance, and performance of reversible solutions, yes/no responses were recorded in Tables 1 to 6.

A color-coded classification was then adopted: a green profile for satisfactory performance when more than 90% of the sub-items were met; a yellow profile when 75% to 90% were met, indicating specific imbalances; and a red profile when less than 75% were met, indicating unsatisfactory performance and priority challenges for sustainability (Table 7).



This procedure enabled a preliminary and comparable reading of the sustainable profile of the interventions observed at the BMCC. As a qualitative diagnostic matrix, the results should be understood as support for decision-making and for defining future monitoring priorities, rather than as quantitative proof of energy savings or measured CO_2 reductions.

4. Results and discussion

4.1 Technical and heritage diagnosis:

From an architectural perspective, the BMCC presents a symmetrical composition, a regular rhythm of arched openings, and a language typical of industrial architecture, with exposed solid brick masonry and large spans designed to favor natural lighting and ventilation (Croce (2021)). These characteristics give the building relevant passive potential for environmental comfort.

The restoration carried out in the 1990s, after the partial structural collapse of the building, adopted metal profiles as the main consolidation solution (Figure 3). This strategy is technically appropriate from both heritage and environmental perspectives, since steel offers durability, recyclability, formal distinction from the original structure, and a high degree of reversibility, meeting contemporary principles for the sustainable rehabilitation of historic buildings (Gomide et al. (2019); De Wolf et al. (2020); ICOMOS (2021)).

BMCC MDE MM

Figure 3 - Metal profiles.

Regarding social and cultural indicators, the BMCC stands out for its strong community involvement, consolidating itself as a space for cultural production, education, and access to collective memory, thereby reinforcing its contribution to social sustainability (Croce (2021)). The technical and heritage assessment indicates that, although the building has successfully preserved its historical identity and reactivated its functionality, requalification strategies need to be improved, especially regarding energy efficiency, potential CO_2 reduction, management and maintenance, and the enhancement of reversible solutions already adopted.

4.2. Inspection *in loco*

The technical inspection was based on the integration of intrinsic and extrinsic inspections, as these make it possible to assess the actual conditions of use, conservation, and performance of the building. In accordance with Brazilian standards, such as NBR 16747 (2020), NBR 5674 (2024), and NBR 15575 (2025), the procedure supported the identification of anomalies, the evaluation of the state of conservation of building systems and the envelope, and the

verification of compatibility between use and performance. Extrinsic inspection, based on systematic observation of façades, construction interfaces, and the immediate surroundings, was essential for diagnosing pathological manifestations and defining intervention strategies compatible with existing buildings (Morais and Lordsleem (2019); Hasselmann and Norat (2023); Pereira and Silva (2024); Tavares et al. (2024); Dabous and Hosny (2025)). Tables 1 and 2 present the results.

The analysis of Tables 1 and 2 indicates that the intrinsic and extrinsic inspections recorded satisfactory conditions of habitability, environmental performance, functionality, and structural safety, with no relevant structural anomalies. Thermal comfort through natural ventilation, lighting, indoor air quality, and the reuse of metal profiles from railway tracks stand out positively, demonstrating strategies aligned with durability, material reuse, and the reduction of environmental impacts. The main weaknesses are related to seasonal rising damp, localized detachment of façade coating, and the absence of properly marked escape routes, despite the presence of basic firefighting equipment. Overall, the results indicate favorable conditions for the implementation of sustainable retrofit strategies, provided they are guided by compatibility, reversibility, and the improvement of safety and maintenance management.

Table 1 - Intrinsic inspection.

Requisite	Index	Check parameter	BMCC	MDE	MM
			Inspection		
Habitability	Tightness	Moisture (permeation and air)	No	No	No
		Rising damp (seasonal)	Yes	Yes	No
	Thermal comfort	Cross ventilation	Yes 1	Yes	Yes
		Shading	Yes	Yes	Yes
	Acoustic comfort	Noise insulation	Yes 2	Yes	Yes
	Lighting comfort	Natural	Yes	Yes 4	Yes
		Artificial	Yes	Yes 5	Yes 9
Health	Indoor air quality	Pollutants and microorganisms	No	No	No
Sustainability	Durability	Maintenance service	Yes	Yes	Yes
	Maintainability	Ease of maintenance	Yes	Yes 6	Yes 10
	Environmental impact	Selection of building materials	Yes 3	Yes	Yes
Safety	Structure	Cracks and deformation	No	Yes 7	No
	Fire prevention	Passive protection (fire door, escape route, etc.)	No	No 8	Yes 11
		Active protection (fire extinguishers, sprinklers, etc.)	Yes	Yes	Yes
	Accessibility	Universal criteria	Yes	Yes	Yes

[1]Air-conditioning system in the theater; [2]Limited to the theater; [3]Durable materials and reuse of waste and rejects; [4]Dependence on artificial lighting in the reading room; [5]Suspended artificial lighting, with industrial luminaires distributed along the structure; [6]Periodic maintenance; [7]The coating presents diffuse microcracking with a low degree of severity; [8]There is a risk of entrapment because alternative exit routes are absent and the main door is

the only means of evacuation; [9]The modular grid ceiling allows direct integration with recessed artificial lighting; [10]Execution of maintenance services according to guidelines established in the manual; [11]The signage is legible, contrasting, and well positioned.

Table 2 - Extrinsic inspection.

Requisite	Index	Check parameter	BMCC	MDE	MM
			Inspection		
Durability	Anomalies	Crack (dimension < 0.5 mm)	Yes	No	No
		Crack (0.5 < dimension < 1.5 mm)	No	No	No
		Coating detachment	Yes 1	Yes	No
		Moisture	No	No	Yes

1 Localized coating detachment.

4.3. Sustainability indicators

The evaluation of indicators related to energy efficiency, potential CO_2 emission reduction, management of maintenance services, and performance of reversible solutions is based on contemporary approaches that understand the existing building as an integrated system throughout its life cycle. Recent studies show that retrofit strategies oriented toward energy performance and embodied-carbon mitigation offer significant environmental advantages when compared with replacement of the building stock (Croce (2021); UN-HABITAT (2022)). The literature also shows that maintenance management is essential for the stability of operational performance, while reversible and adaptable solutions contribute to the reduction of future impacts, risk mitigation, and extension of the service life of historic buildings (Opher et al. (2021), IEA (2022); Wu and Shen (2023)). Tables 3 to 6 present the data collected.

The analysis of the requisites presented in Tables 3 to 6 shows an overall performance favorable to sustainable retrofitting, with positive results especially in the potential for CO_2 reduction, in management and maintenance, and in the performance of reversible solutions. The preservation of the existing structure, the adoption of non-invasive interventions, the use of low-carbon materials, and the high reversibility and spatial adaptability of the adopted solutions stand out. In summary, the results indicate that the building has consistent technical conditions for the progressive improvement of its environmental performance, while preserving the principles of compatibility, reversibility, and minimal intervention.

		Removable	Yes	Yes	Yes
Visual	Flexibility	Layout	Yes	Yes	Yes

Finally, an integrated analysis of the BMCC was carried out based on the data evaluated in Tables 1 to 6. For this purpose, a color-coded classification was used, synthesizing performance into three levels: green (satisfactory, with more than 90% of favorable sub-items), yellow (intermediate, with 75% to 90% of favorable sub-items), and red (unsatisfactory, with less than 75% of favorable sub-items). This procedure allows a systemic reading, comparison among indicators, and prioritization of retrofit actions oriented toward sustainability and performance, as shown in Table 7.

The overall performance of the BMCC shows a predominance of green profiles in habitability, health, sustainability, potential CO_2 reduction, management and maintenance services, and performance of reversible solutions. Yellow profiles are concentrated in specific aspects of safety and durability, such as seasonal moisture, localized coating defects, and escape-route limitations. This profile indicates that the building presents favorable technical conditions for sustainable retrofit, allowing the progressive improvement of environmental and functional

performance, provided that future actions are guided by compatibility, reversibility, minimal intervention, and strengthened maintenance management.

4.4. Methodological scope and implications

The results should be read within the scope of the adopted method. The inspection matrix does not replace energy monitoring, dynamic thermal simulation, or life-cycle carbon accounting; rather, it organizes field evidence into a structured diagnostic capable of indicating which aspects of the building already support sustainable retrofit and which aspects require further verification. This distinction is relevant because historic buildings frequently combine architectural value, material heterogeneity, and limitations on intrusive testing. In such contexts, an initial qualitative assessment can reduce decision uncertainty, identify risks, and guide the selection of subsequent quantitative procedures without compromising the heritage fabric.

The contribution of the BMCC case therefore lies in connecting conservation principles with operational performance criteria in a transparent and reproducible manner. The green profiles indicate components and practices that can be maintained or strengthened, such as the preservation of the existing structure, the reuse of materials, and reversible fastening systems. The yellow profiles identify priorities for targeted action, especially moisture control, façade-maintenance routines, and escape-route management. By translating these observations into retrofit priorities, the study supports a gradual intervention strategy compatible with heritage conservation, avoiding overgeneralized claims about decarbonization while still demonstrating how the existing building can act as a platform for environmental improvement.

For future stages, the diagnostic framework should be complemented by quantitative indicators, including pre- and post-intervention energy consumption, indoor temperature and humidity monitoring, envelope-performance assessment, operational-carbon estimates, and embodied-carbon scenarios for alternative retrofit measures. Such data would allow the observed potential for CO_2 reduction to be converted into measurable performance gains and would make the case, more directly comparable with international retrofit studies. The present analysis is therefore positioned as a necessary first step in a broader research sequence, establishing the technical, heritage, and management basis required for more robust environmental evaluation.

5. Conclusions

This study showed that the retrofit of historic buildings can constitute a relevant strategy for the ecological transition of the built environment by reconciling heritage preservation, energy efficiency, potential CO_2 emission reduction, and improved performance in use. The analysis of the Bernardo Mascarenhas Cultural Center (BMCC) indicates that existing buildings, especially those with historical value, should be understood as environmental and cultural assets whose reuse offers substantial advantages when compared with the replacement of the existing building stock.

The integrated application of intrinsic and extrinsic inspections, based on Brazilian standards, made it possible to develop a systemic reading of the building in use, identifying anomalies, weaknesses, and potentialities. The results indicate satisfactory overall performance in habitability, structural safety, functionality, social responsibility, and the performance of reversible solutions, highlighting the reuse of metal profiles from railway tracks, the preservation of the original structure, and the adoption of compatible and non-invasive interventions. With regard to the sustainability indicators analyzed, a particularly positive performance was observed in the potential for CO_2 reduction, associated with the retention of existing components, the use of lower-impact materials, and the extension of the building's service life. Management and maintenance services proved functional, with operational clarity and ease of inspection and repair. Conversely, energy efficiency still presents opportunities for improvement.

It is therefore concluded that the BMCC presents technical and constructive conditions favorable to the consolidation of sustainable retrofit strategies, provided that future interventions are guided by the principles of compatibility, reversibility, minimal intervention, and life-cycle management. The study also demonstrates the need to complement qualitative diagnostic matrices with quantitative procedures in subsequent stages, including energy monitoring, thermal simulation, life-cycle carbon assessment, and scenario analysis, so that the environmental gains associated with retrofit can be measured and compared more robustly.

Abstract: In educational buildings, particularly universities, energy consumption is linked to needs such as air conditioning, lighting, and equipment use. Approximately, 40% of the total consumption, particularly in warm regions is linked to internal heat gains (high occupancy, equipment, lighting, and solar radiation). Artificial lighting follows as another major consumer, ranging from 20% to 45% of consumption, despite being essential for ensuring environments suitable for teaching and research. In this regard, this study aims to analyze strategies to decrease energy consumption for electric lighting of nine representative buildings inside the Darcy Ribeiro Campus at the University of Brasilia (UnB) in Brazil. The method consisted of selecting 45 buildings inside the campus, sorting them into 3 clusters. Three buildings of each cluster were simulated with the software ClimateStudio to analyze the energy consumption for lighting, considering the addition of external shadings, window film to reduce visible transmission from the windows – from 88% (clear glass) to 62%, and automation of electric lighting. Results demonstrated that passive strategies, of optimizing the sun-shading devices and the addition of the window film were extremely efficient to control daylight entering the room, keeping useful daylight illuminance levels (between 300 and 3000 lux) above 69% in eight of the nine buildings, while reducing areas with disturbing glare in more than 5% of daylit hours. Regarding results of energy consumption for lighting, a decrease between 24% and 52% was observed between the original cases and the optimized ones, with all passive strategies and automation of the lighting systems applied. Therefore, a balance between the luminous comfort and a decrease in the energy consumption for lighting was found in the nine representative buildings inside the Darcy Ribeiro Campus at the University of Brasilia.

Keywords: Zero Energy District. University Buildings. Brasilia. Warm climate. Daylight simulations.

1. Introduction

Buildings account for 36% of the global final energy consumption and 40% of energy-related greenhouse gas emissions, a figure that could reach 50% if no strategy is implemented to reduce these impacts (United Nations, 2023; Zhang et al., 2021). In Brazil, commercial, public, and service buildings accounted for nearly 45% of the national electricity demand in 2024, with 24% for residential, 14.6% for commercial, and 6.3% for the public sector (Ministry of Mines and Energy 2025).

Furthermore, 56% of the world's population lived in cities in 2021, and this figure is projected to rise to 68% by 2050 (United Nations 2025). Consequently, several programs aimed at mitigating the impacts of climate change, coupled with strategies for creating more sustainable cities and communities (Arshad, Haleem, and Nadeem 2025). In the European context, where buildings account for 40% of energy demand and 36% of CO_2 emissions, regulatory frameworks such as the Energy Performance of Buildings Directive (EPBD) have established nearly zero-energy buildings (nZEB) as a mandatory standard for new construction, reflecting

the European Union's commitment to a fully decarbonized building stock by 2050 (European Union 2024). Technically, net-zero and nearly-zero energy buildings are characterized by the ability to meet annual energy demands through renewable self-generation or procurement, achieved in new constructions and comprehensive retrofits involving building envelope optimization, high-efficiency technical systems, and the integration of on-site renewable energy generation (Pless and Torcellini 2009). To achieve the Net-Zero Energy Building (NZEB) standard, three main objectives must be met. First, it is essential to reduce energy waste through improved building envelopes and enhanced HVAC systems. Second, the performance of renewable energy systems must be enhanced using hybrid systems capable of adapting to fluctuations in energy demand. Third, in terms of decarbonization, extensive integration of local renewable energy sources must be implemented in both new and existing buildings (Hainoun et al. 2025). In 2020, the European Union has triggered the transformation of Europe's neighbourhoods into energy districts (Aram, Taherkhani, and Šimelytė 2022; European Union 2024).

In educational buildings, particularly universities, energy consumption is linked to needs such as air conditioning, lighting, and equipment use. Air conditioning is the primary contributor, accounting for up to 40% of total consumption, particularly in hot regions, due to internal heat gain (high occupancy, equipment, lighting, and solar radiation). Artificial lighting follows as another major consumer, ranging from 20% to 45% of consumption (Litardo and Hidalgo-leon 2021). In the Brazilian context, university buildings are categorized into the "public" and "commercial" groups. However, there is no disaggregated information on the energy consumption of this type of building in the National Energy Balance (Garcia 2022). Factors such as the intensive use of equipment, lighting, and solar gain through the building envelope increase the building's thermal load, and consequently, affect the building's overall energy consumption.

Despite its essential role in creating comfortable and productive study and work environments, artificial lighting constitutes a significant source of energy consumption (Quevedo, Geraldi, and Melo 2023). Tests conducted in a full-scale experimental room in Iowa (United States – 40° North/ 93° West) under multiple orientations and sky conditions showed that dynamic shading paired with two glazing options effectively balanced daylight availability, glare control, and thermal performance. The integrated system achieved substantial energy savings, equivalent to 25.4% in cooling and 48.5% in lighting.

In light of this challenge, various approaches can be adopted to improve the energy efficiency and environmental quality of university buildings. Elements such as building morphology, envelope treatment, and internal zoning play a fundamental role in the ability to utilize passive resources, such as natural ventilation and lighting, as they determine the degree of permeability and the possibilities for controlling these flows (Arshad, Haleem, and Nadeem 2025). Furthermore, the adoption of specific technical solutions, such as the modernization of lighting, HVAC, and high-energy-consumption equipment systems, is a relevant strategy (Luo et al. 2022). Studies conducted by Kunwar *et al.* (2020) demonstrated that combining shading devices, different glazing types, and automated lighting controls can significantly reduce a building's energy demand while improving indoor comfort. Additionally, for the well-being of users inside a building, the presence of daylight is of extreme importance and this is linked to a higher productivity as well (Wei et al. 2014; Kokatnur et al. 2025).

In this regard, this study aims to analyze strategies to decrease energy consumption for electric lighting of nine representative buildings inside the Darcy Ribeiro Campus at the University of Brasilia (UnB) in Brazil. This research is inserted into a research project with the main goal of analyzing the feasibility of transforming the Campus into a Zero Energy District (ZED).

2. Method

The object of this study is the Darcy Ribeiro Campus at the University of Brasilia (UnB) in Brazil. The first step of the method was to map the buildings. After that 45 buildings were selected with predominant use of classrooms, professors' rooms, and administrative offices. The second step was to cluster these 45 buildings

by morphological similarities, and 9 were selected for simulation studies. The third step was to gather technical drawings, plans, and collect data regarding electric systems, including the number of computers, lamps, luminaires etc. The fourth step consisted of computer simulations of electric lighting using ClimateStudio software. As there was no separate measurements for the different end uses of electricity in Campus, the energy consumption for lighting was estimated by simulations. Energy consumption for electric office equipment was estimated using DesignBuilder. Figure 1 illustrates the method flowchart. All this process was documented by Soares (2024) and Amorim, and, Cronemberger and Bones (2024).

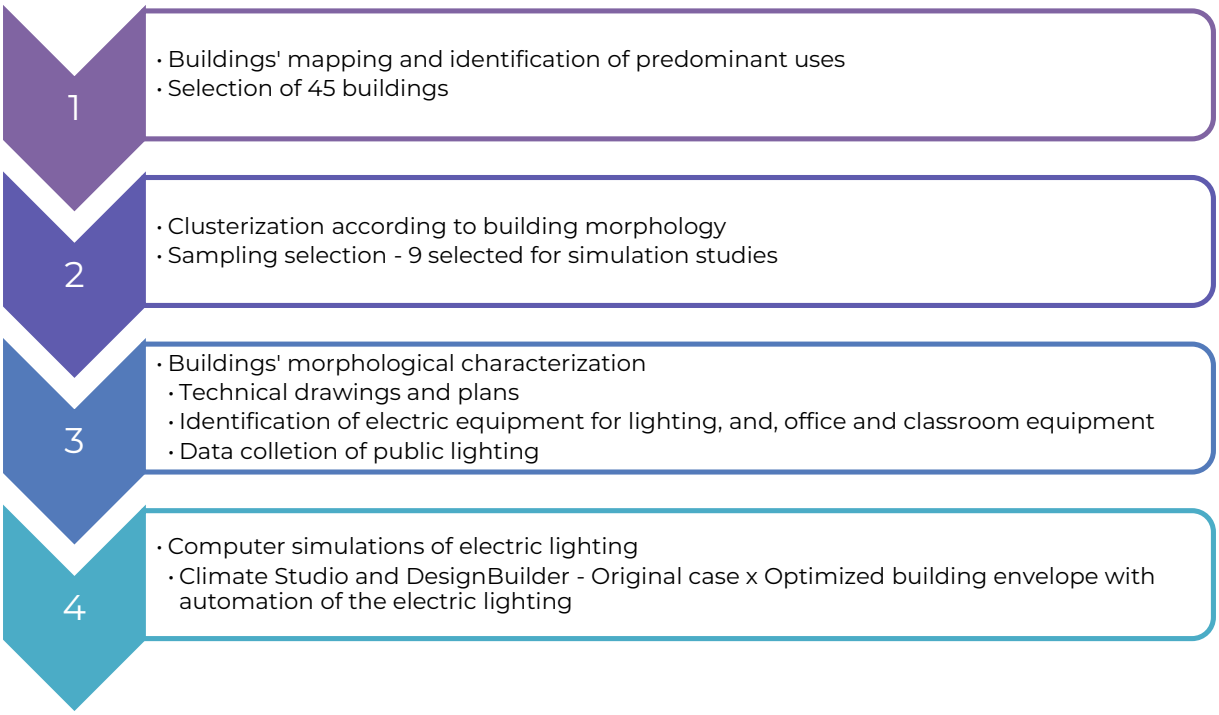

Figure 1 – Method flowchart. Source: The Authors.

The Campus and the selection of buildings are described in the following section.

2.1 The Darcy Ribeiro Campus at the University of Brasilia – Brazil and selection of buildings

The Darcy Ribeiro Campus of the University of Brasília, located in the northern part of the capital, stands out both for its academic significance and for its influence on the urban environment. The campus covers an area of 3,950,579.07 m² and has a built-up area of 552,171.40 m² (CEPLAN/UnB, 2025). In total, there are 93 buildings inside the Campus and the predominant uses are: professors' offices, classrooms, administrative offices, hospital premises and medical uses, laboratories, and residential buildings (Guerreiro *et al*. 2025).

For this study, buildings with the predominant uses of professors' offices, classrooms and administrative rooms were selected. Then, 45 buildings were selected and divided by a cluster analysis, which was carried out based on the homogeneity of use, replicability, the presence of energy monitoring, facades' solar orientation, form factor[1], window-to-wall ratio (WWR) and presence of solar shading devices (Soares 2024).

Guerreiro *et al.* (2025) and Soares (2024) determined that 9 buildings were sufficient to represent the three clusters with an adequate margin of error and confidence interval. Figure 2 shows the selected buildings for the daylight simulation studies. These buildings were chosen to ensure that the simulated buildings served as a representative sample of the different typologies on the campus, assuming that buildings with similar morphological and design characteristics exhibit comparable patterns of environmental impact and energy

[1] Calculated by the ratio between the area of the building envelope in relation to the volume (Inmetro 2021).

consumption. In Cluster 1, the selected buildings were the IPOL/IREL building (Institutes of Political Science and International Relations), the Academic Administration Office (SAA), and the Faculty of Law (FD). In Cluster 2, the selected buildings were the North Classroom Block (BSAN), the Technology Development Support Center (CDT), and João Calmon Pavilion. In Cluster 3, the selected buildings were the Center for Sustainable Development (CDT), Faculty of Technology (FT), SG-10, and CEPLAN.

Figure 2 – Facades of the selected buildings. Source: adapted from adapted from Soares (2024) and Amorim, Cronemberger and Bones (2024).

The climate of Brasilia and the simulation parameters are described in the next sections.

2.2 Climate of Brasilia: present day and in 2050

Brasilia (15° South/47° West) has two distinct seasons marked by a hot-humid period, with a rainy summer, from October to April (with temperatures ranging from 18 °C to 27 °C), and a hot-dry period with a dry winter, from May to September (with temperatures ranging from 15°C to 25°C. Brasilia presents high solar irradiation levels, with a daily average of 467 Wh/m².day. In the hottest months, the means of maximum temperatures reach 30°C (CODEPLAN 2020). The annual daily average of sky cover is 46%, with annual low daily average of 15% and annual high daily average of 83%. Annual averages of global horizontal illumination is 50.358 lux, annual average of daily high, 83.521 lux and annual average of daily low is 20.050 lux. These data were directly extracted from the climate file of Brasilia TMY 2009-2023 (Crawley and Lawrie 2023).

By 2050 the temperature range in the summer (October to April) is expected to vary approximately between 22°C and 28°C, while in the winter (hot and dry season) temperatures will range from about 18 °C to 27 °C. Solar irradiation is projected to increase between 4% and 14% from September to November, resulting in a slightly higher annual daily average of 470 Wh/m² per day. The annual daily average of sky cover remains constant at 50% at every simulated hour in the future climate file of 2050. This is observed as a limitation and does not reflect the sky cover seasonal variations typical of Brasilia's present climate. Annual daily averages of global horizontal illumination remain similar to current values, reaching 51,499 lux, with daily highs of 85,596 lux and daily lows of 11,141 lux. These data were directly extracted from the climate file of Brasilia with prediction models for the year of 2050 (Bracht et al. 2023).

2.3 Workflow of the computer simulations and variables

For the daylight simulations, two climate files were used to represent the climate of Brasilia. The first climate file encompassed the years from 2009 and 2023 and the second one was derived from model projections of the Coordinated Regional Downscaling Experiment, CORDEX project. The details are described in the study of Bracht *et al.* (2023). The inputted climate files were:

- BRA_DF_Brasilia-Kubitschek.Intl.AP.833780_TMYx.2009-2023
- BRA_DF_Brasilia-Kubitschek.Intl.AP.833780_RCP2.6_HadGEM2_regcm_2050s_BrazFuture.zip

The nine buildings were modeled using Rhinoceros v. 7. After this process, ClimateStudio, v. 2.1 was used for daylight calculations and energy consumption of electric lighting (Solemma 2023). Figure 3 shows the workflow of the daylight computer simulations.

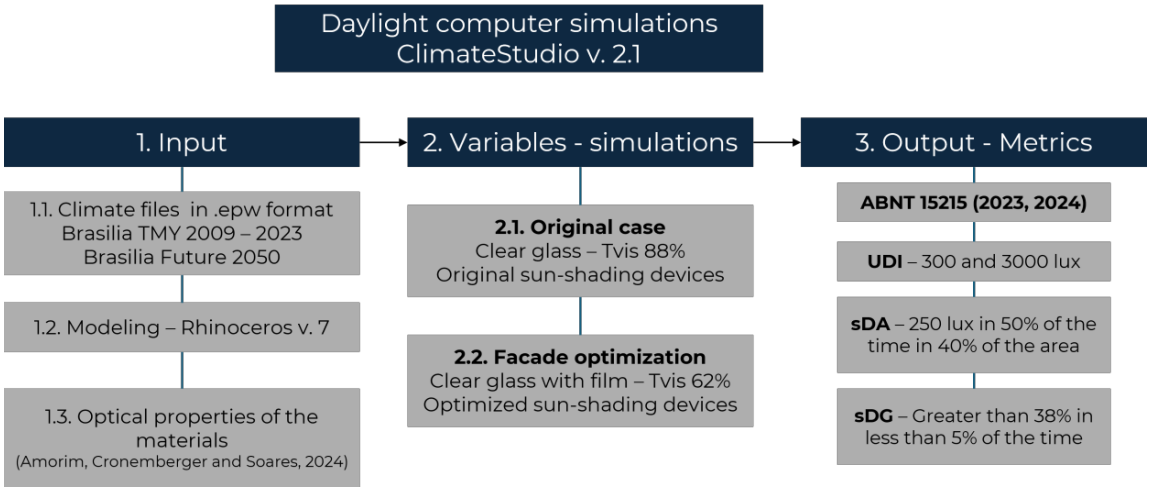

Figure 3 – Workflow of the daylight computer simulations. Source: Adapted from Soares (2024) and Amorim, Cronemberger and Soares (2024).

The nine buildings were modeled as the original case. After that, a facade optimization process was designed in order to add or improve the sun-shading devices and a window film was added to decrease the visible transmissivity of the windows. For all nine buildings in the original case, clear glass with 6 mm was the predominant glass type, with g-value of 0.85 and visible transmittance (Tvis) of 0.88. Regarding the passive strategies, the shading device analysis was carried out by generating a shading mask for each building using the Analysis Sol-AR software, which helps determine the alpha - vertical (α), beta - horizontal (β), shadow angles. For the Glass Type (Film), a gray film was selected with specific characteristics of g-value 0.64 and visible transmittance (Tvis) of 0.62 (Vitro Architectural Glass 2026). A visible transmittance above 40% with a reduced shading coefficient compared to the original condition helps to balance daylight penetration and glare control, improving visual comfort for occupants (Costa, Amorim and Silva 2020; Correia 2024).

The sun-shading devices were individually evaluated for each building, assessing the existing solution and, when inadequate, proposing a new protection angle—either horizontal or vertical—defined on a case-by-case basis. Depending on the buildings' characteristics (such as SG-10 and the School of Technology – FT), or because the existing shading elements did not require modification (as in the Faculty of Law – FD – and the Technology Development Center – CDT), the sun-shading devices were not modified. The sun-shading devices were modelled with a fixed angle. The details regarding the optical properties, including solar absorptance, reflectance, and angles of the sun-shading devices of the nine buildings for each orientation were described by Amorim, Cronemberger and Soares (2024).

The automation of the electric lighting was calculated using DesignBuilder software based on the daylight simulations according to the daylight autonomy levels. DesignBuilder simulates the incidence of daylight throughout the day, and the artificial lighting control system dims or switches off the electric lights when there is sufficient natural light to meet the desired illuminance levels of 500 lux (DesignBuilder Software Ltd., 2024; ABNT, 2013). The strategies for the facade optimization process of the nine buildings are illustrated in Figure 4.

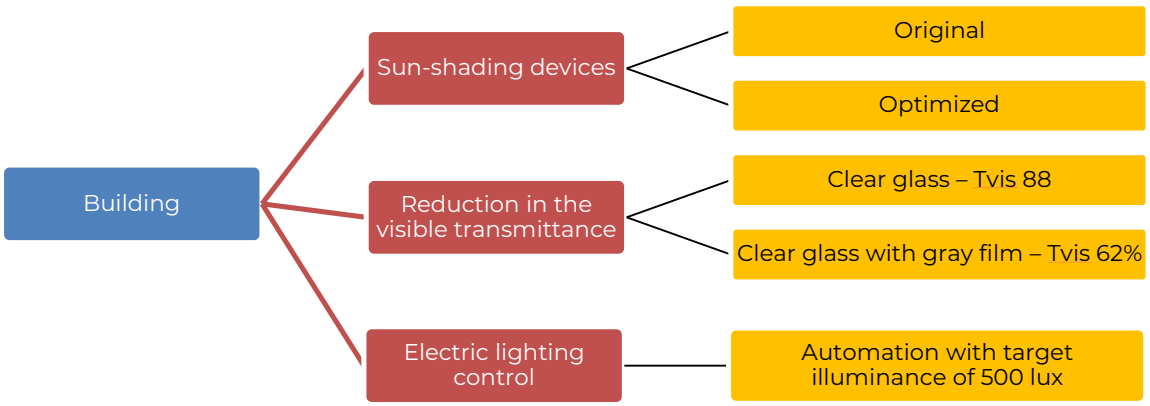

Figure 4 – Strategies for the facade optimization process of the nine buildings. Source: The Author with adaptations from Bones (2024).

The evaluated metrics were, useful daylight autonomy (UDI), spatial daylight autonomy (sDA) and annual glare, which are all climate-based (IES 2023; ABNT 2022; Tregenza and Mardaljevic 2018). To evaluate daylight quality of the indoor environments, such as, classrooms, professors' rooms, and administrative offices, the following parameters were considered between daylit hours, from 8 a.m. and 6 p.m.:

- Useful daylight illuminance (UDI): within the range of 300 to 3000 lux (visual comfort range) for at least 50% of the daylight hours, as recommended by the Brazilian Standard ABNT NBR 15215-4 (2023).
- Spatial daylight autonomy (sDA): with a target illuminance of 250 lux for 50% of the time in 40% of the floor area (Level I), as recommended by ABNT NBR 15215-3 (2024).
- Spatial discomfort glare (sDG): below 5% of the occupied hours: i.e. sDG higher than 38% (disturbing glare) below 5% of the occupied hours, as recommended by ABNT NBR 15215-3 (2024).

The results are presented in the next section.

3. Results and discussion

When combining the morphological variables, form factor (FF) and window-to-wall ratio, with the visual classification of buildings across the three clusters, patterns were observed, as described by Table 1. Cluster 1 buildings (IPOL/IREL, SAA, and FD) show lower form factors (0.32–0.33) and WWR values below 50%. Cluster 2 buildings (BSAN, CDT, and PJC) present similar form factors (0.35–0.38) as cluster 1 buildings, but higher WWR levels, ranging from 50% to over 75%. Cluster 3 buildings (CDS, FT, and SG-10) have the highest form factors (0.44 – 0.48) and higher variations of WWR levels. Results for three of the buildings are presented here by means of example – i.e. one building for each cluster. Following the initial simulations, it was found out that the nine buildings have daylight levels well above those required by the Spatial Daylight Illuminance (sDA) criterion. Consequently, it was decided to analyse them solely using the Useful Daylight Illuminance (UDI) criterion, which covers the range from 300 to 3000 lux, whilst also identifying potential glare issues.

Table 1 - Morphological characteristics related to the form factor and window-to-wall ratio of the simulated buildings. Source: The authors with adaptations from Amorim, Soares and Cronemberger (2024).

Cluster	Buildings	Form factor (FF)	Window-to-wall ratio
1	IPOL/IREL SAA FD	0.32 – 0.33	Equal or less than 50%
2	BSAN CDT PJC	0.35 – 0.38	Between 50% and 75%
3	CDS FT SG-10	0.44 – 0.48	SG-10 - Less than 50% FT: 50% to 75% CDS – Greater than 75%

The results of the daylight simulations are described next.

3.1 IPOL/IREL - Institutes of Political Science and International Relations

The IPOL/IREL building performed well in terms of daylighting, based on the useful daylight illuminance (UDI) criterion, with 74% of its areas falling within illuminance levels between 300 to 3000 lux. Most of the building's spaces are adequately lit for daily activities without causing visual discomfort. However, some specific areas, particularly rooms facing east and west, have illuminance levels exceeding 3000 lux. In the optimized case, with reduction of the visible transmittance, the increase in the average UDI (300 – 3000 lux) was 12%, and for 2050, 4%. Regarding results of sDG (annual glare), approximately 47% of the evaluated views presented more than 5% of the time with disturbing glare (DGP > 38%). In the optimized case, this number dropped by 3.5% and in the future, 3.4%. Figure 5 shows the results of UDI and sDG of IPOL/IREL building.

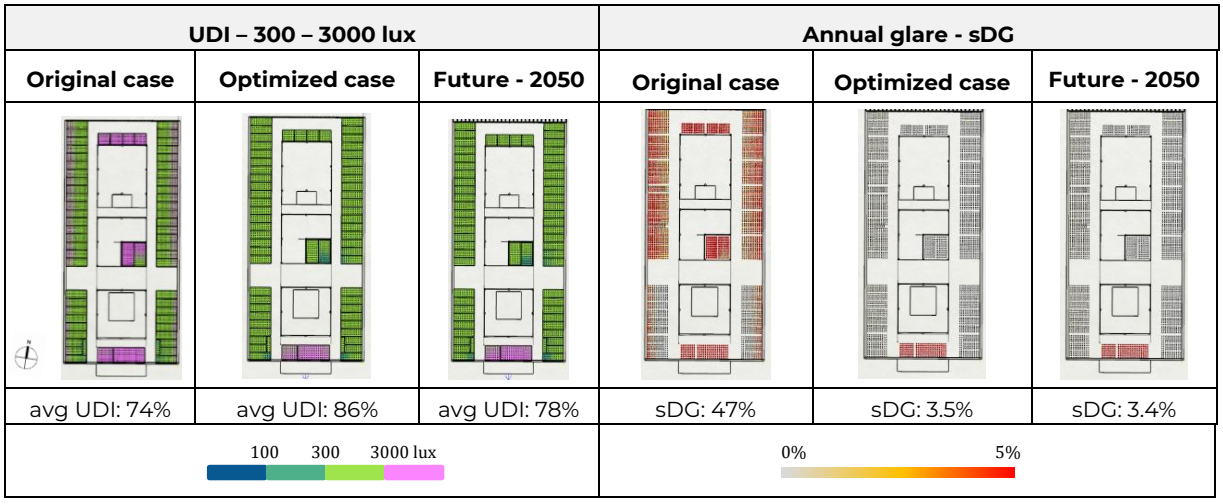

Figure 5 – Results of Useful Daylight Autonomy (UDI) for IPOL/IREL. Source: Climate Studio (2024).

The results of BSAN building are described next.

3.2 BSAN - North Classroom Block

The BSAN building (Figure 6) performed well in terms of daylighting, with 83% of its areas falling within the comfortable illuminance range (300 to 3000 lux). Specific areas, particularly rooms facing north and north-west, have illuminance levels exceeding 3000 lux between 1 p.m. and 5 p.m. This excessive light can be problematic, causing visual discomfort to occupants and indicating the need for adjustments to the solar control devices. In the optimized case, the average UDI dropped from 83% to 78%, and to 72% by 2050.

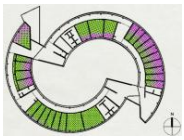
UDI – 300 – 3000 lux			Annual glare - sDG		
Original case	**Optimized case**	**Future - 2050**	**Original case**	**Optimized case**	**Future - 2050**
					
avg UDI: 83%	avg UDI: 78%	avg UDI: 72%	sDG: 40%	sDG: 1.1%	sDG: 0.8%
					

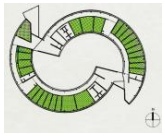
Figure 6 – Results of Useful Daylight Autonomy (UDI) for BSAN. Source: Climate Studio (2024).

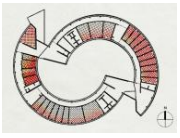
It was observed that BSAN also exhibited a high glare probability index, with 40.3% of views exposed to levels exceeding the ideal threshold for more than 5% of occupied hours. This is caused mainly by the inefficiency of the sun-shading devices, resulting in excessive illuminance levels, thus impairing visual comfort. When the window film was added, causing a drop in the visible transmittance, the sDG dropped from 40% of the area above 5% with disturbing glare, to 1.1% of area, and to 0.8% by 2050, as shown in Figure 6.

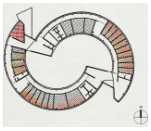
3.3 CDS - Center for Sustainable Development

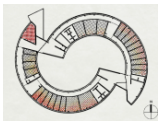
The CDS building (Figure 7) performed well in terms of daylighting, with 74% of its areas falling within the comfortable illuminance range (300 to 3000 lux). Some specific areas, particularly rooms facing north and north-west, have illuminance levels exceeding 3000 lux. In the optimized case, the average UDI increased from 74% to 82%, and by 80% for 2050, with a decrease in the overlit areas.











UDI – 300 – 3000 lux			Annual glare - sDG		
Original case	**Optimized case**	**Future - 2050**	**Original case**	**Optimized case**	**Future - 2050**
					
avg UDI: 74%	avg UDI: 82%	avg UDI: 80%	sDG: 42%	sDG: 22%	sDG: 20%
					

Figure 7 – Results of Useful Daylight Autonomy (UDI) for CDS. Source: Climate Studio (2024).

Based on the results of annual glare (Figure 6), it was observed that the building also exhibited a high glare probability index, with 42% of views exposed to levels exceeding the ideal threshold for more than 5% of occupied hours. This is also a high level, caused mainly by the inefficiency of the sun-shading devices and high window-to-wall ratio, resulting in excessive illuminance levels. When the window film and improved sun-shading devices were added, causing a drop in excessive daylight penetrating the room, sDG dropped from 42% of the area above 5% with disturbing glare, to 22% for the optimized case and to 20% by 2050. Nevertheless, compared to the IPOL/IREL and BSAN buildings, CDS presented the worst performance regarding the avoidance of glare. An overview of the results of the daylight simulations are described next.

3.4 Overview of the daylight simulations and energy consumption for electric lighting

When the original buildings (cases) were compared with the optimized ones, the impact of the strategies employed is evident in almost all buildings. Cluster 1 showed the greatest improvement in natural lighting, with an average increase of 9.13% in hours with adequate UDI – between 300 and 3000 lux. The building that saw the greatest improvement in daylighting was SG-10, with almost 24% more hours of comfortable lighting when comparing the original case with the optimized case. It is worth noting that some buildings would face a deterioration in the quality of natural lighting in a future scenario and in the optimized case, indicating that these improvements were punctual and did not work for all cases. For example, a drop of 5.2% was observed for BSAN, as previously observed, PJC – with a drop of 15% and FT, with a drop of 11%. Figure 8 shows the overall results for lighting comfort (quality of natural lighting), based on the percentage of hours with adequate Useful Daylight Illuminance, between 300 and 3000 lux.

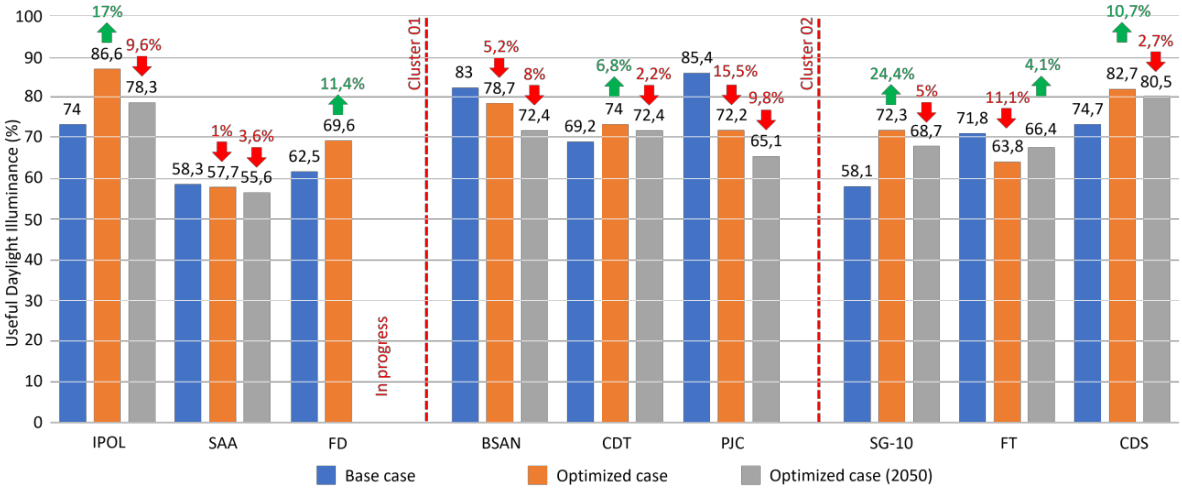


Figure 8 – Summary of Useful Daylight Illuminance results evaluating the quality of daylight of the nine buildings regarding the original buildings (cases), optimized case and future scenario in 2050.

Results showed that for all three clusters, the energy consumption for lighting decreased more than 25% and significant differences were observed, as shown in Table 2. Similar results were seen in clusters 1 and 3. In general, the energy decrease was between 31% and 62%. However, in cluster 2 the decrease in energy consumption for lighting was between 21% and 28%. Besides that, it was possible to verify that the highest energy consumptions for electric lighting was found in the buildings of cluster 2, encompassing BSAN, CDT and PJC.

Results of UDI and annual glare showed improvements in some aspects of daylighting quality inside the indoor environments across all the nine buildings. This is of extreme importance, because the presence of adequate daylighting can increase the productivity of students, professors and other professionals, while increasing the well-being of users inside. Additionally, this was observed in the studies of Wei *et al.* (2014) and Kokatnur *et al.* (2025).

Table 2 – Energy consumption for electric lighting: comparison between the original cases and the optimized cases with all strategies applied. Source: The Authors with adaptations from Amorim, Cronemberger and Soares (2024).

Cluster	Building	Original case (kWh)	Optimized case (kWh)	Change in percentage %
1	IPOL/IREL	107.736,30	66.553,58	-44,27%
1	SAA	86.353,84	50.199,81	-53,21%
1	FD	145.301,05	82.401,31	-47,11%
Avg. decrease				**-48,20%**
2	BSAN	101.901,43	75.868,52	-25,55%
2	CDT	85.994,83	67.936,79	-21,00%
2	PJC	54.868,38	39.282,09	-28,41%
Avg. decrease				**-24,98%**
3	SG-10	18.650,03	7.043,27	-62,23%
3	FT	35.554,70	24.315,76	-31,61%
3	CDS	28.679,75	10.700,52	-62,69%
Avg. decrease				**-52,18%**

The conclusions are presented in the next section.

4. Conclusion

Results demonstrated that passive strategies, of optimizing the sun-shading devices and the addition of the window film were extremely efficient to control daylight entering the room. This was achieved by reducing the visible transmittance from 88% to 62%, and, optimizing the sun-shading devices for each building and window orientation. From the perspective of daylighting, these strategies helped to control glare and improve UDI levels between 300 and 3000 lux inside the evaluated buildings.

Besides that, the passive strategies with the addition of automation in the lighting systems according to daylight autonomy and glare control were efficient strategies to decrease in 24% to 52% the energy consumption for lighting. In general, no relationship was observed among energy consumption for lighting, form factor and window-to-wall ratio, as described in Table 1. Reasons for the differences in the energy consumption decrease are an aspect that is worth further investigation.

Regarding the future scenarios in 2050, despite some deteriorations observed in some cases, UDI levels and annual glare were not significantly different from the optimized cases. Additionally, the climate file for Brasilia in 2050 does not reproduce seasonal variations in sky cover, failing to represent both the hot and dry winter and the hot and rainy summer months. The discussion regarding climate change is more focused on thermal comfort and energy consumption for artificial cooling, but the discussion of future scenarios regarding daylighting and energy consumption for electric lighting in the future is of paramount importance. Different climates and latitudes must be considered as well.

It is concluded, therefore, that a balance between the luminous comfort, with the increase of useful daylight illuminance levels with the reduction of glare, and a decrease in the energy consumption for lighting was found in the nine representative building inside the Darcy Ribeiro Campus at the University of Brasilia. This is extremely important to increase the energy efficiency of the Campus. Among the main limitations of the study, a cost-benefit analysis of the strategies was not included and experimental studies in the Campus' buildings were not conducted. These aspects will be approached in further studies.

Abstract: The residential building stock in Peru accounts for a significant share of the country's seismic exposure and often exhibits progressive functional degradation driven by construction deficiencies, inadequate maintenance, and incremental vertical expansion. Given that seismic demand varies markedly across Peru's distinct hazard zones, "one-size-fits-all" design spectra can mask true vulnerability and lead to suboptimal retrofit strategies. This study proposes a probabilistic framework that couples time-dependent functional degradation, SFD(t), with hazard-consistent seismic demand, UHS(TR), to quantify the evolving likelihood of functionality loss. This evolution is summarized through a practical "resilience clock." The research targets representative 3-, 6-, and 9-story residential buildings located in seismic hazard zones 2, 3, and 4, under three return periods (TR) essential for performance evaluation: 31, 475, and 975 years. Building conditions are characterized via structured field inspections of common building pathologies and, where feasible, in-situ non-destructive testing. These observations are synthesized into SFD as a random variable to explicitly capture uncertainty. Two representative age states are considered (t ≈ 10 and t ≈ 30 years), with SFD distributions estimated by hazard zone and building height. The SFD is mapped to degraded structural capacity, C(t), by penalizing key mechanical properties: stiffness, strength, and ductility. Seismic performance is evaluated through three limit states—Immediate Occupancy (IO), Life Safety (LS), and Collapse Prevention (CP). The probabilistic coupling of demand and capacity produces age-, hazard-, and height-conditioned fragility functions. The primary deliverable is a set of age–risk curves—the resilience clock—enabling the identification of critical ages and supporting risk-informed prioritization of structural interventions before functionality becomes unacceptable.

Keywords: Seismic resilience, Functional degradation, Uniform Hazard Spectrum (UHS), Performance-based assessment, Limit states (IO/LS/CP).

1. Introduction

Peru lies along one of the world's most active subduction margins, where high seismic hazard converges with extensive residential exposure and a highly heterogeneous building stock. In this context, the key question is no longer only whether buildings avoid collapse, but whether they remain functional—habitable, operable, and recoverable within socially acceptable timeframes. Recent research has therefore shifted resilience from a qualitative notion of robustness to a performance-based, recovery-oriented metric defined by functional trajectories, downtime, and restoration pathways. Building-level probabilistic models now account not only for damage, but also for mobilization, repair sequencing, and recovery states. For example, a tall reinforced-concrete core-wall building was reported to require about 3–6 months for functional recovery under service-level shaking, 8–13 months under design-level shaking, and 12–16 months under

maximum-considered shaking, despite no expected collapse. The core message is clear: functionality can be lost well before life safety is compromised, and societal losses are often governed more by downtime than by collapse itself (Terzic *et al.*, 2021; Terzic and Kolozvari, 2022; Kolozvari and Terzic, 2023; Li, Kunnath and Zhao, 2023; Opabola and Galasso, 2024; G *et al.*, 2025; Wu *et al.*, 2025).

This issue is especially critical in Peru because the residential stock is shaped by self-construction, incremental expansion, uneven technical oversight, and strong territorial variability. Evidence from Lima highlights the scale of the problem. In a sample of 120 self-built houses, measured concrete compressive strength ranged from about 110 to 200 kg/cm², over 65% of buildings showed structurally relevant pathologies, and estimated structural functionality degradation reached 3%–38% over 1–30 years, with representative elastic drifts of about 1.2% (Velasquez *et al.*, 2025). These findings show that the Peruvian residential problem is not simply one of vulnerable typologies, but of progressively degraded capacity embedded in a high-hazard environment. Velasquez et al. (2025) further addressed this through an Intelligent Circular Resilience (ICR) framework, linking inspection, materials testing, structural analysis, and functionality estimation through 11 structural evaluation parameters. This was a key conceptual advance, since many resilience approaches implicitly assume an initial functionality of 100%, whereas self-built stock often begins service with non-negligible deficits in stiffness, strength, and ductility. Earlier, Aroquipa and Hurtado (2022) had already proposed a simplified resilience-assessment methodology that incorporated repair time, workforce, and losses into seismic decision-making.

The hazard side is equally important. Modern performance-based assessment has shown that seismic demand must be hazard-consistent, explicitly tied to local hazard, controlling sources, and structural period. In this framework, the Uniform Hazard Spectrum (UHS) derived from Probabilistic Seismic Hazard Analysis (PSHA) remains fundamental because it provides period-specific ordinates associated with a consistent exceedance probability, although recent developments have sought to balance realism and conservatism in target spectra and record selection (Xu and Zhou, 2022; Li, Kunnath and Zhao, 2023; Lai *et al.*, 2024). For Peru, this issue is no longer abstract. A recent PSHA-based study by Aroquipa et al. (2026) computed UHS for 25 Peruvian cities using 22,399 earthquakes, 33 source models, 6 ground-motion prediction models, and five return periods, showing that for some soil classes and periods, UHS ordinates can reach up to about three times the elastic design spectrum prescribed by the Peruvian code. This confirms that future functionality cannot be inferred from typology alone; it must be coupled with local hazard and epistemic uncertainty (Joyner *et al.*, 2021; Ji *et al.*, 2024; Mazumder and Sutley, 2024).

A further dimension is that both vulnerability and functionality are time-dependent. Recent studies on reinforced-concrete systems subject to deterioration have shown that capacity distributions evolve with age, uncertainty widens, and exceedance probabilities can increase substantially when degradation is modelled explicitly rather than treated as background noise (Chen *et al.*, 2024; Otárola *et al.*, 2024; Zhang, Liu and Yu, 2024). In addition, post-earthquake functionality is often governed not only by the structural system, but also by non-structural components and service interdependencies. Utility disruption, acceleration-sensitive elements, and aftershock effects can materially alter downtime and vulnerability, especially in residential occupancies (D'Angela, Magliulo, and Cosenza, 2021; Li, Kunnath, and Zhao, 2023; Mohammadgholibeyki, Koliou, and Liel, 2023; Hosseini *et al.*, 2024). In Peru, where self-construction, uneven quality control, and service dependency are structural features of the housing system, these are not secondary refinements but essential conditions for a defensible resilience assessment.

The main contribution of this study is a unified probabilistic framework that couples condition-based functional degradation, SFD(t), with hazard-consistent seismic demand, UHS(TR), to derive resilience functions simultaneously conditioned on age, hazard level, and building height. Methodologically, unlike conventional functional-recovery studies that assume ideal initial functionality or rely on highly detailed component inventories, the proposed framework treats initial condition as a degraded random variable explicitly linked to losses in stiffness, strength, and ductility. Practically, the resulting resilience is synthesized into a "resilience clock"—age–risk curves and intervention thresholds that identify when functionality

becomes unacceptable under engineering return periods. In doing so, the study closes a critical gap between degradation-informed resilience assessment for self-built housing and hazard-consistent UHS-based demand modelling for Peruvian cities, moving from diagnosis to a hierarchy of actionable resilience metrics for the residential sector (Velasquez *et al.*, 2025; Aroquipa *et al.*, 2026).

2. Methodology

The proposed framework formulates seismic resilience as a time-dependent, hazard-conditioned performance metric by coupling: (i) a hazard-consistent seismic demand represented through Uniform Hazard Spectra, UHS(TR); (ii) a baseline resilience metric expressed through the Simplified Resilience Index (SRI); and (iii) a time-dependent functionality degradation function, SFD(t), which captures the progressive loss of structural functionality due to aging, construction deficiencies, deterioration, and cumulative service-life effects. The final output is a Resilience Clock (RC), defined as an age–risk descriptor that quantifies how the resilience state evolves as a function of both the return period of the seismic action and the age-dependent degradation of the building stock. The workflow is organized into eight sequential steps grouped into four main stages, as illustrated in Figure 1: (1) study definition, (2) hazard characterization through UHS, (3) structural condition assessment and baseline resilience quantification, and (4) time-dependent degradation and resilient-clock synthesis.

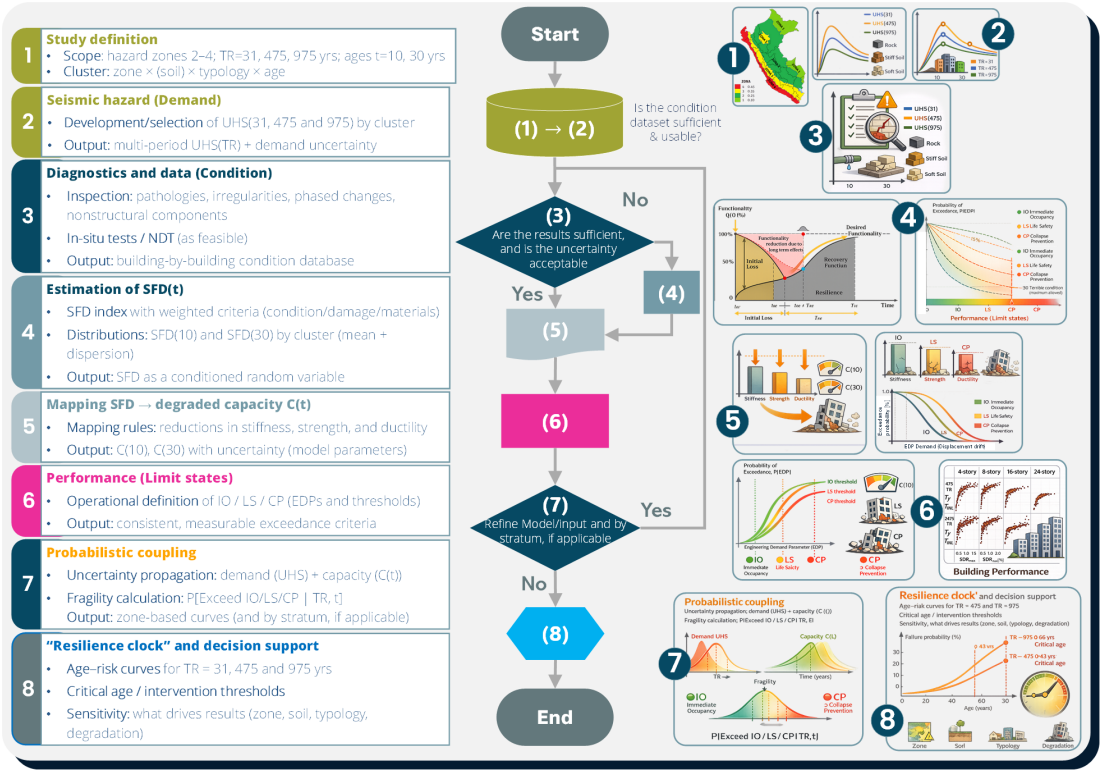

Figure 1 – Flowchart of the proposed methodology for estimating the resilient clock

From a probabilistic standpoint, the methodology extends conventional seismic risk assessment (SRA) by explicitly introducing a time-varying capacity modifier into the resilience estimation. While conventional SRA combines hazard, exposure, and damage to quantify expected consequences, the present approach incorporates the fact that the actual response of residential buildings is not stationary over time. In practical terms, the framework assumes that the resilience state of a building at time t_j, under a seismic demand associated with the return period RP_i, can be expressed as:

$$RC(RP_i, t_j) = SRI(S_a|UHS(RP_i)) \; x \; SFD(t_j) \qquad (1)$$

where $RC(RP_i, t_j)$is the resilient state, $SRI(S_a \mid UHS(RP_i))$is the baseline simplified resilience index conditioned on the spectral acceleration derived from the UHS corresponding to the return period RP_i, and $SFD(t_j)$is the time-dependent structural functionality modifier evaluated at age t_j. Equation 1, therefore, represents a multiplicative coupling between demand-consistent resilience and age-conditioned residual functionality, allowing resilience to be tracked in time under different seismic performance levels.

2.1 Study definition

At this stage, the scope of the assessment shall be established by grouping the building stock into archetypal buildings or taxonomies, followed by identifying their spatial locations to properly define the seismic hazard using the UHS linked to the targeted performance objectives via the return periods. All these factors shall account for aspects related to the representation of actual conditions at the locations where the archetypal buildings are located, while providing a more reliable risk metric for the resilience clock. Also, it should include the status and age of evaluation for incorporating the degradation.

2.2 Uniform Hazard Spectrum (UHS)

The first stage defines the hazard-consistent seismic demand through UHS obtained from PSHA for the target return periods adopted in the study (RP = 31, 475, and 975 years). Unlike generalized code-based spectra, the UHS explicitly reflects local tectonic environment, source predominance, and site effects, and is therefore more suitable for performance-oriented resilience assessment. The estimation follows the procedure proposed by Aroquipa et al. (2026), including seismic source characterization (SM), earthquake catalog processing, ground-motion prediction models, soil classification (ST), and source-dominance thresholds. The resulting spectra provide the period-dependent seismic demand $S_a(T|ST, SM, RP)$ required to evaluate building performance under consistent hazard scenarios and performance objectives correlated via RP.

2.3 Simplified Resilience Index

The second stage defines the baseline resilient condition of each building using the Simplified Resilience Index (SRI) at the damage definition stage proposed by Aroquipa and Hurtado (2022) and modified by Hurtado et al. (2026). The SRI is a reduced-order resilience metric that condenses the conventional elements of seismic risk—damage, losses, repairability, and recovery—into a normalized indicator suitable for comparative evaluation. In the present framework, the SRI is conditioned on the seismic demand extracted from the UHS and interpreted relative to performance objectives such as Immediate Occupancy (IO), Life Safety (LS), and Collapse Prevention (CP). Thus, the SRI provides the reference resilience level assuming nominal structural functionality, prior to introducing the effects of age-dependent degradation. Then, the SRI could be obtained by solving Eq. 2, adapted from Eq. B-6 from Hurtado *et al.* (2026).

$$SRI(im_T = S_a(T|ST, RP, SM)) = 1 - \int_{im}^{im_T} RC(im)dim \Big/ \int_{0}^{im} RC(im)dim \tag{2}$$

where, $SRI(im_T = S_a(T|ST, RP, SM))$ is the SRI for a specific intensity measure (im_T) defined in terms of the $S_a(T|ST, RP, SM)$ which is obtained from the $UHS(RP_i)$ calculated at the previous stage, and $RC(im)$ is the resilience curve, which can be calculated following the step-by-step instructions listed in Appendix B of Hurtado et al. (2026).

2.4 Functional degradation

The third stage incorporates the time-dependent functionality degradation, $SFD(t)$, as a modifier of the baseline resilience state. This term accounts for the progressive reduction in structural functionality resulting from aging, inadequate construction practices, deterioration mechanisms, lack of maintenance, and cumulative in-service effects. The remaining structural functionality is defined as:

$$D(t) = 100\left[1 - P_{\max}\left(1 - e^{-t/f(T_s, C)}\right)\right] \tag{3}$$

where $D(t)$is the remaining structural functionality, $P_{\max}$is the maximum admissible loss, T_s is the structural fundamental period, and C is the global structural quality coefficient. Therefore, the degradation factor is then written as:

$$SFD(t) = \mathrm{D(t)}/100 \tag{4}$$

thereby converting the residual functionality into a dimensionless coefficient ranging from 0 to 1. The coefficient C is obtained through a structural-condition assessment based on geometric, mechanical, constructive, and pathological indicators identified from inspection and, when available, non-destructive or in-situ testing. In this way, $SFD(t)$introduces into the resilience formulation a representation of the actual structural state, rather than assuming invariant capacity throughout the service life.

2.5 Resilient clock

The final stage combines the hazard-conditioned SRI and the time-dependent degradation factor to produce the Resilience Clock (RC). The RC is a synthetic descriptor of resilience evolution over time and hazard intensity and can be represented as age–risk curves, resilience bands, or intervention thresholds. At the end, for each building typology and city, Equation 1 is evaluated at discrete ages $t_j$and return periods RP_i, generating a matrix of resilient states:

$$\mathrm{RC} = \begin{bmatrix} RC(RP_1, t_1) & \cdots & RC\big(RP_1, t_j\big) \\ \vdots & \ddots & \vdots \\ RC(RP_i, t_1) & \cdots & RC\big(RP_i, t_j\big) \end{bmatrix} \tag{5}$$

This matrix is subsequently interpreted in terms of resilience classes and critical thresholds for retrofit prioritization. Because the RC is explicitly conditioned on both local hazard and age-dependent functionality, it provides a more realistic representation of residual resilience than conventional static approaches, particularly for residential stocks where nominal code compliance does not necessarily reflect actual structural condition.

Although the present implementation was developed for residential RC-MRF archetypes, the proposed framework is structurally extensible to other building typologies, provided that the corresponding hazard-consistent demand representation, resilience formulation, and degradation rules are calibrated for the target system. In the same way, the methodology can be expanded to include non-structural and secondary components, particularly when post-earthquake functionality is controlled by acceleration-sensitive or drift-sensitive elements.

3. Results

3.1 Structural archetypes and analytical

The case study was conducted on three representative reinforced-concrete moment-resisting frames (RC-MRF) residential archetypes with 3-, 6-, and 9-story heights, selected to represent the low-, mid-, and relatively high-rise ranges commonly found in the Peruvian residential stock. The three configurations were defined under a common structural logic to isolate the influence of building height on hazard-conditioned resilience. As shown in Figure 2, the structural layouts correspond to regular framed systems with continuous beam-to-column connectivity and repetitive vertical configuration, allowing a consistent comparison of response and degradation effects across building typologies. In the adopted idealization, the estimated fundamental periods were 0.272 s, 0.580 s, and 0.886 s for the 3-, 6-, and 9-story models, respectively. These values place the three archetypes within the short-to-intermediate period range, where the UHS results indicate the highest spectral demand for the analyzed cities. Detailed descriptions of archetypal buildings can be found in Aroquipa Velásquez (2016).

Also, these structural archetypes were intentionally defined with a common structural logic to isolate the effect of building height as the governing parameter within the proposed probabilistic framework. This modelling strategy allows direct comparison of age-conditioned structural performance under different

hazard levels while maintaining typological consistency. Accordingly, the selected building set provides a robust basis for quantifying how the coupled effects of functional degradation SFD(t) and hazard-consistent seismic demand UHS(TR) propagate into age-, hazard-, and height-conditioned resilience functions, and ultimately into the proposed resilience clock for intervention prioritization.

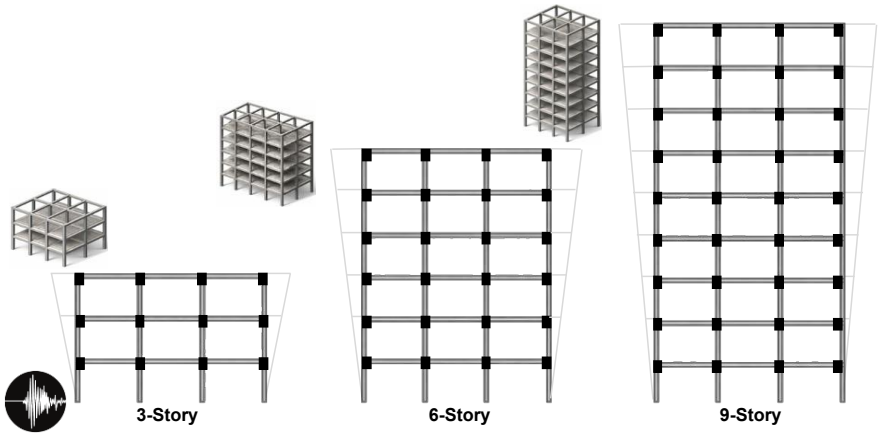

Figure 2 – Building configuration for 3-, 6-, and 9-story

3.2 Uniform Hazard Spectrum (UHS)

In this case study, hazard was considered for three return periods: 32, 475, and 975 years. Each RP is linked to a performance objective of immediate occupancy, life safety, and collapse prevention, respectively. Figure 3 shows the UHS obtained at three representative cities: Lima, Arequipa, and Cusco, associated with seismic zones 4, 3, and 2, respectively. In addition, two soil conditions were assessed within the UHS framework, reflecting the most representative soils in Peru where buildings are built (soft soils, classes D and E, following the NEHRP classification).

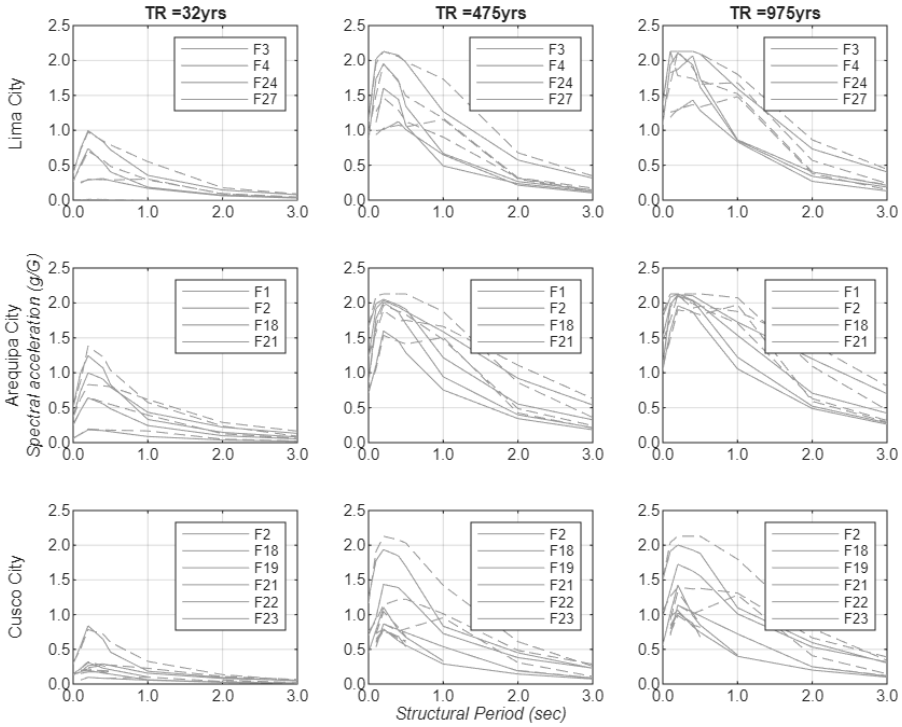

Figure 2 – Results of UHS for seismic Zones 2, 3, and 4

The results indicate a systematic increase in spectral ordinates with return period, together with marked differences in spectral shape and source-to-source variability. For RP = 32 years, the demand is generally moderate and concentrated at short periods, with peak values of about 0.8–1.0 g in Lima, 0.7–1.3 g in Arequipa, and mostly below 0.3 g in Cusco, except for isolated peaks approaching 0.7–0.8 g. For RP = 475 years, the demand rises significantly: Lima and Arequipa reach peak ordinates on the order of 1.7–2.1 g, while Cusco exhibits a wider dispersion, with peaks ranging approximately from 1.0 g to 2.0 g, depending on the controlling fault set. Under RP = 975 years, the most severe spectra in Lima and Arequipa remain close to 2.0–2.1 g, while Cusco also reaches comparable values for specific source scenarios despite belonging to seismic zone 2.

A relevant result is that the highest UHS ordinates are concentrated in the short-to-intermediate period range (approximately 0.2–0.8 s), which directly overlaps the fundamental periods of the three analyzed archetypes. This is particularly critical for the 3- and 6-story buildings, whose periods lie close to the spectral peaks, but it is also relevant for the 9-story system, since the spectral decay toward longer periods is gradual rather than abrupt. In addition, the results reveal strong fault-to-fault dispersion within the same city and return period, particularly for RP = 475 and 975 years, where peak differences between individual spectra are on the order of 0.4–0.7 g in Lima and Arequipa, and even larger in relative terms for Cusco. These findings confirm that generalized code-based spectra are insufficient to represent the actual severity of local seismic demand and justify the use of hazard-consistent $UHS(RP_i)$ as the demand input for resilience assessment.

3.3 Simplified Resilience Index

The baseline resilience assessment indicates that resilience decreases nonlinearly as the intensity measure defined in terms of $S_a(T)$ increases, although the degradation rate differs significantly across scenarios. As shown in Figure 3, the three archetype buildings exhibit similar trends with few differences in the intensity range of $S_a(T)$ between 0.30 and 0.80 g. These results indicate that the same $S_a(T)$ demand may lead to substantially different functional consequences depending on the residual capacity and recovery potential of the system.

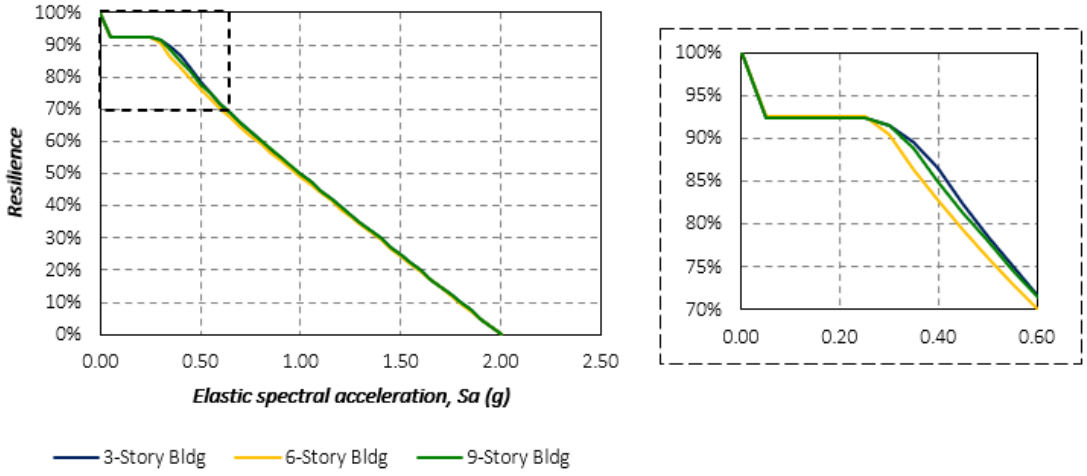

Figure 3 – Resilience curves for buildings assessed

From a performance-based perspective, the most critical reduction in resilience occurs at two points. The first point has a lower $S_a(T)$ of around 0.10g, with a drop of about 8% in resilience, while the second one starts at $S_a(T)$ greater than 0.30g, in which the drop remains constant with almost no noticeable variation among building archetypes. These conditions reflect the influence of the controlling points proposed by the methodological approach used to calculate the SRI. Also, this confirms that $S_a(T)$ is an effective engineering

demand parameter for discriminating resilience loss, but also that the damage–resilience relationship is not unique and must be interpreted in a scenario-dependent manner.

3.4 Time-dependent functionality degradation

Figure 4 presents the evolution of remaining structural functionality, $D(t)$, for the three RC -MRF archetypes. The time-dependent degradation model yields a rapid initial loss of functionality followed by asymptotic stabilization, which is fully consistent with the exponential formulation adopted in Section 2. Using the assumed periods $T_s = 0.272,\ 0.580$, and 0.886s for the 3-, 6-, and 9-story buildings, respectively, the three models start from $D(t = 0) = 100\%$ and decrease to approximately 92.2%, 93.0%, and 93.8% at 5 years, corresponding to losses of about 7.8%, 7.0%, and 6.2%. At 10 years, the curves converge to approximately 92.1%, 92.1–92.2%, and 92.5%, while at 30 years they stabilize near 92.0%, 92.1%, and 92.2%, indicating long-term losses of around 7.8–8.0%.

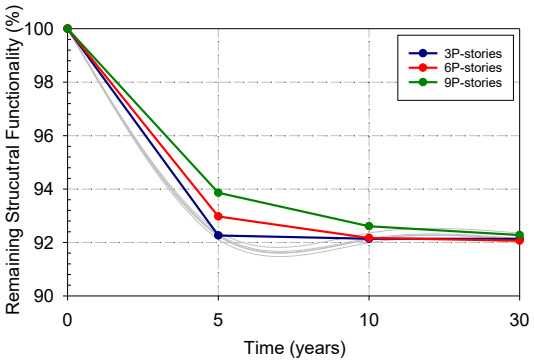

Figure 4 – Functional degradation versus time for the three RC-MRF archetypes. Blue, red, and green curves correspond to the 3-, 6-, and 9-story buildings, respectively

Figure 4 presents the evolution of remaining structural functionality, D(t), for the three RC-MRF archetypes, where the blue, red, and green curves represent the 3-, 6-, and 9-story buildings, respectively. A relevant observation is that, within this formulation, the 9-story archetype exhibits the slowest degradation rate. This does not imply lower seismic vulnerability in absolute terms but rather reflects the role of the degradation-rate function $f(T_s, C)$, which is maximized when the structural period approaches unity. Since the 9-story period ($T_s = 0.886$ s) is closest to that condition, the exponential decay is delayed, and the functionality loss progresses more slowly. Overall, the results indicate that the most significant reduction in functionality occurs within the first 5 years, whereas differences among the three building heights become progressively smaller over time, converging toward a narrow long-term functionality band of approximately 92%.

3.5 Resilient clock

The combined effects of hazard intensity, building height, soil condition, and time-dependent degradation are synthesized in the Resilience Clock shown in Figure 5. The results indicate a consistent reduction in the Seismic Resilience Index (SRI) as building height increases, soil conditions worsen, and the return period becomes more severe. The 3-story buildings generally remain within the high-to-medium-resilience range, the 6-story buildings show an intermediate response, and the 9-story buildings tend to shift toward the low-resilience domain, particularly under adverse soil conditions and higher return periods. This trend is mechanically consistent: taller buildings are more flexible and more sensitive to stiffness degradation and lateral deformation demand, whereas softer soils amplify the response, and larger return periods impose stronger hazard-consistent spectral demand.

The city-specific results show that Lima has the most critical resilience condition, followed by Arequipa, while Cusco generally maintains higher SRI levels, consistent with its location in seismic zones 4, 3, and 2,

respectively. However, the results also show that code-based expectations alone are insufficient: in several cases, especially for taller buildings in Lima and Arequipa under RP = 475 and 975 years, the computed resilience falls below the medium-resilience threshold, despite the normative reference line associated with E.030. This indicates that code compliance does not necessarily guarantee functional resilience, particularly when age-dependent degradation and site-specific hazards are introduced explicitly. Therefore, the Resilience Clock provides a more realistic basis for identifying critical ages, hazard levels, and structural typologies for which intervention becomes necessary.

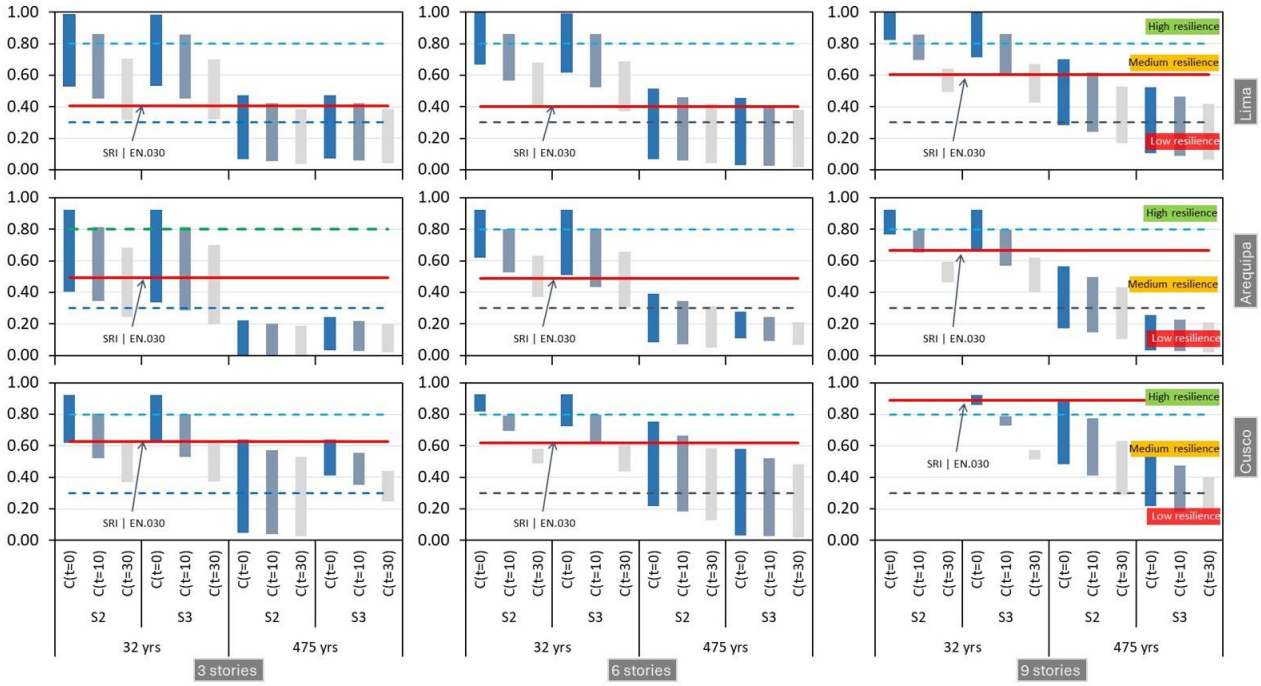

Figure 5 – Results of the resilient clock

4. Discussion

The results show that seismic resilience in residential RC-MRF buildings is governed by the combined effects of local hazard, structural period, and time-dependent functional degradation, rather than by code-based classification alone. The UHS results demonstrate that the spectral demand in Lima (zone 4) and Arequipa (zone 3) reaches peak ordinates on the order of 1.7–2.1 g for RP = 475–975 years, while Cusco (zone 2) may also approach 2.0 g under specific fault scenarios, despite its lower zonation level. Since the fundamental periods of the analysed archetypes (0.272 s, 0.580 s, and 0.886 s) fall within or near the most demanding spectral range, the three building classes are directly exposed to the critical portion of the hazard spectrum. This explains why the resilience loss is more pronounced for taller buildings, softer soils, and larger return periods, and why the E.030 normative reference is not always sufficient to represent actual functional performance. In this regard, the results confirm that hazard-consistent demand models are necessary when the objective extends beyond life safety and includes functionality and recovery.

A second major finding is that incorporating SFD(t) materially improves the realism of resilience estimation. The degradation model shows that the most significant functionality loss occurs during the first years of service, with the three archetypes reaching long-term residual functionality values close to 92% after 30 years, albeit at different decay rates. When this age-dependent condition is coupled with the baseline SRI,

the resulting Resilience Clock clearly distinguishes resilience states by city, height, soil condition, and return period, identifying cases in which resilience drops from medium to low even when a nominal code-based interpretation would suggest acceptable performance. Therefore, the proposed framework bridges the gap between nominal design compliance and actual structural condition, providing a more defensible basis for resilience-based prioritization of retrofit interventions in residential building stocks exposed to variable hazards and progressive degradation.

Taken together, the results confirm that the resilience of residential RC-MRF buildings cannot be adequately described from a static or code-only perspective. The most critical findings are: (i) UHS(RP) reveals local demand levels that may substantially exceed generalized code spectra; (ii) baseline resilience is highly sensitive to Sa(T) demand and structural scenario; (iii) time-dependent degradation causes a non-negligible early functionality loss, even under comparable quality conditions; and (iv) the resulting Resilience Clock clearly differentiates the effect of city, height, soil condition, and age on the transition from acceptable to critical resilience states. Accordingly, the proposed framework provides a technically consistent basis for age-informed retrofit prioritization and hazard-consistent decision-making in residential building stocks.

5. Conclusions

This study proposed a probabilistic resilience framework that couples hazard-consistent seismic demand, represented by UHS(RP), with time-dependent structural functionality degradation, SFD(t), to quantify the evolving resilience of residential reinforced-concrete frame buildings through a Resilience Clock. Based on the results obtained for 3-, 6-, and 9-story archetypes in Lima, Arequipa, and Cusco, the following conclusions can be drawn:

- The use of UHS(RP) reveals a substantially richer and more demanding hazard representation than code-based spectra alone. For RP = 475 and 975 years, Lima and Arequipa reached peak spectral accelerations on the order of 1.7–2.1 g, while Cusco also exhibited values approaching 2.0 g under specific fault scenarios. This confirms that local-source predominance and site effects must be explicitly considered in resilience-oriented assessments.
- The short-to-intermediate spectral range is the most critical for the analyzed residential typologies. The fundamental periods of the assessed archetypes (0.272 s, 0.580 s, and 0.886 s) lie within or near the most demanding UHS band, meaning that low- and mid-rise residential buildings are directly exposed to the highest hazard-consistent demand.
- Resilience decreases systematically with increasing building height, worsening soil conditions, and larger return periods. The Resilience Clock showed that 3-story buildings generally remain in the high-to-medium resilience range, 6-story buildings exhibit intermediate behavior, and 9-story buildings tend to migrate toward low-resilience states, particularly in Lima and Arequipa under RP = 475–975 years.
- Time-dependent degradation is not negligible and must be incorporated explicitly. The functionality model showed that the main degradation occurs in the early service-life stage, while the long-term residual functionality of the three archetypes converges toward approximately 92% after 30 years. This demonstrates that resilience cannot be treated as a static property of the structural system.
- Code compliance alone does not guarantee functional resilience. Several cases fell below the medium-resilience threshold despite the normative reference associated with E.030, indicating that actual resilience depends strongly on the interaction between local hazard, building height, soil condition, and age-dependent structural state.

Overall, the proposed methodology provides a technically consistent and operational tool for linking hazard, degradation, and resilience into a single decision-support framework. Its main practical value lies in

identifying critical ages, hazard levels, and structural typologies for which intervention becomes necessary, thereby supporting risk-informed retrofit prioritization for residential building stocks.

As a limitation, the present study considered simplified structural archetypes and a degradation function calibrated at the building level; therefore, future work should incorporate more refined nonlinear models, broader validation with field data, and explicit treatment of non-structural components and recovery interdependencies.

Beyond its analytical contribution, the proposed framework provides a practical basis for resilience-based decision-making by identifying critical ages, hazard levels, and structural configurations for which intervention becomes necessary.

Abstract: The Church of Santo Tomás de Aquino, located in Rondocan (Peru), lies in the Andean highlands of the Cusco region. The building, constructed with thick adobe walls, is representative of the architectural and cultural heritage of the 17th century. In 2016, the church was declared as National Cultural Heritage due to the construction techniques, traditional architecture, and decorative elements, including the wall paintings. Adobe structures are particularly vulnerable to seismic actions because of their brittle behavior. Although the church underwent conservation works in the 1990s, it still exhibits structural vulnerabilities, mainly related to the separation of the walls, especially in the rear façade. A seismic assessment was carried out using a finite element model calibrated with in situ data. Nonlinear pushover analyses revealed a poor seismic performance of the structure. The proposed strengthening strategy includes the construction of adobe buttresses. Timber keys are used to connect the buttresses to the existing walls and to strengthen the wall-to-wall intersections, while geogrids are installed to enhance tensile capacity of the buttresses. The numerical model was subsequently updated to incorporate these interventions. The results of the nonlinear pushover analyses indicate a substantial improvement in structural performance, with an increase in lateral load capacity ranging from 30% to 50% and a reduction in displacements of up to 55% at the Damage Limitation limit state. The proposed intervention reduces the expected damage under frequent seismic events, contributing to the protection of the wall paintings.

Keywords: Adobe building; historic masonry building; strengthening; nonlinear pushover analysis; seismic assessment

1. Introduction

Adobe is a widely used traditional construction material in seismic regions, particularly in the Andean highlands, where historic churches possess high cultural and architectural value. However, adobe structures are highly vulnerable to seismic actions due to their brittle behaviour, low strength, and poor connections between structural elements. These limitations often lead to damage such as wall separation, in-plane shear cracking, and out-of-plane collapse, further exacerbated by the absence of box-like behaviour due to weak connections and flexible diaphragms. To address these challenges, the Getty Conservation Institute (GCI) has developed key initiatives, including Getty Seismic Adobe Project and Seismic Retrofitting Project, aimed at advancing compatible and minimally invasive seismic retrofitting techniques for historic adobe structures (Tolles, Kimbro, and Ginell 2000; Cancino and Lardinois 2012).

This paper presents the seismic assessment and strengthening proposal of the Church of Santo Tomás de Aquino, a 17th century adobe church located in Rondocan, in the Cusco region. The building consists of a single nave with a presbytery and two annexed spaces: a baptistery and a sacristy. Thick adobe walls support

a timber roof system composed of wooden trunks and clay tiles, with some of the walls reinforced with buttresses. The church underwent conservation work between 1995 and 1997. The present study was carried out under the auspices of the GCI, with fieldwork, testing, and numerical analyses conducted by the University of Minho.

The adopted methodology is based on a macro-modelling approach, in which adobe and stone masonry are represented as homogeneous continua, incorporating nonlinear behaviour through a total-strain rotating-crack model. Material properties were derived from in situ testing conducted by the University of Minho and complemented with literature data, while the numerical model was calibrated using ambient vibration test results. The assessment employs nonlinear static (pushover) analysis to identify critical failure mechanisms and to estimate seismic capacity with respect to the demand defined by the Peruvian seismic code. Particular attention is given to the out-of-plane response of walls (Nochebuena-Mora et al. 2025).

Based on the identified vulnerabilities, a strengthening strategy using compatible and reversible techniques is proposed. The intervention includes the addition of new buttresses to enhance out-of-plane resistance, the use of timber keys to improve interlocking at wall intersections and buttress connections, and the incorporation of a polymeric geogrid to increase the flexural and shear capacity of the buttresses. A timber frame is introduced at the top of the walls to improve global behaviour and support a reconstructed roof system, while existing tie beams are repositioned and properly anchored to ensure effective performance under seismic loading. The effectiveness of the proposed intervention is evaluated through comparative nonlinear pushover analyses between the unstrengthened and strengthened configurations. For brevity, the results presented here are limited to a force-based assessment using two performance levels defined by the Italian code, namely the Damage Limitation (DL) and Life Safety (LS) limit states.

2. Building description and current damage state

The Church of Santo Tomás de Aquino is a 17th-century adobe structure located in the Peruvian Andes (Figure 1). The church is situated on a site with an approximate slope of 10% and comprises a single nave with a presbytery, along with a baptistery and a sacristy on the south side (Figure 1b). The interior space defined by the nave and presbytery measures approximately 34.0 m in length and 8.0 m in width.

The structural system consists of a rubble stone masonry bonded with earth mortar in the foundation, which rises above ground level; adobe masonry in walls and buttresses, with the nave walls approximately 2.0 m thick and those of the baptistery and sacristy ranging between 1.0 and 1.2 m; and a gable roof constructed with timber beams in a *par y nudillo* configuration supporting clay tiles. Between 1994 and 1997, the church underwent conservation works, including the replacement of the roof system and adobe units, as well as the addition of timber keys (MINCUL 1998).

The main façade (Figure 1c), oriented west toward the plaza, reaches a height of approximately 11.5 m above the reference level (0.0 m). It is characterized by the principal entrance, consisting of a doorway with stone jambs and a semicircular arch on the exterior face, while the interior face is configured with splayed jambs (embrasures) that support a timber lintel. Above the entrance, a richly decorated choir loft is supported by a timber framework resting on four *quincha* columns and further anchored to the nave walls and the main façade (Figure 1d). The rear façade, located on the east side, rises to approximately 9.7 m above ground level (13.6 m relative to the reference level). This wall features a window with an embrasure with a niche above it (Figure 1d). The triumphal arch is formed by adobe pilasters that carry a *quincha* structure, which constitutes both the arch and its spandrels.

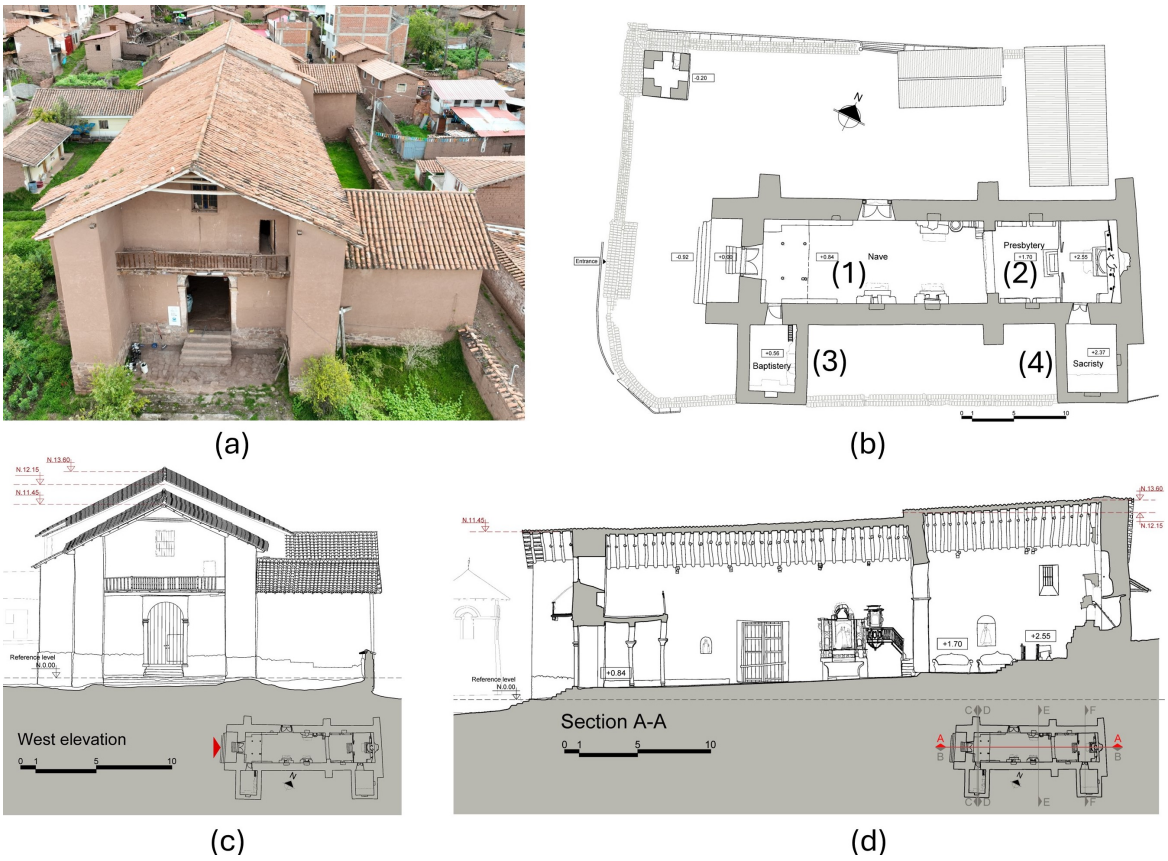

Figure 1 – Church of Santo Tomás de Aquino, in Rondocan, Peru: (a) general view, (b) plan view with North indicated (1-Nave, 2-Presbytery, 3-Baptistery, 4-Sacristy); (c) main façade; and (d) longitudinal section. (Dimensions in meters)

The roof structure is formed by timber trusses made of round wooden members and spaced at intervals of 0.60–0.75 m (Figure 2). Each truss comprises two upper rafters (*sobre pares*) supported on the tops of the lateral walls, two lower rafters (*pares*) resting on an internal timber wall plate, and a collar tie (*nudillo*) connecting the upper ends of the lower rafters. All trusses are linked longitudinally by a continuous ridge beam. The upper rafters extend outward by approximately 0.50 m, forming the eaves and supporting a multilayered roof assembly consisting of canes, an earth–straw mixture, and clay tiles. At wall plate level, nine timber tie beams ensure transverse connectivity between the lateral walls. Additional tie beams are incorporated within the baptistery (two) and the sacristy (two).

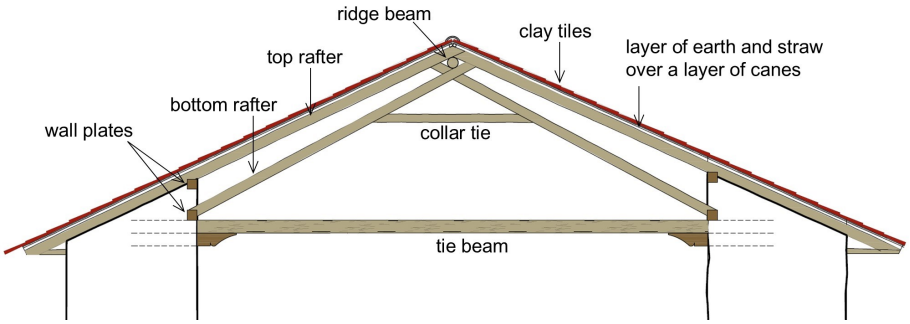

Figure 2 –Roof structure

Mural paintings extend continuously across the interior wall surfaces, covering their full height. In addition, the church contains several movable artworks, many of which are attributed to Bernardo Bitti (Tejada Farfán 2019, 2023). In recognition of its traditional construction techniques, architectural character, and artistic importance, the building was declared a National Cultural Heritage site in 2016 (*Resolución Vice Ministerial Nº 078-2016-VMPCIC-MC* 2016).

An on-site assessment conducted in 2024 documented extensive deterioration and structural damage, despite the conservation works carried out in the 1990s. Cracks were identified at the intersections between the lateral walls and both the main and rear façades, along with separation at the choir loft connections. In the main façade, vertical cracks extending over the full height were observed at its junctions with the nave walls, visible on both the interior and exterior (Figure 3a). The choir loft exhibited partial detachment from the façade and lateral walls, resulting in deformation of its timber components. The most critical damage affected the rear façade, where vertical cracking at the wall intersections (Figure 3b) led to an almost complete loss of connection. Borescopic inspection at a height of 2.0 m revealed crack depths of at least 0.30 m at the south corner and 0.50 m at the north corner. Additional vertical cracking was observed at midspan of the gable walls in the baptistery and sacristy. The spandrels of the triumphal arch exhibited out-of-plane rotation toward the nave, generating cracking at their interfaces with the lateral walls. Moreover, localized material loss was observed at the tops of the walls, primarily associated with water infiltration (Figure 3c).

Figure 3 – Crack as the corners of (a) main façade and (b) rear façade; (c) material loss

3. Strengthening proposal

The proposed strengthening strategy aims to enhance the lateral capacity of the building, particularly its out-of-plane response, using compatible and traditional techniques. Figure 4 illustrates the overall strengthening scheme. The intervention includes the addition of buttresses and timber reinforcement. Seven new buttresses are introduced to improve the lateral capacity of the north and south walls, as well as the rear façade. To ensure effective interlocking, the buttresses are connected to the existing walls using timber keys, primarily designed to resist shear forces (Figure 4a). In addition, a polymeric geogrid is incorporated to enhance both the flexural and shear capacity of the buttresses through horizontal layers embedded within the masonry courses and vertical layers applied to the external surfaces. The proposed buttresses along the lateral walls of the nave were dimensioned and verified through kinematic analysis. Conversely, the buttresses at the rear façade were defined based on architectural criteria.

Timber keys embedded at multiple levels are also proposed to strengthen all building corners and the intersections between the baptistery, sacristy, and nave walls. Additional timber keys are introduced to improve the connection between existing lateral buttresses and the walls. A timber frame (collar beams), embedded at the top of the walls, is designed to support a new roof (constructed using the same *par y*

nudillo system) and to improve the flexural response of the walls (Figure 4b). The existing tie beams will be relocated to have a more uniform distribution along the nave and presbytery, and their anchorage system will be designed to ensure effective performance under both tension and compression during seismic loading. The cross-sections of the new timber elements range from $4 \times 4\ in^2$ to $6 \times 6\ in^2$ (10×10 to $15 \times 15\ cm^2$).

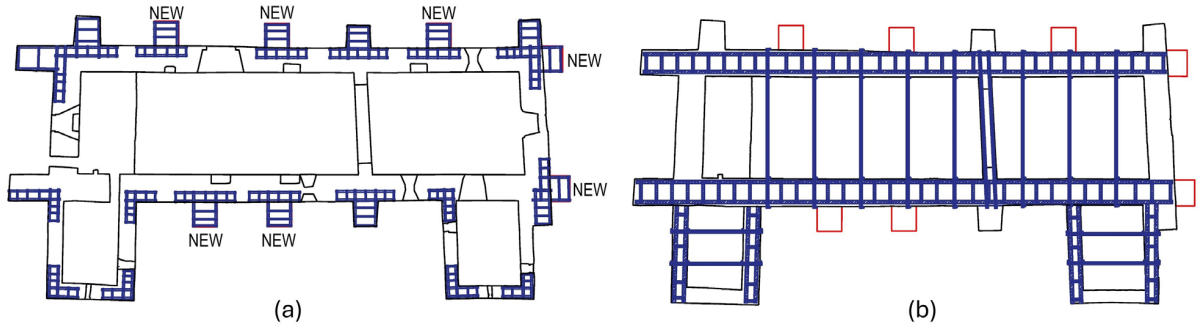

Figure 4 – General strengthening scheme (a) timber keys and buttresses (b) collar beams and tie beams

4. Numerical model

A three-dimensional geometry created in AutoCAD 2024 (Autodesk Inc. 2023) was used to generate the finite element (FEM) model in DIANA 11.0 (DIANA FEA BV 2025). The model comprises the nave, presbytery, baptistery, and sacristy, along with the timber tie beams and the foundation, accounting for elevation changes due to the ground slop (Figure 5a). The choir loft and the spandrels of the triumphal arch were not included, as their contribution to the global structural response of the church was deemed negligible. Boundary conditions were defined by restraining all degrees of freedom at the base of the foundation. The mesh was generated with an average element size of 0.5 m, resulting in four elements across the wall thickness (Figure 5a). The foundation, walls, buttresses, and lintels were represented by twenty-node isoparametric solid elements with quadratic interpolation. The tie beams were modelled as two-node truss elements with an equivalent circular cross-section of 0.20 m in diameter. Stress concentrations at tie–wall connections were minimized by modelling the beam ends as embedded in the walls using reinforcement bar elements continuous with the truss elements and having identical mechanical properties. The roof was omitted from the model as it does not behave as a rigid diaphragm and has a limited contribution to the global seismic response. Instead, its mass contribution was simulated through an equivalent density applied to the upper parts of the walls. Regarding the proposed strengthening strategy, all the timber reinforcement and the polymeric geogrid were incorporated as embedded elements (Figure 5b and c).

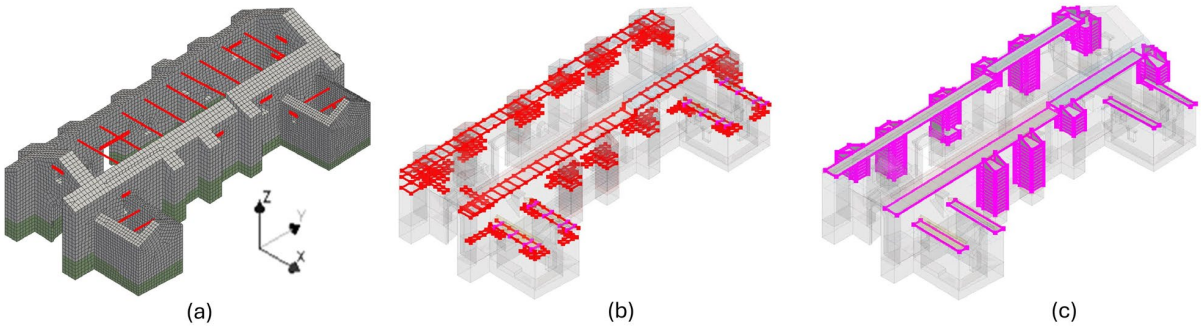

Figure 5 – Numerical model: (a) mesh and material distribution (green-rubble masonry, grey-adobe, red-timber); (b) embedded timber reinforcement; and (c) embedded geogrid reinforcement

4.1 Mechanical properties of the materials

The mechanical properties assigned to the model were defined combining literature data and in situ experimental testing conducted by the University of Minho in April 2024 (Karanikoloudis, Mendes, and Lourenço 2024). The material distribution (Figure 5a) includes rubble stone masonry for the foundation, adobe masonry for the walls, buttresses, and triumphal arch pilasters, and timber for the lintels and tie beams. Adobe and rubble masonry were assumed homogeneous and isotropic, with nonlinear behaviour simulated using a total-strain rotating-crack model. The Young's moduli were obtained from sonic testing and subsequently calibrated by matching the numerical model to ambient vibration test results, using natural frequencies and the Modal Assurance Criterion (MAC) (Allemang and Brown 1982). Compressive response was described by a parabolic hardening–softening law, while tensile response followed an exponential softening relationship (Ferreira 2024). Strength parameters and fracture energies were taken from the literature (Karanikoloudis and Lourenço 2018; Nochebuena-Mora et al. 2025).

Timber elements were modelled as linear elastic materials with properties representative of Eucalyptus species. Existing elements were assigned a density of 420 kg/m³ and a Young's modulus of 5700 MPa (Karanikoloudis, Mendes, and Lourenço 2024), while reinforcement timber was defined with a density of 890 kg/m³ and a Young's modulus of 9316 MPa (Torrealva and Samuel 2025). The geogrid was represented using a perfect plastic law, with a Young's modulus of 538 MPa and a tensile strength of 153 MPa, based on experimental data (Torrealva and Samuel 2025). A summary of the adopted material properties is provided in Table 1.

Table 1 – Mechanical properties

Mechanical properties		**Rubble stone masonry**	**Adobe**	**Existing timber**	**New timber elements**	**Geogrid**
Density	ρ (kg/m³)	1900	1900	420	890	-
Young's modulus	E (MPa)	1400	335	5700	9316	538
Poisson's ratio	v (-)	0.2	0.2	0.3	0.3	-
Compressive strength	f_c (MPa)	0.60	0.45	-	-	-
Tensile strength	f_t (MPa)	0.06	0.05	-	-	153
Compressive fracture energy	G_c (N/mm)	1.80	1.38	-	-	-
Tensile fracture energy	G_f^I (N/mm)	0.01	0.01	-	-	-

5. Seismic assessment of the strengthening proposal

Nonlinear pushover analyses were carried out to evaluate the global performance of the structure and to assess the effectiveness of the proposed strengthening intervention through comparison between the current (unstrengthened) and strengthened states. The model was first subjected to self-weight, followed by incremental monotonic lateral loads simulating seismic inertia using a mass-proportional load pattern (Lagomarsino and Cattari 2015). Due to the irregular geometry, a multidirectional pushover approach was adopted (Kalkbrenner, Pelà, and Sandoval 2019), applying loads along the X and Y axes in both positive and negative directions until ultimate capacity was reached to capture the variability of potential collapse mechanisms. The response was assessed through capacity curves relating load factor (interpreted as

equivalent ground acceleration in g) to control point displacements at the top of the walls. Damage was assessed using principal tensile strain distributions.

For sake of brevity, only the force-based assessment is presented in this work. The reference ground acceleration was defined according to the Peruvian seismic code E.030 (Ministerio de Vivienda Construcción y Saneamiento 2016) for Zone 2 (a_g = 0.25 g), soil type S2 (S = 1.2), and importance factor U = 1.3, resulting in 0.39 g. However, reductions are permitted depending on structural typology. For adobe buildings, code E.080 (Ministerio de Vivienda Construcción y Saneamiento 2017) specifies a lower value of 0.29 g. In line with recommendations for heritage structures, which discourage the use of very high accelerations, a reference value of 0.30 g (a_g = 0.25 g and S = 1.2) was adopted in this study. Two limit states were defined following the Italian code: Damage Limitation (DL, 50-year return period) and Life Safety (LS, 475-year return period). (Ministry of Infrastructure and Transport 2019, 2018). The DL action was obtained by scaling the reference acceleration by 0.47 in accordance with Eurocode 8 (European Committee for Standardization 2004) resulting in 0.14 g. For the LS limit state, the seismic action is divided by a factor q=2 (Ministry of Infrastructure and Transport 2019, 2018), leading to a ground acceleration of 0.15 g. The displacement responses derived from the capacity curves for the unstrengthened and strengthened models were subsequently compared at these two seismic demand levels.

Figure 6 compares the pushover results for the unstrengthened and strengthened conditions in three directions, showing capacity curves and principal tensile strain distributions (corresponding to crack openings ≤ 1.0 mm). As expected, the strengthening intervention improves the global response of the building, increasing both lateral stiffness and load capacity, which results in reduced displacements. In the positive X direction (Figure 6a), the lateral capacity increases by approximately 19%, while displacements at both seismic demand levels are reduced by about 50% in the nave (south wall, also referred to as the Epistle wall). The analysis indicates that, even at 0.15 g, the structure can withstand the seismic action without any damage.

In the negative X direction (Figure 6b), the north wall (also referred to as the Evangelio wall) exhibits a greater increase in lateral capacity, of approximately 30%, together with a reduction in displacements of about 55% in both the nave wall and the existing buttress at the two seismic demand levels. The capacity curves indicate that, in the current condition, the Evangelio wall tends to behave as two distinct segments prior to peak load, with the nave wall being more flexible than the portion adjacent to the buttress. In the post-peak phase, however, the wall transitions into a single rocking mechanism, characterized by diagonal cracking extending from the base toward the corners (Figure 7a). The buttress fails due to shear stress at its connection with the wall. In contrast, the strengthened configuration shows a more uniform response, with the Evangelio wall behaving as a single body throughout the analysis. The damage pattern is characterized by vertical cracking at the corners and the formation of a well-defined hinge along the base, at the interface between the rubble masonry foundation and the adobe wall. For the buttresses connected to the Evangelio wall, failure is governed by crushing of the adobe at the foundation interface, with no evidence of shear damage, indicating the proper functioning of the timber keys.

In the longitudinal direction (positive Y, Figure 6c), the strengthening intervention leads to a significant increase in lateral capacity of approximately 110%, together with a substantial reduction in displacements of up to 90% for both seismic demand levels. In the strengthened configuration, damage localizes at the upper corners of the rear façade, with crack openings not exceeding 1.0 mm and minimal propagation at 0.15 g. In the unstrengthened state, failure is governed by an out-of-plane mechanism that develops under low seismic demand, characterized by corner cracking and the formation of a base hinge, ultimately leading to complete detachment of the façade (Figure 7b). This behaviour is associated with weak wall connections, absence of diaphragm action, and lack of buttresses. In contrast, the strengthened configuration exhibits a more global structural response. The out-of-plane behaviour of the rear façade is coupled with more distributed damage, including shear cracking in the gable walls of the sacristy and baptistery, as well as shear failure in both presbytery walls.

6. Conclusions

This study presented the seismic assessment and strengthening proposal for the Santo Tomás de Aquino Church, a 17th century adobe structure representative of Andean earthen heritage. The numerical analyses highlighted the high seismic vulnerability of the building in its current condition, primarily governed by out-of-plane mechanisms of the walls. The results showed that the lateral capacity of the structure is consistently low, with critical deficiencies associated with weak wall connections, absence of diaphragm action, and limited transverse restraint.

The proposed strengthening strategy, based on compatible and reversible techniques, proved effective in significantly improving the seismic performance of the structure. The introduction of additional buttresses, timber keys, timber collar beams, and geogrid reinforcement enhanced both lateral stiffness and load-carrying capacity, while promoting a more global structural response. Nonlinear pushover analyses demonstrated substantial increases in lateral capacity (up to approximately 110% in the longitudinal direction) and significant reductions in displacement demand, reaching up to 90% in some cases. Moreover, the strengthened configuration mitigates localized failure mechanisms, leading to more distributed and controlled damage patterns, particularly in the longitudinal direction, which is the most vulnerable. The comparison between the unstrengthened and strengthened conditions confirms that the intervention effectively addresses the main structural deficiencies, especially by improving wall interconnections and out-of-plane stability.

Overall, the study demonstrates that the proposed intervention significantly enhances the seismic safety of the church, enabling it to better meet the required performance levels for both damage limitation and life safety limit states. This aspect is particularly relevant given the presence of mural paintings within the

interior of the church. Beyond improving safety under strong seismic events, the intervention aims to minimize damage to these artworks during more frequent earthquakes. The results indicate that the reduction in structural displacements contributes to decreasing the risk of damage to the walls and, consequently, to the preservation of the painted surfaces.

The adopted methodology, combining advanced nonlinear numerical modelling, experimental data, and conservation-oriented design, provides a robust framework for the assessment and strengthening of similar adobe heritage structures in seismic regions. In this context, the study contributes by quantitatively demonstrating that compatible strengthening techniques can effectively transform local out-of-plane failure mechanisms into a more global and controlled structural response, while simultaneously improving seismic performance and limiting damage in heritage adobe buildings.

Abstract: Buildings of cultural value often present limitations regarding the availability of technical documentation and detailed knowledge of their conservation state. In this context, non-destructive methods become essential to support diagnostic, documentation, and maintenance actions. This study aims to integrate a digital HBIM model with infrared thermography data of the masonry of the Church of São Sebastião, located in the municipality of Russas, Ceará, Brazil. In this works thermograms were interpreted with the support of Computer Vision and Image Processing techniques to detect patterns and map damage in the masonry and roofing systems of the asset. The building geometry was obtained through terrestrial laser scanning, resulting in a three-dimensional point cloud used as the basis for the development of the HBIM model. Infrared thermography surveys were conducted on internal masonry, facades and roof, using both handheld thermal cameras and aerial thermal images acquired by a drone equipped with a thermographic sensor, in order to identify thermal contrasts associated with constructive interfaces, material layers, moisture presence, and other anomalies. The adopted methodology comprised six main stages: (i) geometric survey using mobile laser scanning; (ii) execution of thermographic inspections on the different surfaces of the building; (iii) processing and organization of data obtained from the laser scanner and thermographic images; (iv) development of the digital HBIM model based on the point cloud; (v) analysis of thermographic and damage images using computer vision; and (vi) integration of thermographic information into the HBIM model. The results indicate that the proposed approach enables the integrated organization of geometric, thermographic, and informational data within a unified digital environment. The proposed approach enables the integrated organization of geometric, thermographic, and informational data in a unified digital environment, allowing their association with HBIM elements for technical documentation and systematic recording of the building's conservation condition.

Keywords: Infrared thermography, HBIM, Image Processing, Pathological manifestations, Heritage buildings.

1. Introduction

Historic heritage represents the cultural identity of a society, and its conservation is essential for preserving collective memory. In this context, understanding the current state of degradation of such buildings is fundamental for monitoring conservation conditions and identifying deterioration processes that develop over time, whether caused by natural agents or human action.

Given the need to assess these structures without compromising their physical integrity, investigation techniques that do not damage the original elements become particularly relevant. In this regard, non-destructive testing (NDT) stands out, as it is widely used in the diagnosis of historic structures because it

allows the assessment of materials and construction systems without direct interference with their constitution [1,2]. NDT encompasses different inspection procedures capable of providing information on construction heterogeneities, the presence of moisture, voids, discontinuities, and behavioral changes in masonry and rendering components [3].

Among the various NDT techniques applied to heritage assets, infrared thermography has gained prominence due to its ability to identify thermal anomalies associated with construction defects and superficial or subsurface alterations. It is a non-destructive, non-contact, safe, and rapid data acquisition technique whose interpretation is based on recording the infrared radiation emitted by materials and converting it into thermal images [1,4,5]. Its applications include the identification of moisture, detachments, air pockets behind coatings, hidden elements, and areas with thermal behavior distinct from the surrounding surface [1,6,15]. In historic buildings and rendered façades, thermography has also been used to establish quantitative thermal contrast criteria and to analyze the visibility of anomalies as a function of solar orientation, inspection time, and exposure conditions [15,16].

In the specific case of historic façades and masonry, thermogram interpretation requires attention to factors such as architectural geometry, emissivity, incident radiation, and material heterogeneity, since these variables directly influence the observed thermal distribution [6,7]. Beyond traditional qualitative interpretation, recent studies have expanded the use of thermography for quantitative analyses, including the delimitation of anomalous areas, the evaluation of thermal gradients, and the comparison between regions with different thermal behaviors [15,17,18].

In recent years, non-destructive techniques applied to heritage assets have evolved significantly, particularly through the incorporation of computer vision and Image Processing methods into image processing and interpretation. This advance is associated with the need to automate analytical stages, reduce the subjectivity of manual interpretation, and enhance the ability to identify thermal patterns under different inspection conditions [8,9]. In the specific field of thermography, methods based on machine learning, automated detection, and explainable image processinhave been applied to the analysis of thermal images, yielding promising results in the identification of anomalies in façades and building surfaces [9,19].

At the same time, computer vision has contributed to transforming the thermogram into data that can be segmented, quantified, and geometrically interpreted, extending the use of thermography beyond simple qualitative observation. In this context, digital image processing procedures make it possible to isolate regions of interest, recognize thermal patterns, detect contours, and estimate the extent of anomalous areas, thereby providing more systematic support for diagnostic analysis [17,19]. This type of approach is particularly relevant for heritage surfaces, where the presence of ornamentation, moldings, and material variations may hinder the distinction between geometric effects and actual pathological manifestations [16,19].

This technological development has also fostered the integration of diagnostic results into digital representation and management environments. In this context, approaches based on HBIM (Heritage Building Information Modelling) have become particularly relevant, as they enable geometric, constructive, and diagnostic information to be brought together within a three-dimensional building model [10–12]. The incorporation of data derived from non-destructive inspections into HBIM models has been identified as a relevant strategy for documenting, organizing, and querying information on built heritage, especially when associated with visual records and analytical data [13,20,21].

Thus, the application of computer vision to the interpretation of thermographic images, combined with the insertion of results into HBIM environments, constitutes a line of research directly related to the diagnostic documentation of historic heritage. Although recent advances have expanded the use of digital models in historic buildings, a significant portion of research is still concentrated on geometric representation, indicating the need for approaches that more systematically incorporate inspection and analysis data into the information model [8,14].

In this context, the present study aims to apply computer vision techniques to the interpretation of data derived from infrared thermography surveys, in order to support the detection of thermal patterns and the identification of pathological manifestations in the masonry of a historic building. In parallel, the study proposes the integration of this information into an HBIM environment, with the objective of structuring and centralizing, within a unified digital model, the geometric, imaging, and diagnostic records produced throughout the investigation.

2. Methods and materials

Initially, the Church of São Sebastião, located in Russas, Ceará, was selected due to its historical, cultural, and constructive relevance. Next, the geometric and documentary survey of the building was carried out through the acquisition of a 3D point cloud using terrestrial laser scanning and photogrammetry with an unmanned aerial vehicle, in order to record its architectural configuration and generate the basis for the church's HBIM modelling.

In the following stage, thermographic surveys and photographic records were conducted on the external masonry areas showing the greatest concentration of visible damage, aiming to identify thermal patterns associated with possible pathological manifestations. After acquisition, the thermograms were subjected to digital image processing and computer vision techniques for the segmentation of anomalous regions, recognition of thermal patterns, and quantification of affected areas. Finally, the obtained results were integrated into the HBIM model, as shown in Figure 1, which summarizes the complete methodological workflow of the research.

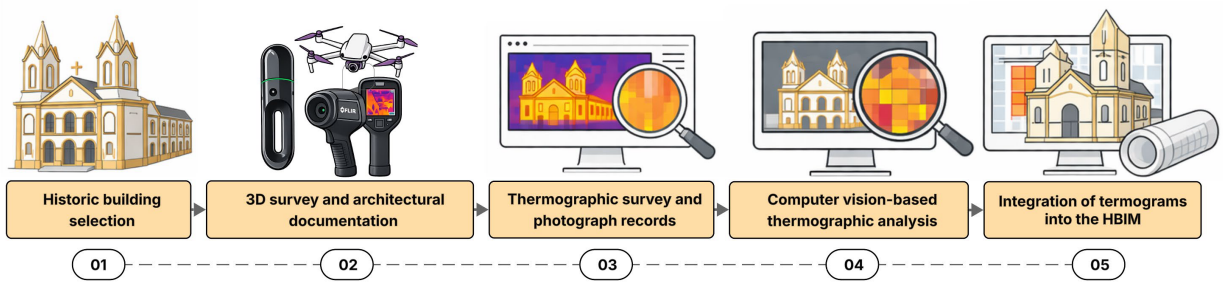

Figure 1 – Workflow of the methodological procedure adopted in the research.

2.1. Historic building selection

O The study was carried out at the Church of São Sebastião, located in Russas, in the state of Ceará. The building was selected due to its relevance to the urban and religious memory of the municipality and for preserving architectural features representative of the local historic construction tradition. In addition to its symbolic importance to the community, the church presents a constructive configuration compatible with the proposed investigation, particularly because of the presence of rendered masonry and surfaces suitable for thermographic analysis.

The consolidation of the church within the local context is associated with the historical formation of devotion to Saint Sebastian in the municipality. Records indicate that, between 1816 and 1817, the region was affected by severe drought and epidemic outbreaks, a context in which popular devotion to Saint Sebastian was strengthened, leading to the idea of constructing a temple dedicated to the saint as part of the local religious imagination [22]. This devotion was later materialized through the construction of the church, completed in 1872, which has since occupied a central role in the city's religious practices and traditional festivities [23].

From a material standpoint, the building is predominantly composed of brick masonry and still preserves architectural elements that retain formal features of its original conception. Over time, however, the building underwent conservation and improvement interventions, with works recorded in different periods, including actions related to the execution of the ceiling structure in the early decades of the twentieth century and later services involving the repair of renderings, repainting, and localized replacement of deteriorated components [22,23]. This history of permanence, continuous use, and partial maintenance provides a relevant condition for investigating thermal patterns associated with superficial alterations and pathological manifestations in its masonry. Figure 2 shows the church in its current condition.

Figure 2 – Photographs of the Church of São Sebastião (2025).

2.2. 3D survey and architectural documentation

Data acquisition for the building was carried out in two complementary stages. The first comprised the geometric and documentary survey through terrestrial laser scanning using the portable Leica BLK2GO device and aerial photogrammetry using a DJI Mavic 3T unmanned aerial vehicle, both adopted as the basis for the three-dimensional modelling of the building.

2.2.1. 3D laser scanning and photogrammetry

Initially, laser scanning of the church was carried out using the portable Leica BLK2GO device, based on LiDAR capture, with the aim of recording the spatial geometry of the architecture and generating a three-dimensional point cloud of the building. The acquisition of the church's internal geometry was performed with the portable scanning sensor, manually operated throughout the interior spaces, and monitored in real time through an iPad Pro tablet connected to the system. During the survey, a reference unit was positioned at a stable location inside the church, while the portable sensor was operated through continuous walking across the surveyed areas. This procedure allowed real-time control of data quality during acquisition and the correction of possible gaps in spatial coverage.

At a later stage, a photogrammetric survey was carried out using a DJI Mavic 3T unmanned aerial vehicle, employed to obtain aerial images of the external regions and difficult-to-access areas, especially the roof, façades, and upper portions of the building. The complementary use of photogrammetry made it possible to expand the geometric documentation of the building and to record areas not fully captured by terrestrial laser scanning. The point cloud obtained from the laser scanning survey was processed in Cyclone Register 360, while the images captured by the drone were processed in RealityScan 2.1.0, which was responsible for generating the building's photogrammetric model. Figure 3a presents the point cloud obtained from mobile laser scanning, used as the geometric basis for the spatial representation of the church, whereas Figure 3b shows the model generated by photogrammetry, providing greater visual detail of the external surfaces and roof.

Figure 3 – Geometric survey and organization of capture points: (a) 3D point cloud of the church; (b) 3D model generated by photogrammetry.

Subsequently, the outputs generated by these two techniques were submitted to the registration and integration stage in CloudCompare, with the aim of constituting a unified geometric basis of the building. This procedure involved the definition of homologous points between the surveys, enabling the spatial alignment between the point cloud obtained by laser scanning and the model generated by photogrammetry. Figure 4a presents the reference points adopted in the laser-scanning model, while Figure 4b shows the corresponding points defined in the photogrammetric model for the alignment process. At the end of this procedure, the unified base was exported to Autodesk Revit, serving as support for the three-dimensional modelling and spatial organization of the analyzed areas.

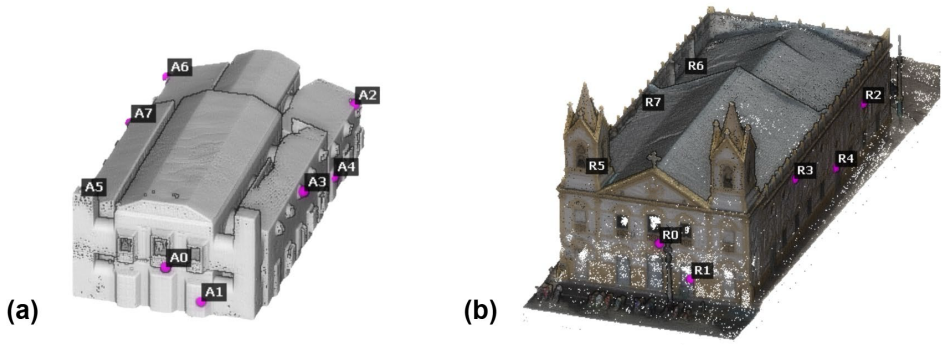

Figure 4 – Definition of homologous points for geometric integration in CloudCompare: (a) reference points in the laser scanning model; (b) corresponding points in the photogrammetric model.

2.2.2 Digital modelling and information structuring

Com With the integrated point cloud completed, the building modelling stage was initiated in Autodesk Revit 2023, using the consolidated geometric base as reference for the construction of the three-dimensional model of the church. The model was structured to represent the architectural configuration of the building and to organize the information produced throughout the research. The masonry elements were defined as the main focus of the investigation and prepared to receive non-geometric attributes associated with the field analyses. For this purpose, the Project Parameters feature in Revit was used, through which parameters linked to the wall category were created, all defined as Text, allowing the standardized insertion of descriptive information into the properties of each analyzed element.

Among the created parameters, the following stand out: ID's, for the individual identification of the wall or analyzed area; Visual inspection, for recording the observations obtained during visual inspection; Thermography analyses, intended to describe the patterns observed in the thermograms; Damage detection, for recording the identified pathological manifestations; Final report, aimed at the final synthesis of the analysis; Digital image, corresponding to the reference of the associated photographic image; and Thermography image, intended for the reference of the corresponding thermogram. Native Revit fields

within the Identity Data group, such as Comments and Mark, were also used to complement the identification of the survey and the building.

In addition to the textual information, the model incorporated the visual records obtained during the research. For this purpose, photographic images and thermograms were inserted over the analyzed elements through decals, a feature used to associate the images with the modelled surfaces according to the investigated region. In this way, the model came to integrate, within a single digital environment, the building geometry, the field records, and the image products generated by the thermographic survey.

2.3 Thermographic survey and photograph records

The thermographic survey was carried out in conjunction with the photographic documentation of the external masonry surfaces of the building, so that each analyzed point included both a visible digital image and its corresponding thermogram. For this purpose, the portable FLIR TG165-X thermal camera, shown in Figure 5a, was used to acquire thermal records of the surfaces with greater exposure to solar radiation. The capture strategy was defined based on passive thermographic analysis, in which solar incidence acts as a natural thermal stimulus, favoring the formation of contrasts on the investigated surfaces. Under this condition, acquisitions were performed during the morning period in order to better exploit solar exposure on the masonry and enhance the visibility of temperature variations associated with possible pathological manifestations. The adopted measurement mode was by reflection, and thermogram interpretation was conducted qualitatively, considering failures in thermal patterns, discontinuities in surface behavior, and their correspondence with anomalies observed in the photographic records.

Throughout the survey, approximately 60 capture points were defined around the perimeter of the church, prioritizing regions with visible indications of pathological manifestations on the external masonry surfaces. As a result, a database composed of 69 color digital images and 69 thermograms was established, corresponding to the same capture locations. The acquisitions were concentrated on the building façades, covering different portions of the external masonry and seeking to include areas with greater solar incidence and higher potential for damage occurrence. The spatial distribution of these points along the building is shown in Figure 5b.

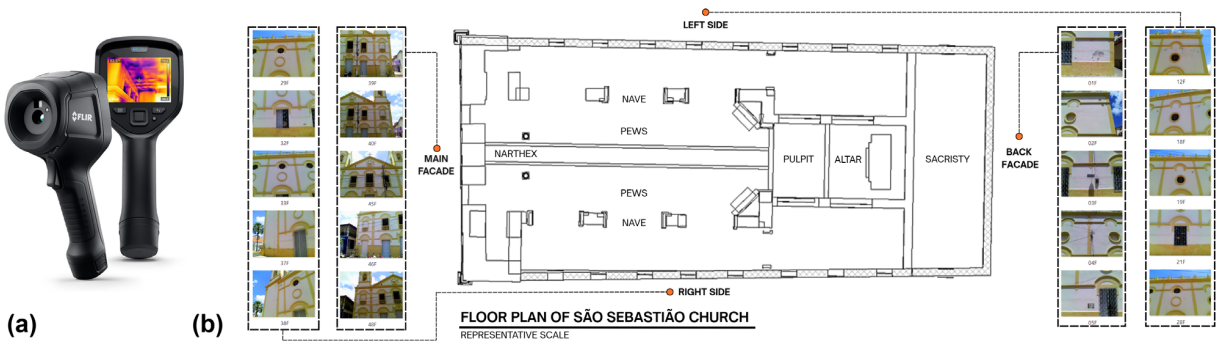

Figure 5 – Thermographic acquisition of the building: (a) FLIR TG165-X thermal camera used in the survey; (b) mapping of the main capture points for photographic images and thermograms.

The organization of the capture points made it possible to relate the location of the records to the apparent surface conditions and the observed thermal patterns. This procedure enabled the formation of a paired dataset composed of corresponding photographic and thermographic images, which was later used in the digital processing and computational analysis of the investigated regions.

2.4 Computer vision-based thermographic and image acquisition

The computational analysis stage of the thermograms was developed in Python, with the integrated use of the OpenCV (cv2), NumPy, and Matplotlib libraries, respectively responsible for image reading and processing, matrix manipulation of the data, and generation of the final analytical visualizations. Initially, the input parameters of the algorithm were defined, including the path of the image to be processed, the number of thermal clusters to be adopted in the segmentation, and the real width of the scene in meters, which was later used for the metric conversion of the detected area. The thermal image was then loaded and converted to the RGB color space, allowing the data to be prepared for the subsequent stages of analysis. At this stage, the Region of Interest (ROI) was also defined by technically cropping the useful portion of the thermogram in order to remove graphical elements external to the analyzed surface, such as scales, logos, and camera interface markers, as summarized in Figure 6.

```

Figure 6 – Computational processing workflow applied to the thermograms.

After the Region of Interest (ROI) was defined, a structural segmentation stage was carried out using the K-Means algorithm, adopted to group the image pixels into thermal zones with similar behavior. This operation simplified the interpretation of the thermal field by organizing the surface into transition regions and areas with greater apparent heat concentration. In parallel, for the quantitative extraction of anomalies, the ROI was subjected to a bilateral filter in order to reduce noise without compromising the definition of thermal edges.

Subsequently, the smoothed image was converted from the RGB color space to the HSV color space, a procedure adopted to facilitate the parametric segmentation of the chromatic ranges associated with thermal anomalies. Based on the definition of lower and upper thresholds for the target tones, a binary mask was generated to isolate the regions exhibiting anomalous thermal behavior. Mathematical morphology operations were then applied to this mask, especially morphological closing, in order to fill internal discontinuities and consolidate the segmented region as a continuous body.

Once the final mask was defined, the contours of the segmented areas were detected and a minimum-area filter was applied to remove residual noise and preserve only the regions most relevant for analysis. The areas detected in pixels were then converted into real metric units based on the scale factor calculated from the real width of the scene provided as an input parameter to the algorithm. This procedure allowed the

quantification of the anomalous area in square meters, which was used as a supporting parameter for result interpretation.

Finally, the processing generated an analytical panel composed of different visual products, including the original ROI, the K-Means segmentation, the alert overlay highlighting anomalous areas, the isotherm mapping, and the final image with the quantification of the detected area, as shown in Figure 7. In addition, the algorithm generated a final report containing the reference values of the scene, the number of pixels classified as anomalous, and the total quantified area. To convert the segmented area from pixels into square meters, a real dimensional reference of the analyzed scene was required. In this procedure, the user must provide an estimated dimension of the photographed surface, such as the actual width of the captured masonry panel, allowing the algorithm to establish the scale factor between the image and the corresponding physical dimension. When this information is not incorporated during image acquisition, the metric quantification depends on the dimensional estimate adopted for each image. This set of outputs was used as the basis for the technical interpretation of the thermograms and for the comparison between the thermal patterns observed on the analyzed surfaces.

Figure 7 – Results of the computational processing of the thermograms.

2.5 Integration of termograms into the HBIM

After the acquisition and processing of the thermograms, the results of the analyses were incorporated into the building's HBIM model in order to associate the obtained information with the corresponding masonry elements in the digital environment. This stage was carried out in Autodesk Revit, using the previously developed three-dimensional model as the basis for locating the investigated areas. The integration was performed by linking the modelled masonry elements to the data produced during the inspection. Thus, each analyzed section came to store, in its properties, descriptive records related to visual inspection, thermographic interpretation, and the synthesis of the identified damage. In addition to textual information, the visual products obtained in the field, including photographic images and thermograms, were also associated with the model and inserted over the analyzed elements through decals.

In a complementary manner, the results derived from the computational processing of the thermograms, such as the identification of anomalous regions and the quantification of detected areas, were linked to the corresponding elements in the model. In this way, the HBIM environment came to integrate, within a single framework, the building geometry, the photographic records, the thermograms, and the analytical information associated with the investigated masonry surfaces.

3. Results and discussion

3.1 3D survey and HBIM model development

From the integrated processing of laser scanning and photogrammetry, a unified geometric basis of the Church of São Sebastião was obtained and subsequently used for the three-dimensional modelling of the building in Revit. The resulting model represented the architectural configuration of the building in different views, including the main façade, the side façade, and the overall three-dimensional perspective, as illustrated in Figure 8. The modelling included the main volumetric and compositional elements of the church, with emphasis on the external masonry, openings, towers, roof, and decorative mouldings.

In addition to geometry, the model was structured to receive non-graphic data associated with the analyzed masonry. The modelled elements were assigned information related to visual inspection, thermographic analysis, damage identification, and the corresponding photographic and thermal images. This parametrization made it possible to associate the field records with the investigated sections in the digital model, establishing a correspondence between each element, its spatial location, and the analytical information produced.

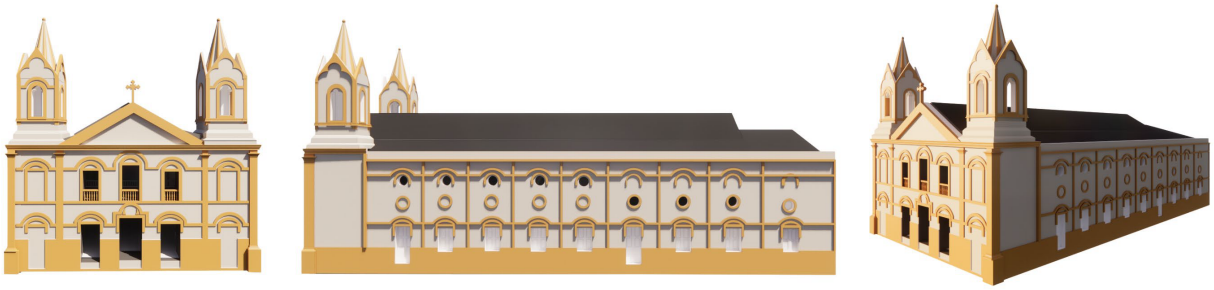

Figure 8 – Architectural 3D digital model of the Church of São Sebastião.

3.2. Thermographic and photographic analysis of masonry surfaces

The integrated analysis of visual inspection, photographic images, and thermograms made it possible to compare the visible expression of damage with the thermal patterns observed in the external masonry of the building. In the areas where the photographic images revealed coating detachment, surface degradation of the mortar, localized exposure of the substrate, and stains associated with moisture, the thermograms showed thermal anomalies spatially compatible with these regions, particularly in the lower bands and central portions of the masonry panels. In these cases, the thermal contrast was more pronounced in zones of adhesion loss and on surfaces showing altered surface behavior of the coating.

In other areas, the photographic images did not clearly reveal coating detachments, cracks, or loss of render, and the thermal behavior appeared more homogeneous. In these situations, temperature variations were concentrated in projecting geometric elements, such as moldings, frames, and opening contours, without direct correspondence to visible surface damage. Areas were also identified in which the thermograms indicated greater thermal heterogeneity than that observed in the photographs, suggesting alterations not clearly perceptible in the visible spectrum, possibly related to internal moisture, discontinuities between layers, or constructive interfaces.

Figure 9 presents, in four cases, the comparison between the photographic and thermographic records of the analyzed surfaces, as well as the processing stages applied to each image. In Cases 1, 2, and 3, the photographs show coating detachment, surface degradation, and localized substrate exposure, while the corresponding thermograms register zones of higher thermal contrast spatially coincident with these areas. In Stages III to VI, K-Means segmentation, damage alert, isotherm analysis, and final quantification allowed the anomalous regions to be isolated and delimited, resulting in estimated areas of 0.494 m^2, 0.296 m^2, and 0.268 m^2, respectively.

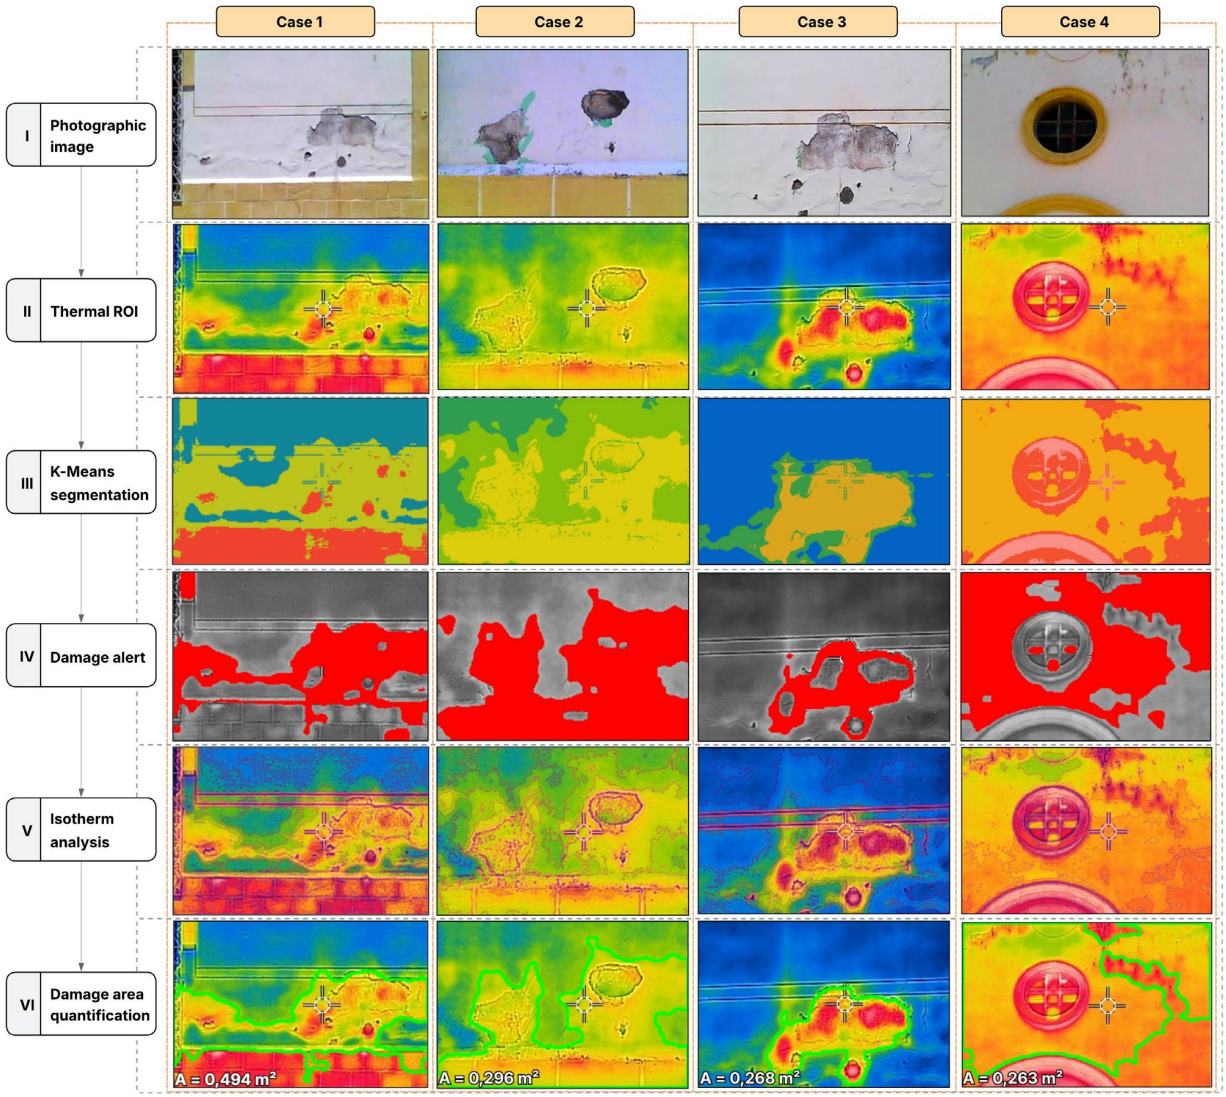

Figure 9 – Processing of four cases for the identification and quantification of surface damage using photographs and thermograms.

In Case 4, the photographic image shows less concentrated visible surface damage; however, the corresponding thermogram indicates a relevant thermal contrast around the circular opening and its immediate surroundings, with an estimated area of 0.263 m². Taken together, the results shown in Figure 9 indicate spatial correspondence between the visible damage identified in the photographic images and the thermal contrasts observed in the thermograms, supporting the applicability of the proposed workflow for inspection purposes while also highlighting areas with anomalous behavior not fully perceptible through visual inspection alone.3.3. Integration of thermo-photographic data into the HBIM environment

After the interpretation of the thermograms and the photographic survey of the damage, the results obtained through visual inspection and computer vision techniques were linked to the corresponding masonry elements in the HBIM model. This integration was carried out by associating each analyzed section with its respective textual and image-based records, bringing together, within the same digital environment, the building geometry, the photographic images, the thermograms, and the analytical information. Figure 10 illustrates this procedure by showing the association between the modelled wall elements, the photographic records of the damage, the thermograms, and the descriptive parameters inserted in the Revit properties palette.

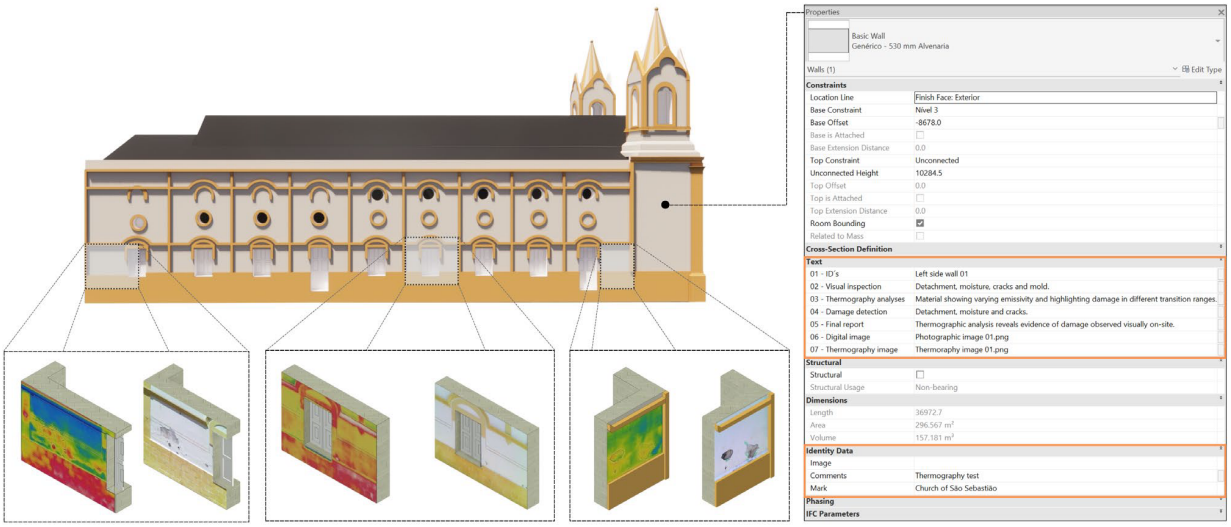

Figure 10 – HBIM model containing data from the thermographic and photographic analyses.

Within the model, the masonry elements were assigned fields for identification, visual inspection, thermographic analysis, damage detection, final report, and references to the image files. In addition, the photographic and thermographic records were applied to the elements by means of decals, allowing each analyzed area to be associated with its spatial location and with the set of information generated during the analytical process.

4. Conclusion

The obtained results show that the integration of geometric survey, thermo-photographic inspection, computer vision, and HBIM modelling enabled the structuring of a technical workflow for the analysis and documentation of the masonry of the Church of São Sebastião. Laser scanning and photogrammetry provided the geometric basis for the digital model, while thermographic and photographic acquisition supported the comparison between visible damage and thermal patterns on the analyzed surfaces. The computational processing of the thermograms allowed the segmentation of anomalous regions, the identification of thermal contrasts, and the quantification of damage areas in metric units. The association of these results with the modelled elements enabled the integration of geometry, inspection images, thermograms, and analytical information within the same digital environment. As a result, the HBIM model concentrated spatial and diagnostic data linked to the investigated masonry, supporting the organization, recording, and updating of inspection information in historic buildings.

Structural Fire Risk in Historic Urban Districts: A Component-Based Analysis of its Relationship with Multidimensional Poverty

Nuria Chiara Palazzi [1], Diego Vásquez [2], Pilar Baquedano-Juliá [3]

[1] Facultad de Arquitectura, Arte, Diseño y Comunicaciones, Universidad Andrés Bello, Santiago, Chile, nuria.palazzi@unab.cl

[2] Facultad de Economía y Negocios, Universidad Andrés Bello, Santiago, Chile, diego.vasquez@unab.cl

[3] Departamento de Arquitectura, Universidad Tecnica Federico Santa Maria, Santiago, Chile, pilar.baquedano@usm.cl

Abstract: Fire risk represents a critical challenge in historic urban districts, where dense building patterns, aging building stock, and limited emergency accessibility coexist with complex socioeconomic conditions. This study examines structural fire risk in the historic district of La Chimba (Santiago, Chile) using a component-based Fire Risk Index (FRI) and its relationship with an adapted Multidimensional Poverty Index (MPI), integrating building-scale indicators with spatial analysis.

The FRI is decomposed into ignition, fire spread, evacuation, and fire suppression components, enabling the identification of distinct risk mechanisms within the historic urban fabric. The results show that overall fire risk is not primarily driven by ignition-related conditions but by constraints associated with fire spread, evacuation performance, and fire suppression capacity, which exhibit greater internal consistency among their underlying indicators and stronger spatial clustering. In contrast, ignition-related conditions display a more fragmented and localized distribution.

The comparison with multidimensional poverty reveals a weak and non-linear relationship at the aggregate level. Poverty shows a moderate positive association with ignition-related conditions, whereas its associations with fire spread and evacuation are moderate and negative, and its association with fire suppression constraints is weak. These findings suggest that poverty acts primarily as a mediating condition that may exacerbate specific fire-risk mechanisms without uniformly increasing overall fire risk.

The results highlight the limitations of fire risk management approaches that focus predominantly on ignition prevention in historic urban districts. Instead, effective fire risk reduction requires integrated strategies addressing evacuation feasibility, fire suppression capacity, and block-scale urban configurations, together with improvements in housing conditions. The proposed component-based framework provides a robust basis for analyzing fire risk in historic urban environments characterized by physical, social, and spatial heterogeneity.

Análise Patológica de Edificação Histórica com Proposta de Reabilitação: Um estudo de caso no Estado do Ceará, Brasil

Gabriele de Sousa RODRIGUES[1]

[1] Fortaleza, Ceará, Brasil, gsr.engcivil@gmail.com

Resumo: O artigo analisa manifestações patológicas e propõe a reabilitação da Casa Juvenal Galeno, prédio histórico em Fortaleza, Ceará. Construída em 1886, foi transformada em espaço cultural em 1919, institucionalizada em 1981 e tombada em 2016 pelo Conselho Estadual do Patrimônio Cultural do Ceará (COEPA), reforçando seu valor histórico (SECULT, 2013). A vistoria técnica identificou manifestações patológicas comuns em edificações históricas e definiu diretrizes de intervenção para garantir segurança, desempenho e preservação. Foi utilizada vistoria não destrutiva, com inspeção visual sistemática, registros fotográficos e consulta à literatura especializada. A avaliação classificou e analisou as anomalias quanto às causas, mecanismos de deterioração e impactos, observando fissuras, infiltrações, umidade, descolamento de revestimentos, deterioração da madeira, oxidação em armaduras, falta de manutenção e deficiências em drenagem e estanqueidade. As recomendações priorizam intervenções mínimas, compatibilidade de materiais, correção de coberturas e drenagem, tratamento da umidade e reforço de elementos comprometidos. A análise destaca a importância da engenharia diagnóstica e da manutenção preventiva, orientando práticas contínuas de conservação e reabilitação para garantir a originalidade e a transmissão do patrimônio histórico. Ressalta a necessidade de preservação, capacitação de profissionais especializados e monitoramento constante, assegurando não apenas a integridade física, mas também a relevância social e cultural da edificação para a comunidade e pesquisadores da história arquitetônica da região.

Palavras-chave: Patologia das construções; Edificações históricas; Manutenção preventiva; Vistoria técnica.

Abstract: The article analyzes pathological manifestations and proposes the rehabilitation of Casa Juvenal Galeno, a historic building in Fortaleza, Ceará. Built in 1886, it was transformed into a cultural space in 1919, institutionalized in 1981, and listed in 2016 by the State Council of Cultural Heritage of Ceará (COEPA), reinforcing its historical value (SECULT, 2013). The technical inspection identified pathological manifestations common in historic buildings and established intervention guidelines to ensure safety, performance, and preservation. A non-destructive inspection was conducted, including systematic visual inspection, photographic documentation, and consultation of specialized literature. The evaluation classified and analyzed anomalies regarding their causes, deterioration mechanisms, and impacts, observing cracks, infiltrations, moisture, detachment of coatings, wood deterioration, reinforcement oxidation, lack of maintenance, and deficiencies in drainage and waterproofing. Recommendations prioritize minimal interventions, material compatibility, correction of roofing and drainage systems, moisture treatment, and reinforcement of compromised elements. The analysis emphasizes the importance of diagnostic engineering and preventive maintenance, guiding continuous conservation and rehabilitation practices to ensure the building's originality and the transmission of its historical heritage. It highlights the need for preservation, training of specialized professionals, and continuous monitoring, safeguarding not only the physical integrity but also the social and cultural significance of the building for the community and researchers of the region's architectural history.

Keywords: Building pathology; Historic buildings; Preventive maintenance; Technical inspection.

1. Introdução

Edificações de valor cultural seguem diretrizes internacionais, como a Carta de Veneza (1964), que orienta a conservação de monumentos e sítios, preservando tanto a obra quanto seu testemunho histórico. No Brasil, essas diretrizes são complementadas pelas normas do IPHAN (Instituto do Patrimônio Histórico e Cultural), que regulam e autorizam intervenções em bens culturais, garantindo autenticidade, integridade e memória coletiva (IPHAN, 2010; IPHAN, 2024).

Na engenharia civil, a reabilitação de edifícios históricos integra normas técnicas atuais, como a ABNT (Associação Brasileira de Normas Técnicas) NBR (Norma Brasileira Registrada) 16747:2020, que estabelece diretrizes para inspeção predial e a ABNT NBR 15575:2013, que trata do desempenho de edificações ao longo de sua vida útil adaptáveis às especificidades do patrimônio. A aplicação criteriosa dessas normas permite identificar anomalias e falhas de manutenção, orientando decisões técnicas que conciliem segurança, funcionalidade, preservação cultural e originalidade.

O estudo focou a Casa Juvenal Galeno, em Fortaleza, Ceará, um marco cultural desde 1919. Realizou-se uma vistoria técnica para identificar manifestações patológicas, resultando em um estudo com recomendações de reparo, reforço e manutenção preventiva, respeitando as características históricas e normativas aplicáveis (ABNT, 2020; Carta de Veneza, 1964; IPHAN, 2010).

O trabalho é relevante por subsidiar intervenções que evitem danos irreversíveis, reduzam custos futuros e assegurem segurança, sem comprometer atributos históricos, integrando a prática e a importância da inspeção predial e conservação do patrimônio para a gestão sustentável da edificação em estudo e podem ser aplicadas a outras edificações.

2. Metodologia

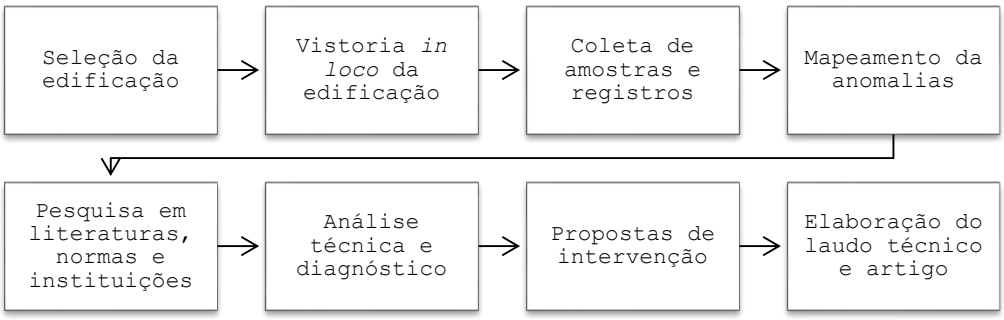
A Casa Juvenal Galeno, construída em 1886, é formada com salão principal, biblioteca, salas múltiplas, banheiros, cozinha, lavanderia, teatro, pátio, depósitos e quintal. Estruturada em alvenaria estrutural de paredes espessas e argamassa, telhado coberto de telhas coloniais, assoalho (piso) de madeira, janelas e portas de madeira trabalhadas, construção típica de edificações da época.

Visita técnica realizada em 1º de julho de 2025, seguindo a norma da ABNT NBR 13752:2024, que orienta para bens históricos, complementada pela ABNT NBR 15575:2013 e orientações do IBAPE:2025 (Instituto Brasileiro de Avaliações e Perícias de Engenharia) e IPHAN:2024, com a objetividade de assegurar clareza e análise das manifestações patológicas existentes.

A vistoria e o laudo foram conduzidos por equipe multidisciplinar, composta por três arquitetos e uma engenheira civil, garantindo cobertura técnica sobre aspectos construtivos e valores históricos e culturais.

A inspeção realizada é do tipo visual e analisou todas as áreas acessíveis, com registro fotográfico e anotações técnicas. Avaliaram-se mobilidade, estanqueidade, acabamento, conservação, integridade estrutural, execução aparente, limpeza e manutenção. Não foram realizados ensaios destrutivos, respeitando restrições de edificações históricas.

A metodologia seguiu quatro etapas: 1) seleção da edificação por relevância histórica e cultural; 2) vistoria detalhada com registro de anomalias; 3) análise técnica com diagnóstico, identificação de causas, prognóstico e indicação de reabilitações compatíveis com normas e diretrizes do IPHAN; 4) confecção de laudo técnico com registro fotográfico das anomalias.



A inspeção identificou fissuras, infiltrações, umidade, bolor, descolamento de revestimentos, deterioração de madeira, oxidação de armadura, obstrução de drenagem e irregularidades elétricas. Cada anomalia foi associada a causas e origem construtiva, permitindo correlacionar mecanismos de deterioração e

sintomas, permitindo diagnóstico e avançando para prognóstico, estimando a evolução dos danos, impactos na segurança e desempenho, e definindo terapias adequadas para mitigação ou reparo.

Após diagnosticar as anomalias, as manifestações patológicas foram classificadas quanto às possíveis causas e origens no sistema construtivo permitindo relacionar causas, mecanismos de deterioração e sintomas, avançando do diagnóstico para o prognóstico. Com base no diagnóstico definiram-se propostas de intervenção técnica adequada para mitigação ou reparo.

O fluxograma, da Figura 1, representa de forma visual o encadeamento das atividades: inspeção detalhada, mapeamento das anomalias confrontadas com normas e diretrizes de conservação, diagnóstico, definição de intervenções e sistematização dos resultados.

Figura 1 – Fluxograma das etapas do trabalho

A falta de documentação arquitetônica ou estrutural limita o conhecimento técnico da edificação, sendo recomendada a elaboração de projeto “as built” para avaliação de armaduras e reforços a implementação de manutenção preventiva sistemática para reduzir falhas recorrentes e garantir a conservação contínua.

As conclusões são preliminares, porém compatíveis com vistoria não destrutiva, e não substituem estudos específicos ou laudos especializados e aprofundados para intervenções complexas. Métodos não invasivos foram privilegiados nesse estudo, aliados às boas práticas de engenharia diagnóstica e conservação de bens culturais.

3. Resultados e Discussão

A metodologia adotada organizou os dados sistematicamente, permitindo síntese das manifestações patológicas mais recorrentes em edificações antigas e identificação de elementos críticos para conservação. Em seguida, discute-se o diagnóstico das principais patologias do estudo de caso, evidenciando sua relevância para a definição de estratégias preventivas e corretivas.

3.1. Principais manifestações patológicas em edificações antigas e históricas

Caporrino (2018) define a Patologia das Edificações como a área que estuda as origens, as manifestações, os mecanismos de evolução e as possíveis soluções para as anomalias que ocorrem em construções, integrando conhecimentos teóricos e práticos.

Fundarò (2018), diz que não se trata apenas de identificar as patologias de uma edificação antiga, mas de garantir que a intervenção siga pilares fundamentais para que a reabilitação seja adequada, considerando o projeto axiológico, o projeto de conservação e o projeto de inovação. Assim, entende-se que o projeto de reabilitação constitui uma combinação equilibrada: inicia-se com um juízo de valor sobre o bem (fase axiológica), seguido pela aplicação de técnicas voltadas à preservação material (fase tecnológica), e culmina na definição de um novo uso ou reuso do bem, adaptado às necessidades contemporâneas (fase de inovação).

Oliveira (2022) apresenta as patologias construtivas observadas na chácara Porangaba, localizada em Fortaleza/CE, datada do final do século XIX (1890-1900). Entre os principais problemas identificados, destacam-se infiltrações provenientes de falhas na cobertura e umidades por capilaridade nas alvenarias. Tais condições evidenciam um processo acelerado de degradação material, comprometendo a durabilidade da edificação e dificultando futuras intervenções de conservação, reabilitação e restauro, sendo essencial a implementação de estratégias preventivas e técnicas apropriadas de preservação para assegurar a integridade estrutural e patrimonial da edificação.

A Casa Juvenal Galeno (1886) e a Chácara de Porangaba evidenciam similaridades nas patologias, destacando infiltrações, umidades ascendentes por capilaridade e manutenção periódica insuficiente, indicando semelhança nos mecanismos de degradação e nos desafios de conservação dessas edificações residenciais históricas.

Coelho e Carvalho (2024), em seu estudo com algumas edificações antigas (Museu Casa de Rui Barbosa – iniciada no século XIX e finalizada 1850 e Pavilhão Mourisco do conjunto da Fundação Oswaldo Cruz foi iniciada por volta de 1905 e concluída em 1918), apesar da diferença temporal das construções, as edificações apresentam padrões comuns de degradação, evidenciando mecanismos de deterioração típicos de edificações históricas brasileiras do século XIX e início do XX.

Como descrito acima, as edificações antigas apresentam anomalias semelhantes, independentemente do ano de construção, do contexto histórico ou dos métodos de conservação adotados. No comparativo entre a Casa Juvenal Galeno (1886), a Chácara de Porangaba (final do século XIX), o Museu Casa de Rui Barbosa (1850) e o Pavilhão Mourisco da Fundação Oswaldo Cruz (1905–1918), observam-se padrões recorrentes de degradação, reforçando a analogia das anomalias entre essas construções: infiltração externa, umidades ascendentes por capilaridade, fissuras em alvenaria, degradação e desplacamento de materiais de acabamento como rebocos, pinturas, pisos e ornamentos, problemas em coberturas e telhados e, principalmente, falhas na manutenção periódica, que intensifica os problemas ao longo do tempo.

Essas similaridades evidenciam que, apesar das diferenças temporais e estruturais, os mecanismos de deterioração em edificações históricas brasileiras seguem padrões comuns, sobretudo ligados à falta de manutenção, reabilitação e a preservação inadequada.

As manifestações descritas a seguir correspondem às mais frequentes em edificações antigas, servindo como introdução e guia ao diagnóstico das patologias observadas na edificação em estudo e se embasa em literatura técnica especializada.

Fissuras, trincas e rachaduras em edificações podem ser causadas por fatores como mudanças térmicas, sobrecargas, deformações estruturais, recalques de fundação e retração de materiais. Em edifícios antigos, esses problemas são mais evidentes devido a métodos construtivos que não utilizavam juntas de dilatação adequadas, favorecendo movimentos descontrolados das estruturas (Thomaz, 2020).

A água pode entrar nas edificações de várias formas, como por precipitação, umidade do terreno, condensação ou falhas em sistemas de abastecimento e drenagem, como caixas d'água e tubulações. Em edifícios antigos, as coberturas são pontos críticos, e a falta de acesso seguro e manutenção periódica favorecem infiltrações e o aparecimento constante de umidade nas paredes, uma das patologias mais comuns (Gomide *et al*., 2021).

A umidade constante nas paredes causa danos progressivos, como manchas, alterações na aparência e condições insalubres, como o crescimento de fungos e bolor. Em edificações antigas, esses efeitos são mais intensos devido à maior porosidade das alvenarias, uso de argamassas menos resistentes e a falta de barreiras de impermeabilização eficientes na época da construção.

O descolamento e desplacamento de revestimentos em edificações antigas ocorrem devido à porosidade das argamassas, que possuem granulometria média a grossa e pouca fração de finos, o que favorece a

perda de aderência entre o revestimento e a alvenaria. Esse problema é agravado pela umidade constante, degradação da argamassa, movimentos estruturais e térmicos, além das incompatibilidades entre revestimentos antigos e materiais modernos, como argamassas ricas em cimento ou pinturas impermeáveis. (VEIGA, 2002).

O descolamento e desplacamento de revestimentos são agravados, ainda mais, pela cristalização de sais solúveis, ação biológica (fungos, algas e raízes), má execução do chapisco, baixa rugosidade da base e uso de areias de baixa fração de finos, comprometendo a aderência. Isso torna o destacamento uma ocorrência comum em fachadas e ambientes internos.

As patologias em estruturas de madeira, segundo Cruz (2001), são causadas por agentes biológicos, físicos e químicos além de fatores atmosféricos e anomalias construtivas, independentemente da época de construção. A falta de manutenção preventiva, combinada com ambientes úmidos e ventilação inadequada, acelera a deterioração, destacando a importância da conservação regular desses elementos.

A degradação da madeira, segundo Brito (2014), vai além desses agentes citados por Cruz (2001) e acrescenta o agente mecânico, dependendo das condições ambientais. Embora seja um processo natural e ecológico, é crítico na engenharia quando afeta elementos estruturais, como coberturas, forros e pisos de edificações antigas por ser mais difícil a restauração e/ou reabilitação e muitas vezes, o elemento tem que ser substituído por completo e com possibilidade de perda de seu *design* original.

3.2. Diagnóstico das principais patologias observadas na Casa Juvenal Galeno.

A matriz-resumo sintetiza as principais manifestações patológicas observadas no objeto de estudo, permitindo identificar padrões recorrentes em edificações antigas ou históricas. Ela evidencia as patologias que apresentam maior frequência e criticidade, servindo como referência para orientar a atenção técnica durante a vistoria *in loco*. Além disso, a matriz contribui para a análise técnica de intervenções preventivas e corretivas, fornecendo uma base sistemática para a análise comparativa de casos e para a implementação de estratégias de conservação, manutenção e reabilitação.

Quadro 1 - Matriz Resumo das principais manifestações Patológicas na Casa Juvenal Galeno

Imagem	Local	Sistema	Manifestações	Diagnóstico	Possíveis Causas	Prognóstico	Recomendações Técnicas
1	Biblioteca	Alvenaria	Fissuras, trincas	Movimentação estrutural	Sobrecarga	Rachaduras	Reparação se houver evolução
2	Hall dos banheiros	Cobertura	Infiltração	Umidade por falta de estanqueidade	Falha no telhado, calhas e vedação.	Evolução de manchas e dano construtivos	Reorganizar telhado e reparar calhas, rufos e vedação
3 e 4	Teatro e depósito	Revestimento	Desagregação	Revestimento degradado por umidade	Umidade e manutenção	Desprendimento do revestimento	Reabilitar com argamassa cimentícia
5 e 6	Depósito	Estrutural	Revestimento	Desplacamento com exposição de armadura	Intempéries, infiltração	Comprometimento estrutural	Reabilitar armaduras
7 e 8	Fiação exposta; Quadro de Força e Luz (QDFL)	Instalações elétricas	Não conformidades elétricas	Falhas de proteção, fixação e segurança	Instalações improvisadas e fora das normas	Risco de choque elétrico e incêndio	Regularizar instalações elétricas, substituindo fiações e conexões inadequadas

As intervenções devem priorizar eficácia, durabilidade e compatibilidade com materiais tradicionais, corrigindo drenagem e impermeabilização em casos de infiltração e aplicando reforços estruturais localizados com resina epóxi ou argamassas cimentícias compatíveis, evitando rigidez excessiva que comprometa o desempenho da edificação.

Para manifestações superficiais, recomenda-se remoção do crescimento fúngico, aplicação de tratamentos antimicrobianos compatíveis com o substrato e controle rigoroso de umidade e ventilação, preservando a integridade física e estética dos materiais originais.

A implementação de intervenções preventivas e corretivas, fundamentadas em diagnósticos detalhados das patologias construtivas, potencializa a segurança estrutural, preservação do valor histórico e longevidade das edificações. Destaca-se a importância de integrar manutenção preventiva sistemática, inspeções periódicas e técnicas compatíveis com o patrimônio histórico, respeitando normas técnicas, critérios de preservação e boas práticas construtivas.

Dois elementos de extrema importância na reabilitação de edificações antigas e históricas são a resina de epóxi e argamassas cimentícias, já citadas aqui. O uso desses elementos permite reforço estrutural, consolidação de elementos deteriorados e proteção contra degradação, assegurando intervenções duráveis, compatíveis e seguras, essenciais para a preservação do patrimônio histórico.

A reabilitação dessa edificação requer técnicas que garantam restauração da integridade estrutural, durabilidade e compatibilidade com os materiais originais. Nesse contexto, o uso combinado de resina epóxi e argamassa cimentícia tem se mostrado estratégico, permitindo restaurar elementos de concreto, alvenaria, pedra e madeira de forma segura e durável (ABNT, 2005a; ASTM INTERNATIONAL, 2023).

A resina epóxi, polímero termoendurecível de alta adesão e baixa viscosidade, é particularmente eficaz para preencher fissuras capilares e macrofissuras, colando internamente os elementos e prevenindo a infiltração de umidade, fator crítico na degradação de estruturas antigas. Suas aplicações incluem consolidação de alvenarias e pedras soltas, reparo e reforço de madeira, ancoragem e fixação de reforços estruturais e proteção contra degradação química e umidade (ASTM C881/C881M-20; ASTM C923-20).

Por outro lado, a argamassa cimentícia desempenha papel complementar, oferecendo resistência mecânica, aderência e durabilidade. É utilizada para preencher fissuras, consolidar alvenarias de pedra ou tijolo e reforçar elementos deteriorados, além de reparos de concreto armado mais recentes (ABNT, 2005b;

ASTM C1713-23, 2023). Contudo, devido à sua rigidez e impermeabilidade, seu uso deve ser criterioso em edificações históricas, pois pode gerar fissuração secundária, retenção de umidade e descolamento de revestimentos. Sempre que possível, recomenda-se o emprego de argamassas à base de cal hidráulica natural (NHL) para garantir flexibilidade e permeabilidade ao vapor de água, assegurando compatibilidade física e química com o substrato histórico.

O planejamento técnico deve envolver: 1. Avaliação estrutural detalhada e identificação de fissuras e patologias; 2. Seleção criteriosa do material, considerando módulo de elasticidade, retração, adesão e compatibilidade mecânica com o substrato; 3. Procedimentos de aplicação controlada, incluindo preparo da superfície, selagem superficial, instalação de bicos de injeção para epóxi, injeção gradual e cura adequada e; 4. Ensaios técnicos conforme normas, garantindo resistência à compressão, tração, aderência e penetração do material (ABNT NBR 13281, NBR 13276, NBR 13277, NBR 13278; ASTM C881/C881M-20; ASTM C923-20; ASTM C1713-23).

A combinação de resina epóxi e argamassa cimentícia, quando aplicada de forma criteriosa e técnica, constitui uma abordagem confiável para reabilitação de edificações antigas, promovendo reforço estrutural, compatibilidade com os materiais originais e conservação em longo prazo do patrimônio histórico.

Para pesquisas futuras o estudo evidencia oportunidades para aperfeiçoamento de materiais e técnicas compatíveis com edificações históricas e para a implementação e/ou melhoramento de estratégias sistemáticas de monitoramento e avaliação de desempenho. Recomenda-se investigação do uso de resinas epóxi para consolidação estrutural e preenchimento de fissuras, considerando aderência, compatibilidade higroscópica, durabilidade e comportamento físico-químico, assim como a avaliação de argamassas cimentícias, incluindo composição, resistência, permeabilidade, retração e compatibilidade com materiais originais, visando à preservação da autenticidade e integridade patrimonial.

4. Conclusão

O presente estudo demonstra que edificações históricas brasileiras apresentam padrões recorrentes de degradação, tais como infiltrações externas, umidades ascendentes por capilaridade, fissuras em alvenaria, desagregação de revestimentos e falhas na manutenção periódica, corroborando os achados de Oliveira (2022) e Coelho & Carvalho (2024). A análise sistemática das manifestações patológicas permitiu a proposição de intervenções compatíveis com os materiais originais e evidenciou a relevância de planos integrados de manutenção preventiva como instrumento estratégico para a preservação estrutural e patrimonial.

A reabilitação de elementos degradados deve contemplar eliminação das fontes de umidade, remoção de revestimentos soltos e preparação criteriosa do substrato, garantindo aderência, compatibilidade higroscópica e integridade estrutural, enquanto a aplicação combinada de resina epóxi e argamassa cimentícia assegura consolidação de fissuras, reforço estrutural localizado, impermeabilização, resistência mecânica e durabilidade, quando controladas espessura, cura e permeabilidade ao vapor d'água.

A integração dessas técnicas, combinada a protocolos rigorosos de inspeção, monitoramento e avaliação do desempenho dos materiais, assegura recuperação funcional, proteção patrimonial e preservação da autenticidade histórica. Recomenda-se a sistematização de procedimentos escaláveis de manutenção preventiva para consolidar boas práticas de conservação, com foco na integridade estrutural e durabilidade dos materiais.

As implicações para práticas profissionais, sobre este estudo, reforça a necessidade de adoção de abordagens integradas e baseadas em evidências no campo da reabilitação patrimonial. Profissionais da engenharia civil, arquitetura e conservação devem priorizar diagnósticos detalhados, planejamento

criterioso e seleção de materiais compatíveis, garantindo intervenções duráveis que respeitem a autenticidade histórica. Além disso, enfatiza-se a importância de protocolos padronizados de manutenção preventiva, permitindo que equipes técnicas programem estratégias replicáveis em diferentes contextos de edificações históricas e antigas.

O estudo aponta a necessidade de pesquisas sobre novos materiais e tecnologias para reabilitação patrimonial, incluindo argamassas modificadas, aditivos impermeabilizantes e resinas de alto desempenho, bem como estudos longitudinais para avaliar desempenho frente a fatores estruturais e ambientais. Ressalta-se a importância de protocolos sistemáticos de monitoramento para detecção precoce de falhas, otimização de intervenções preventivas e preservação da integridade e autenticidade de edificações históricas com suas originalidades.

As literaturas usadas nesse estudo serviram de suporte para embasar narrativas comparativas entre diferentes edificações e criar possibilidades de estratégias de intervenção, podendo subsidiar protocolos de conservação mais eficientes e escaláveis, fortalecendo a base científica para práticas profissionais de preservação patrimonial.

Agradecimentos

Agradeço imensamente aos arquitetos Débora Paz Salles, Grazielle Caldas e Renato Oliveira pela colaboração na elaboração do laudo de inspeção predial, que serviu de base para o desenvolvimento deste artigo, e à minha orientadora, Karol Novaz, por suas valiosas contribuições. Registro também meu reconhecimento aos engenheiros José Soares Teixeira Filho e Jaziel Fernandes pelo aprendizado inicial em engenharia diagnóstica. Agradeço especialmente à minha mãe, dona Nerita, pelo apoio constante, e aos meus irmãos, Jeferson Emídio, Alexandre e Adalberto Júnior, por fazerem parte da minha vida e por serem minha família, junto com seus filhos e esposas.

Resumo: A crescente demanda por intervenções em edificações degradadas evidencia a reabilitação como prática presente na arquitetura contemporânea. Contudo, a pesquisa identificou uma lacuna na formação acadêmica dos arquitetos, os quais, com frequência, concluem a graduação sem a capacitação específica para diagnosticar e intervir em patologias construtivas. Essa limitação afeta a qualidade das intervenções e a atuação técnica dos profissionais diante do patrimônio edificado. Nesse contexto, este estudo analisou os desafios associados à reabilitação de estruturas, com ênfase no papel da formação superior na prevenção de falhas construtivas. Para sustentar a análise, foram examinados dados do Conselho de Arquitetura e Urbanismo do Brasil (CAU/BR), os quais apontam a escassez de disciplinas voltadas ao estudo das patologias construtivas e das técnicas de reparo nas grades curriculares dos cursos de Arquitetura e Urbanismo. Adicionalmente, foram realizadas entrevistas com estudantes de graduação, cujos relatos indicaram percepções críticas quanto à abordagem superficial do tema ao longo da formação. A metodologia adotada permitiu identificar lacunas no ensino e promover reflexões sobre a necessidade de revisão curricular. Os resultados subsidiaram uma análise do modelo vigente de formação, destacando a relevância da inserção de conteúdos específicos sobre patologias e reabilitação de edificações. Concluiu-se que a integração sistemática de conteúdos teóricos e práticos voltados à prevenção e à correção de danos estruturais contribui para a formação de profissionais capacitados a enfrentar os desafios da degradação do ambiente construído, favorecendo maior durabilidade e segurança às edificações. A revisão curricular, nesse sentido, apresenta-se como medida necessária para alinhar a formação acadêmica às exigências atuais do campo profissional e às responsabilidades técnicas e sociais inerentes à prática da arquitetura.

Palavras-chave: Reabilitação de edificações; Patologias construtivas; Formação acadêmica; Arquitetura; Ensino superior.

1. Introdução

O ensino da Arquitetura tem historicamente tratado as disciplinas técnicas e projetuais de maneira fragmentada, o que muitas vezes dificulta a compreensão integrada da estrutura como um elemento essencial no processo criativo. No entanto, o cenário atual exige profissionais capazes de articular técnica, inovação e sustentabilidade de forma coesa. Essa pesquisa nasce da necessidade de repensar os métodos de ensino, propondo uma abordagem mais dinâmica e interdisciplinar, que fortaleça a conexão entre o aprendizado das estruturas e a prática projetual.

A construção curricular no ensino superior deve refletir não apenas as demandas do mercado, mas também as diretrizes pedagógicas e epistemológicas que sustentam a formação crítica e reflexiva dos estudantes. Assim, é essencial adotar concepções de currículos integradores, promovendo um aprendizado situado e contextualizado. No contexto da formação por competências, a construção curricular deve articular saberes

teóricos e práticos, capacitando os estudantes para análises críticas e para a aplicação do conhecimento em contextos reais.

O ensino de estruturas ocupa um papel fundamental, pois a compreensão da lógica estrutural transcende a mera aplicação de cálculos e métodos quantitativos — é um exercício de articulação entre conceito e realidade, capaz de conferir sustentabilidade, segurança e qualidade estética às obras. A simbiose entre forma e estrutura é evidente e necessária, exigindo um retorno às raízes da profissão, onde a responsabilidade pela concepção estrutural volta a ser parte integrante da prática arquitetônica.

Este artigo busca entender como o ensino de Arquitetura e Urbanismo pode evoluir para incluir, de forma mais eficaz, conteúdos sobre reabilitação. A formação acadêmica atual enfrenta desafios que impactam a qualidade das intervenções em edificações existentes. Leite (2005) aponta a falta de disciplinas voltadas para estruturas e sua interação com a arquitetura como uma lacuna que afeta o mercado. Como resultado, arquitetos encontram dificuldades ao lidar com patologias construtivas, devido à falta de conhecimento técnico específico nos currículos universitários. Como destaca Almeida (2008), o desconhecimento sobre as manifestações patológicas mais comuns nas edificações, seus mecanismos de evolução e os métodos adequados de intervenção compromete significativamente a eficiência das soluções aplicadas em projetos de reabilitação. O domínio desses aspectos deve ser considerado um requisito essencial na formação dos profissionais envolvidos com o ambiente construído.

Para Perrenoud (1999), o ensino baseado em competências exige uma abordagem interdisciplinar que articule teoria e prática, proporcionando aos estudantes a capacidade de lidar com desafios reais. No entanto, a realidade mostra que a fragmentação do conhecimento no ensino superior compromete essa integração, levando a dificuldades na atuação profissional. Como aponta Franco (1974), o estudo das estruturas deveria ir além do cálculo matemático, abordando a evolução histórica dos sistemas construtivos para que os futuros arquitetos desenvolvam uma visão mais abrangente das soluções estruturais.

A análise dos dados do Conselho de Arquitetura e Urbanismo do Brasil (CAU/BR), reforça essa percepção. Segundo os registros da entidade, há um número reduzido de projetos de reabilitação estrutural assinados por arquitetos, o que sugere que a formação acadêmica ainda não prepara adequadamente os profissionais para essa área. Esse cenário poderia ser revertido com uma revisão curricular que priorizasse conteúdos sobre diagnóstico de patologias, técnicas de reparo e compatibilização estrutural. Lumi (2003) reforça que a formação em reabilitação arquitetônica exige não apenas o domínio técnico das técnicas de reparo, mas também uma abordagem sensível à preservação da identidade material e simbólica das edificações. A reabilitação eficaz pressupõe uma leitura crítica do edifício existente, integrando conhecimento técnico, histórico e cultural. Como defendem Gamili, Buzar e Pantoja (2022), a transformação do ambiente construído requer profissionais capacitados para compreender a relação entre forma, materialidade e desempenho estrutural, evitando intervenções inadequadas.

Além disso, a falta de comunicação entre arquitetos e engenheiros estruturais compromete a eficiência dos projetos de reabilitação. Carvalho (2003) destaca que a ausência de um vocabulário técnico compartilhado dificulta a colaboração entre as duas áreas, resultando em projetos desarticulados e, muitas vezes, ineficazes. A inclusão de disciplinas que promovam essa interface no ensino superior poderia minimizar esses problemas, preparando os futuros profissionais para uma atuação mais integrada e multidisciplinar.

Portanto, a reformulação curricular se mostra essencial para que o arquiteto seja capaz de compreender e intervir com propriedade no ambiente construído. O fortalecimento das disciplinas voltadas à reabilitação de edificações, aliado a metodologias ativas de ensino, pode contribuir significativamente para a formação de profissionais mais preparados para os desafios da prática contemporânea.

2. Metodologia de obtenção dos dados

A pesquisa adotou duas ações complementares para garantir uma análise mais abrangente e rigorosa dos dados. A primeira ação consistiu na coleta e no tratamento de informações fornecidas pelo CAU/BR, permitindo a identificação de padrões e tendências no campo profissional, com base em dados institucionais amplamente reconhecidos. Essa escolha se justifica pela confiabilidade e pela abrangência das informações disponibilizadas por esse órgão regulador, garantindo uma visão consolidada do cenário atual da profissão.
A segunda ação envolveu a aplicação de formulários direcionados a alunos, visando captar percepções individuais e experiências diretas sobre o tema investigado. Essa abordagem qualitativa permitiu compreender não apenas os dados quantitativos obtidos pelo CAU/BR, mas também interpretar como os estudantes vivenciam e avaliam a formação em patologias construtivas e técnicas de reparo.
Ao final do processo, os resultados das duas metodologias foram confrontados, o que possibilitou avaliar a convergência ou divergência das informações obtidas. Esse cruzamento de dados permitiu uma análise mais aprofundada, garantindo maior robustez às conclusões do estudo e proporcionando uma visão mais holística sobre o tema.

2.1 Coleta de dados do Conselho de Arquitetura e Urbanismo do Brasil (CAU/BR)

Para a obtenção e análise dos dados do CAU/BR, foram coletados 27.785 registros referentes ao período de 2012 a 2024, abrangendo 12 anos de atuação no Distrito Federal. As informações foram organizadas por bairro, região administrativa e tipo de atividade desempenhada, incluindo projeto, execução e gestão. O mapa a seguir ilustra as regiões administrativas mapeadas pelo CAU/BR.

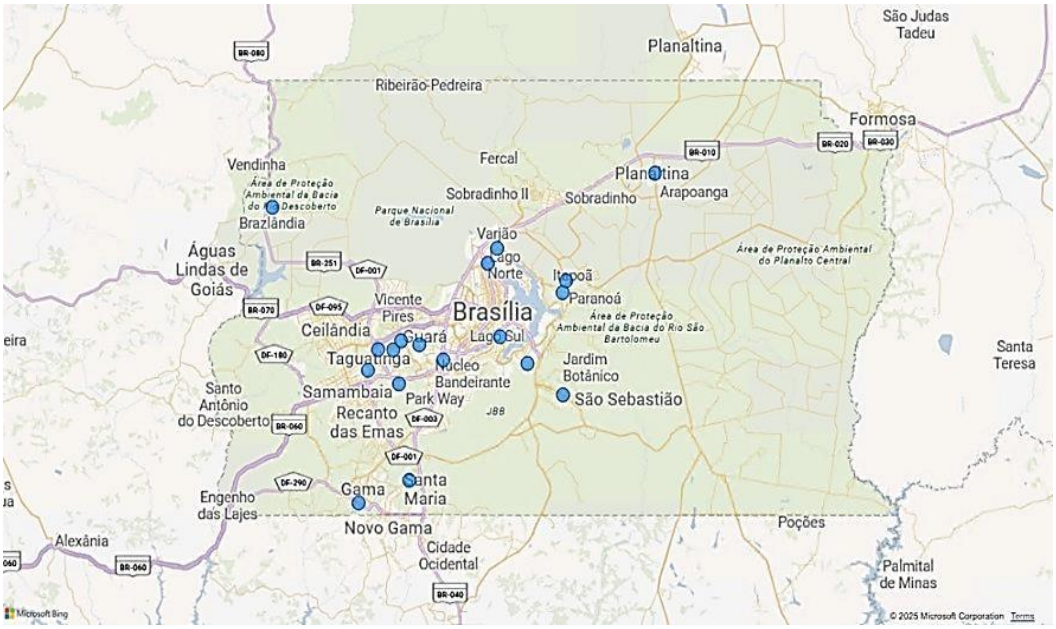

***Figura 1** - Mapa das regiões adminidtrativas do DF mapeadas pela CAU/BR*

O mapa apresentado evidencia a diversidade territorial e a abrangência do levantamento. A inclusão de diferentes áreas do DF é fundamental para compreender as variadas dinâmicas da prática profissional em Arquitetura e Urbanismo, além de reforçar a representatividade dos dados coletados dentro do espaço amostral.

2.1.1 *Tratamento de dados*

O tratamento de dados é uma etapa essencial na pesquisa científica, permitindo a organização, análise e interpretação das informações coletadas. De acordo com Creswell (2014), a forma como os dados são processados impacta diretamente a validade e a confiabilidade dos resultados, tornando indispensável a adoção de métodos adequados para garantir rigor e coerência na análise.

Neste estudo, a etapa de tratamento seguiu um conjunto de procedimentos sistemáticos para transformar as respostas coletadas em informações interpretáveis. Técnicas de categorização e visualização foram aplicadas para identificar padrões e tendências relevantes, enquanto ferramentas estatísticas, conforme recomendações de Hair et al. (2019), foram utilizadas para garantir maior precisão na análise dos resultados.

Os dados CAU/BR, ao serem recebidos, continham dados duplicados e inconsistências que exigiram um processo de refinamento para assegurar sua precisão. Foram aplicados procedimentos de limpeza e padronização, incluindo a remoção de registros duplicados, a verificação de erros e a organização das informações em um formato adequado para análise. Essas etapas foram fundamentais para garantir a qualidade dos dados e uma interpretação confiável dos resultados.

2.2 Questionários aplicados nas turmas de Sistemas Estruturais I e II

No que se refere a abordagem deste trabalho, a aplicação dos questionários para as turmas de sistemas estruturais I e II, oferecido no período noturno da Universidade de Brasília, representou uma estratégia essencial na pesquisa, com o objetivo de compreender a percepção dos estudantes acerca da efetividade e aplicabilidade do currículo em sala de aula. Os questionários aplicados mostram uma aproximação com a realidade da formação, sendo uma forma válida de investigar a percepção sobre ensino e reabilitação. A opinião dos alunos é de grande importância, visto que são os principais receptores do conteúdo acadêmico e podem fornecer informações valiosas sobre a dinâmica das aulas, o processo de aprendizado, as dificuldades enfrentadas, entre outros aspectos relevantes. Os estudantes demonstraram grande receptividade e interesse em responder a todas as questões propostas.

O instrumento foi composto por sete questões, que buscavam captar as opiniões dos alunos sobre diversos aspectos do ensino de Estruturas. As questões abordaram os seguintes tópicos:

1. Em sua opinião, a composição curricular do ensino de Estruturas do seu curso está alinhada com os novos mecanismos e ferramentas tecnológicas recentes?
2. Você percebe alguma dificuldade de comunicação entre arquitetos e engenheiros estruturais?
3. Em sua opinião, a carga horária do ensino de Estruturas é suficiente para um aprofundamento teórico e prático do tema?
4. Você acredita que o ensino de Estruturas poderia ter mais conexões com disciplinas como design arquitetônico, sustentabilidade e construção, ampliando a prática arquitetônica?
5. Você considera que a integração entre teoria e prática poderia fomentar o desenvolvimento de habilidades práticas em projetos reais?
6. O currículo do curso é adequado no que se refere à sustentabilidade, incluindo orientações sobre o uso de recursos de baixo impacto ambiental?
7. Diante das questões abordadas acima, você sugeriria alguma readequação no currículo do seu curso?

Para as sete perguntas, cada aluno podia escolher uma das seguintes opções: Adequado, Pouco adequado, Inadequado e Muito adequado. Em resumo, o objetivo do questionário era realizar uma análise detalhada da percepção dos estudantes em relação à grade curricular. As respostas obtidas forneceram dados valiosos para identificar possíveis lacunas no ensino, além de oferecer sugestões para o aprimoramento do curso.

3. Análise e Resultados

A metodologia dupla desta pesquisa revelou uma lacuna entre as demandas do mercado de trabalho contemporâneo e os resultados da formação acadêmica. A análise dos dados do CAU/BR para a região federal mostrou que apenas 20% dos Registros de Responsabilidade Técnica (RRTs) assinados por arquitetos se referiam a projetos de construção, em comparação com 80% para projetos arquitetônicos tradicionais, conforme ilustrado na Figura 2. Além disso, os projetos de construção representaram apenas 25% dos registros. Essa discrepância quantitativa indica que a formação acadêmica de arquitetos não prioriza adequadamente o ensino de técnicas de construção e reabilitação, levando diretamente a uma diminuição da demanda profissional por esses serviços e ao afastamento gradual dos arquitetos de projetos tecnicamente exigentes. Isso está em consonância com as respostas observadas entre os estudantes na pesquisa; eles percebem essa disciplina como complexa, técnica e inerentemente difícil, o que dificulta sua conexão com o processo criativo de projeto. Ademais, a pesquisa revelou uma distribuição desigual desses projetos. A maioria das Equipes de Resposta Rápida (ERR) está concentrada em áreas densamente povoadas e edifícios antigos, o que reforça a necessidade de treinamento especializado que leve em consideração as características estruturais e a patologia dos edifícios em diversos contextos urbanos, estabelecendo assim uma ligação ainda maior entre teoria e prática.

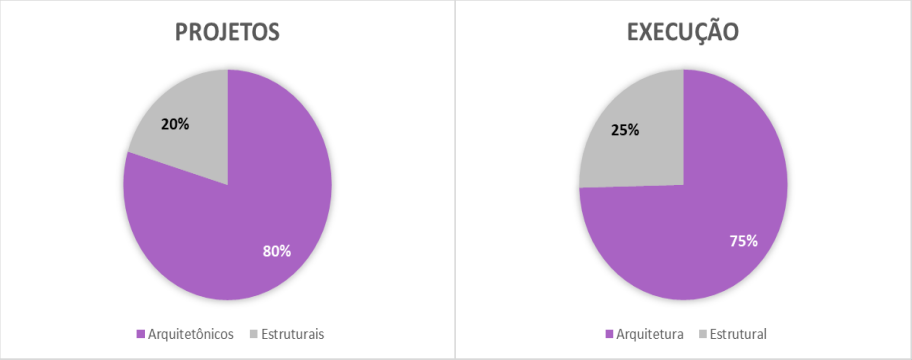

Figura 2 *– RRTs relacionados aos projetos arquitetônicos e estruturais (CAU/BR)*

Em relação aos questionários aplicados aos alunos, os resultados revelaram que 64% concordaram que a carga horária destinada ao ensino da construção civil era insuficiente, enquanto 78% reconheceram dificuldades na comunicação com os engenheiros. A distribuição das respostas entre as quatro opções disponíveis para cada uma das sete perguntas é apresentada na Tabela 1.

Tabela 1 – Resultados dos questionários aplicados

Questionários	Adequado	Pouco adequado	inadequado	Muito adequado	Total
1. Composição Curricular	14	22	4	2	42
2. Comunicação entre engenheiros e arquitetos	11	22	5	4	42
3. Carga horária do Ensino de Estruturas	15	18	5	4	42
4. Ampliação no ensino de Estruturas e conexão com outras áreas	18	2	2	20	42
5. Integração entre Teoria e Prática	16	1	1	24	42
6. Sustentabilidade Estrutural	6	15	17	4	42
7. Necessidade de readequação no currículo	27	5	2	8	42

Para analisar os questionários e fornecer uma visão mais clara das respostas, o diagrama de radar apresentado na Figura 3 exibe as sete questões utilizadas na análise do questionário, ilustrando a distribuição das variáveis, os aspectos proeminentes e os aspectos que necessitam de maior atenção.

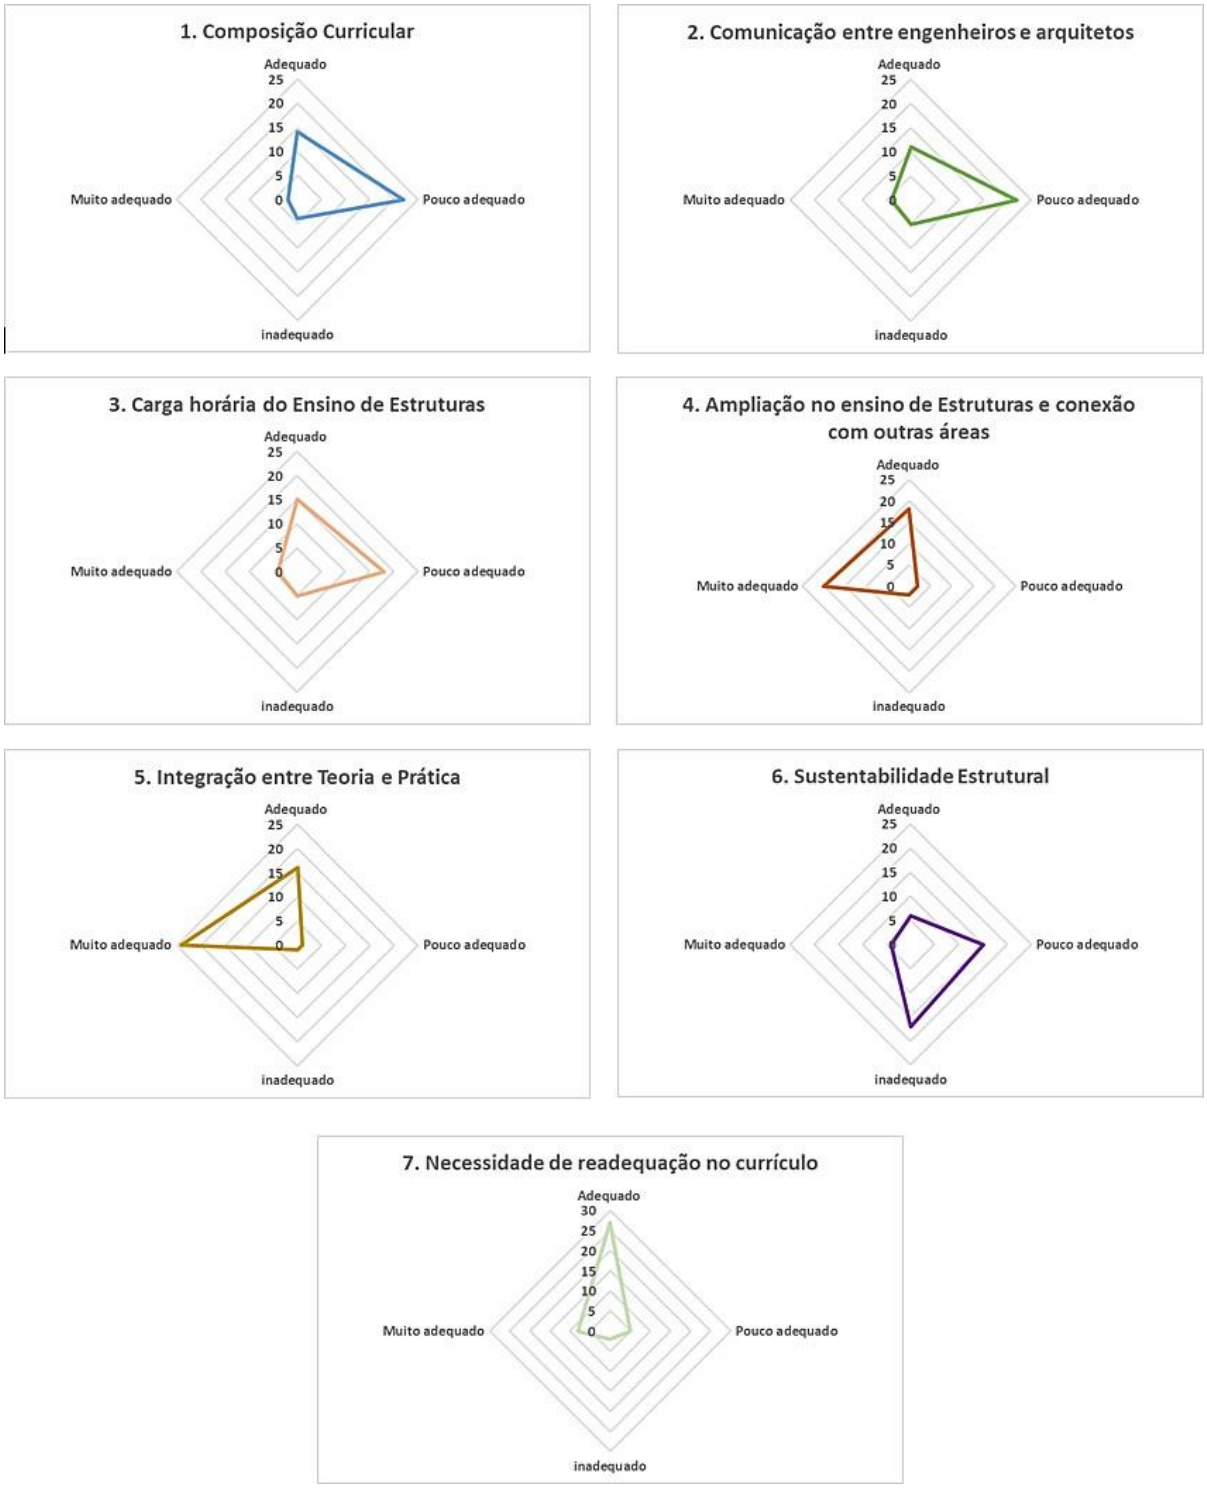

Figura 3 – *Gráficos do tipo radar para os resultados obtidos (CAU/BR)*

Após a análise das respostas dos alunos, os resultados revelaram importantes percepções sobre diversos aspectos do ensino da construção civil no currículo de arquitetura. Em relação ao alinhamento do currículo com os avanços tecnológicos, muitos alunos indicaram que, embora seja parcialmente compatível com as mudanças tecnológicas, ainda requer ajustes para integrar de forma mais eficaz novas ferramentas e desenvolvimentos na área. Quanto à comunicação entre arquitetos e engenheiros civis, uma parcela

significativa dos alunos apontou dificuldades na interação entre essas duas profissões, sugerindo que a formação poderia incorporar mais conteúdo focado na colaboração interdisciplinar para superar esses obstáculos. Em relação ao tempo dedicado ao ensino da construção civil, muitos alunos indicaram que o tempo disponível é insuficiente para uma compreensão profunda dos conceitos e sua aplicação prática, destacando a necessidade de revisar o cronograma do currículo. No que diz respeito à conexão entre o ensino da construção civil e outras áreas do conhecimento, como projeto arquitetônico e sustentabilidade, os alunos manifestaram apoio a uma maior integração dessas disciplinas, o que poderia proporcionar uma formação mais abrangente e alinhada às demandas da prática contemporânea.

Em termos profissionais, os graduados enfatizaram que essas lacunas acadêmicas têm repercussões diretas na prática contemporânea, levando à falta de independência técnica e à baixa qualidade generalizada nas intervenções de reabilitação estrutural. Essa desconexão não só ameaça a integridade estrutural dos edifícios, como também resulta em falhas estruturais que poderiam ter sido evitadas com uma base acadêmica mais coerente. Isso, por sua vez, acarreta consequências econômicas significativas devido à dependência de reparos corretivos dispendiosos em vez de manutenção preventiva. Um aluno expressou esse sentimento, afirmando que se contenta em memorizar equações complexas para passar nas provas, sem ser capaz de traduzi-las em ferramentas para diagnosticar defeitos em edifícios ou avaliar a segurança de estruturas existentes. Isso gera uma ansiedade que os levará a evitar projetos de reabilitação no futuro, temendo a responsabilidade técnica para a qual não foram adequadamente preparados.

Em relação às entrevistas realizadas com membros do corpo docente para analisar o processo educacional, suas declarações revelaram as causas dessa crise e algumas soluções potenciais dentro dos currículos universitários atuais. Os alunos se formam com conceitos básicos, mas carecem da profundidade estrutural necessária para tomar decisões técnicas cruciais. Esse problema foi destacado em uma resposta, que afirmou: "O maior desafio enfrentado pelos alunos não é necessariamente a compreensão dos conceitos estruturais, mas sim a aplicação de fórmulas, devido a deficiências específicas em matemática fundamental". A abundância de cálculos não relacionados ao projeto arquitetônico é um grande obstáculo para os alunos, reforçando a desconexão entre o conteúdo técnico e o processo criativo. Um professor apontou que a ausência de atividades experimentais, como maquetes estruturais e simulações computacionais, dificulta a compreensão dos conceitos. Embora alguns tenham tentado usar modelos de molas e madeira para ilustrar a dinâmica das falhas estruturais, observando que os alunos só compreendem a física da construção quando vivenciam diretamente as limitações e fragilidades dos materiais, esse esforço permanece individualista devido à falta de laboratórios especializados em engenharia estrutural.

4. Conclusão

A ausência de uma formação sólida e direcionada à reabilitação de edificações compromete diretamente a qualidade técnica das intervenções realizadas no ambiente construído. Profissionais que não dominam adequadamente as patologias construtivas e as técnicas de reparo tendem a propor soluções ineficazes, que resultam em falhas recorrentes, comprometendo a durabilidade das obras, a segurança dos usuários e a integridade estrutural dos edifícios. Tais deficiências são especialmente críticas em contextos de reabilitação, nos quais o diagnóstico preciso, a leitura adequada do existente e a compatibilização entre o antigo e o novo são fatores determinantes para o sucesso da intervenção.

Neste cenário, a aproximação entre os conteúdos formativos e as demandas concretas da prática profissional em reabilitação torna-se urgente. Os dados analisados neste estudo reforçam a necessidade de atualização curricular nos cursos de Arquitetura e Urbanismo, com foco explícito em disciplinas voltadas à identificação de patologias, métodos de reabilitação estrutural e intervenções sustentáveis em edificações existentes. Ao mesmo tempo, a integração entre arquitetos e engenheiros, frequentemente fragilizada por falhas de comunicação e formação fragmentada, revela-se como um eixo fundamental para garantir abordagens interdisciplinares mais eficazes.

Embora o currículo atual apresente avanços pontuais, os resultados demonstram que ainda persistem lacunas significativas que comprometem uma formação técnica integrada. É imperativo promover uma reestruturação curricular que preserve o embasamento teórico essencial, mas que também incorpore metodologias ativas, experiências práticas em campo e conteúdos específicos sobre reabilitação de edificações. Só assim será possível preparar arquitetos aptos a atuar com precisão técnica, sensibilidade patrimonial e responsabilidade social.

Além disso, questões como sustentabilidade estrutural, abordagens compatíveis com os desafios ambientais e a ampliação da carga horária dedicada ao ensino de estruturas devem ser trazidas ao centro do debate acadêmico, contribuindo para uma formação mais crítica e conectada às exigências do presente e do futuro da construção civil.

Em síntese, este estudo reforça a urgência de uma formação arquitetônica mais conectada com as práticas contemporâneas de reabilitação, tanto no plano técnico quanto metodológico. Ao defender um ensino que una teoria, prática e interdisciplinaridade, propõe-se não apenas uma revisão curricular, mas um reposicionamento estratégico da formação profissional, capaz de enfrentar os desafios impostos pela crescente demanda por intervenções em edificações degradadas. Fica o convite para que futuras pesquisas explorem novas metodologias pedagógicas voltadas à reabilitação e que políticas públicas e institucionais priorizem a atualização curricular como um passo essencial rumo a uma arquitetura mais qualificada, responsável e transformadora.

Agradecimentos

Este trabalho foi financiado por: Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES), através da concessão de bolsa de estudos à primeira autora durante seu Mestrado no Programa de Pós-Graduação em Arquitetura e Urbanismo da Universidade de Brasília.

Abstract: Heritage Building Information Modelling (HBIM) enables the creation of digital models of historic buildings that can be used for strategic information management throughout the asset life cycle. The definition of the Asset Information Requirements (AIR), according to ABNT NBR ISO 19650-1 (2022), plays a central role in delimiting the scope of the model. For maintenance purposes, especially in historic buildings, an AIR oriented toward operational efficiency may prioritize semantically rich models with lower geometric accuracy, in favour of computational performance and model usability. In building systems such as water supply, sanitary sewage, and stormwater drainage, a lower level of geometric detail combined with a higher level of semantic information, related, for example, to maintenance plans, can result in a model that is highly useful for asset management and operation. This study proposes the development of an HBIM maintenance model for the water supply, sanitary sewage, and stormwater systems of the José de Alencar Theatre, a historic building located in the city of Fortaleza, Ceará, Brazil. The methodology is based on field surveys and the creation of HBIM with a grouped structure, in order to incorporate essential maintenance information for inspections, documentation, and component quantification, while maintaining flexibility for targeted interventions, the creation of identification codes (IDs), and the organization format of this information within the model. The results indicate that the parameterization of HBIM model elements with maintenance-related semantic information enables the creation of a tool for the management and conservation of built heritage.

Keywords: Heritage Building Information Modelling, Information Modelling, Building systems, Maintenance, Autodesk Revit.

1. Introduction

Building Information Modelling (BIM) has established itself as a widely used digital methodology to support different activities throughout the building lifecycle, enabling the integration of geometric and semantic information into a shared digital model among various professionals (Rojas et al., 2019). In this context, HBIM emerges as a specialized extension of BIM focused on the survey, documentation, and management of historical buildings, incorporating information related to the construction, historical, and cultural characteristics of architectural heritage (Murphy et al., 2009).

Unlike traditional BIM applications, where the digital model is generally developed from the design and follows the construction process, HBIM operates on existing buildings. In many cases, these structures have undergone centuries of transformations, adaptations, and interventions, which makes the documentation process more complex. Thus, the digital model needs to be built from the existing reality, using surveys such as laser scanning, photogrammetry, and point clouds to digitally reconstruct architectural elements (Bruno & Roncella (2019); Arayici et al., 2017; Roncella, 2019).

The management and conservation of built heritage require a broad set of information about the building, including materials, construction techniques, intervention history, and the state of conservation of elements.

Obtaining this data often involves documentary research, field surveys, and technical analyses, which can demand a significant investment of time and resources (Meseguer et al., 2023). Furthermore, the study of historical buildings involves knowledge that extends beyond the fields of engineering and architecture, requiring the participation of professionals such as historians, archaeologists, conservators, and cultural heritage experts (Maxwell, 2016). In this sense, HBIM is also characterized by its interdisciplinary nature, allowing the integration of different types of knowledge into a shared digital environment (Historic England, 2017).

Despite the potential of the methodology, several studies indicate that a gap still exists between theoretical advances in HBIM and its practical application. A large part of the initiatives focuses mainly on the geometric modelling of buildings, while the informational structuring of the models receives less attention (Parente et al., 2025; Wang et al., 2025). Although processes known as Scan-to-BIM allow converting three-dimensional surveys into digital models, they do not automatically generate the semantic information necessary for building management. Thus, data related to materials, construction pathologies, state of conservation, and intervention history need to be obtained through on-site inspections and complementary documentary research.

Another recurring challenge relates to the efficiency of the modelling process. In HBIM projects, the creation of parametric components often depends on reverse modellingprocedures based on point clouds, which can make the process time-consuming and complex, especially when it involves irregular geometries or ornamental elements characteristic of historical architecture (Wang et al., 2025). In some cases, this process can result in the simplification or even loss of part of the geometric information captured during the digital survey (Delpozzo, Appolonia, Scala, and Adami, 2022).

In this context, the semantic dimension becomes fundamental for the development of HBIM models capable of supporting the management of built heritage. A heritage information model must go beyond the three-dimensional representation of the building, incorporating data related to the materials, construction techniques, state of conservation, and historical value of the elements that make up the building (Historic England, 2017). This information is particularly relevant when considering the integration between HBIM and Facilities Management (FM), as facility management depends on access to structured data that allows planning maintenance, conservation, and operation activities over time Tsay et al. (2023).

However, the use of BIM for Facilities Management still presents important challenges related to the definition and management of information necessary for the building's operation phase. According to Cao et al. (2019), few studies address the problems related to the clear definition of information requirements demanded by asset owners and managers. Furthermore, Tsay et al. (2022) point out that there is still limited knowledge about the application of BIM in facility management, which hinders the proper definition of the information needed to support operational processes.

Matarneh et al. (2019) also highlight that many research initiatives have focused on developing new technologies, while structural issues related to information organization and flow remain underexplored. For BIM to be used more efficiently in facility management, it becomes necessary to ensure the continuity of information flow between BIM and FM systems, create structured repositories of operational data, and develop mechanisms that allow the sharing and updating of this information across different sectors of the organization.

In conventional BIM projects, the transition between the design model and the operation model often involves the exclusion of information considered irrelevant for the maintenance phase (Gao and Pishdad-Bozorgi, 2019). In the case of historical buildings, however, the opposite problem frequently occurs: the scarcity and fragmentation of available information. Records related to renovations, component replacements, or technical specifications are often not available in a systematized way, which compromises decision-making capacity related to the conservation of built heritage (Martinelli, Calcerano, and Gigliarelli, 2022).

In this scenario, HBIM can assume a strategic role in the organization and reconstruction of the building's technical memory, functioning as a digital environment capable of integrating different types of information related to the heritage asset. For this, the proper structuring of data within the model becomes fundamental.

Families in the model play a central role in this process, acting as the main repositories of semantic information within the HBIM model. Through these structures, it is possible to standardize construction elements, assign unique identifiers to components, link external documents, and incorporate data related to maintenance, inspection, and intervention history (Murphy et al., 2017). The definition of these attributes should be guided by pre-established information requirements, such as Organizational Information Requirements (OIR) and Asset Information Requirements (AIR), as established by ABNT NBR ISO 19650-1 (2022).

Given this context, this study proposes an information structuring system in HBIM that begins with on-site surveying and develops through the organization and structuring of generic families for the semantic feeding of data into the digital model. The approach prioritizes the adequate informational input of these families, allowing the generation of quantity takeoffs and supporting analysis and decision-making processes.

Additionally, it seeks to ensure information interoperability through the use of the Dynamo tool, allowing the integration and updating of data related to building maintenance. The method also considers the optimization of the digital model's performance, prioritizing its computational lightness and ease of manipulation.

The application of the proposed system is directed towards the building facilities systems of the José de Alencar Theatre, with the objective of demonstrating the potential of HBIM as a tool to support the management and maintenance of historical buildings. Thus, the developed model is configured not only as a digital repository of the existing architecture but as an instrument capable of supporting the conservation and management processes of built heritage.

2. Methodology

This study proposes an applied methodology for the development of an HBIM model oriented towards the Operations and Maintenance (O&M) management of the plumbing and drainage systems systems of the José de Alencar Theatre , in Fortaleza–CE, Brazil. The approach is based on prioritizing the informational functionality of the model, balancing geometric simplification and semantic enrichment. Modelling with a low Level of Development (LOD) and a high Level of Information (LOI) was chosen, privileging computational performance, organizational clarity, and practical applicability in the context of building maintenance.

The model was conceived so that its elements would act not only as simplified graphic representations but as structured information containers, capable of integrating technical, operational, and heritage data in an associated and hierarchical manner. Figure 1 presents the methodology organised in five main stages: survey, semantic structuring, family development, coding, and information management, which are articulated in a progressive and interdependent way.

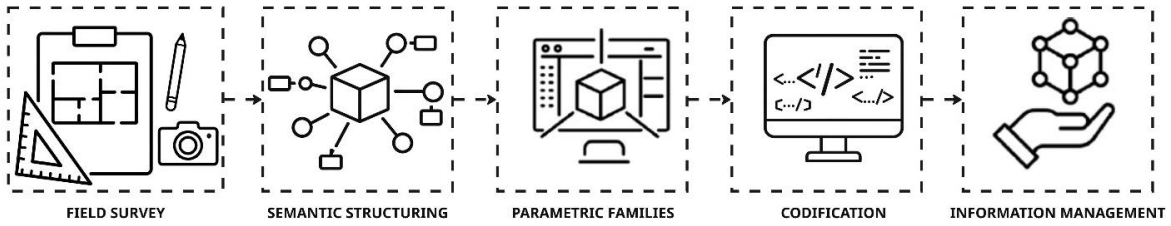

Figure 1 – Methodological process

2.1 Survey and Functional Analysis of the Plumbing and Drainage Systems

The research began with an on-site survey of the building's visible plumbing and drainage systems elements, including washbasins, toilets, faucets, traps, gutters, and other visible components. When available, information regarding brand, manufacturer, model, material, dimensions, colour, system membership, location, installation date, and associated technical documentation was collected.

The survey was complemented by photographic records and the analysis of existing documentation, seeking to consolidate a reliable information base for modelling and semantic enrichment. In parallel, an understanding of the systemic functioning of the hydraulic, sanitary, and stormwater subsystems was developed, recognizing their operational interdependencies.

It was observed that many components operate in an integrated manner within functional assemblies, such as in the case of the washbasin, which brings together elements belonging to different subsystems, but whose performance depends on the articulated functioning of all its components. This finding highlighted the need for constructing associations between elements through information organization, guiding the subsequent semantic structuring.

2.2 Hierarchical Semantic Structuring of the Plumbing and Drainage Systems

Based on the functional analysis, a hierarchical semantic structure was developed at two complementary levels, capable of reflecting both the operational logic of maintenance routines and the technical individuality of the components.

The first level corresponds to the functional assembly, which groups elements located in the same environment and that operate in an integrated manner to perform a specific function. Associated with this level is information related to recurring inspection, cleaning, and preventive maintenance routines, aligning the model with the practice of technical teams.

The second level corresponds to the individual component, to which its own identifiers and specific technical parameters are assigned, enabling asset inventory, quantity takeoffs, and targeted corrective interventions. The coexistence of these two levels allows for hybrid management within the model itself, articulating collective and individual information without redundancies and maintaining organizational coherence, as illustrated in Figure 2.

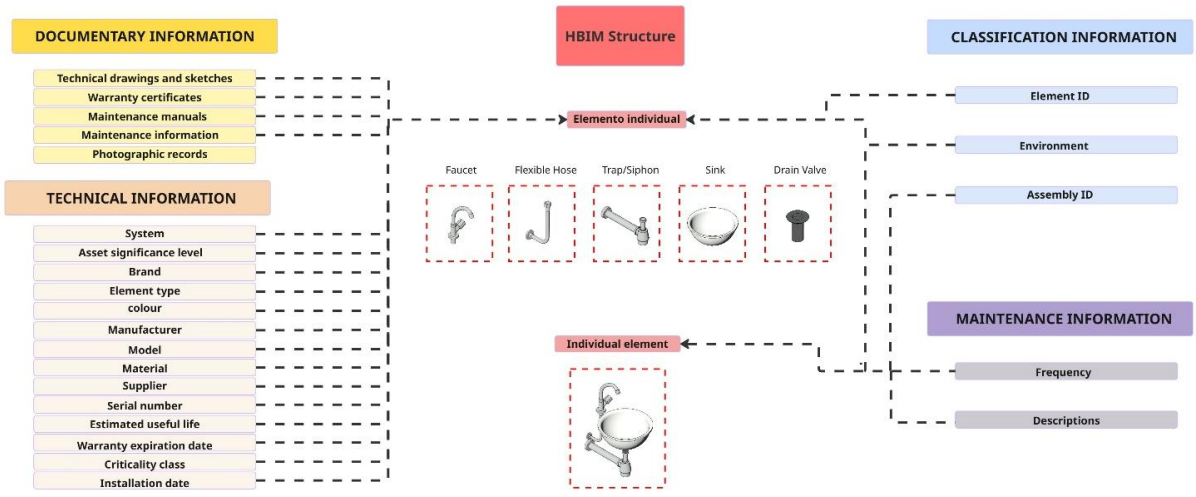

Figure 2 – HBIM Structure for Information Management of Plumbing and Drainage Systems Elements

2.3 Development and Hierarchical Organization of Generic Elements

The implementation of the semantic structure in the HBIM environment occurred through the adaptation and creation of generic elements oriented towards the specific demands of Facility Management (FM). Initially, conventional elements were debugged, with the removal of parameters irrelevant to the operations and maintenance phases. Subsequently, shared parameters were inserted for the incorporation of technical and documentary information, as well as for the creation of new parameters when necessary.

As this is a historic building, some families needed to be custom-developed to ensure coherence with the actual conditions of the construction. Although kept at a generic level and with simplified geometry, these families were adjusted so as not to represent construction typologies incompatible with the existing reality. An example is the case of masonry water tanks, which could not be represented by conventional fiber cement or plastic reservoirs. This adaptation ensured spatial compatibility and interpretive consistency in the model.

To support the hierarchical structure of information, the families were not only debugged or created individually but also organised in a hierarchical manner. Each family is composed of grouped subfamilies, as illustrated in Figure 3 as in the example of the washbasin, which integrates elements such as the faucet, pipes, and trap. These components maintain their individual representation in the model, allowing both the quantification of elements and the insertion of specific information. Simultaneously, the assembly is treated as a single element, enabling the management of collective information, such as cleaning procedures and periodic inspections.

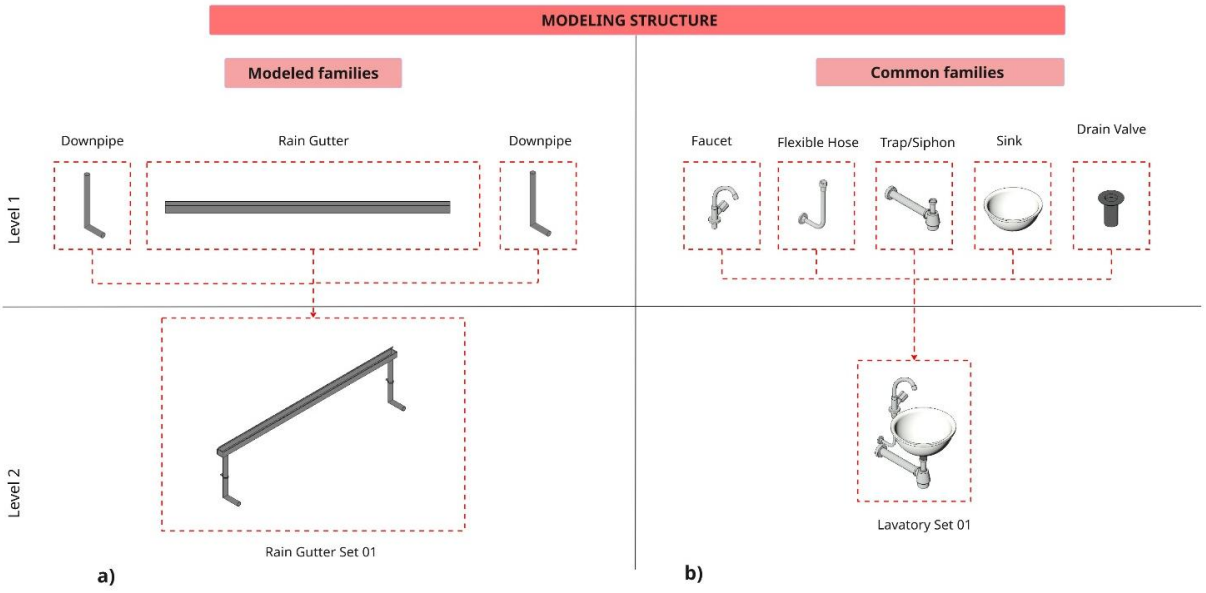

Figure 3 – Illustrates the modelling and hierarchical structuring of elements: (a) geometric modelling process by extrusion in Revit software; (b) generic elements.

Geometric modelling adopted simplified representations, sufficient for the spatial identification of elements, avoiding excessive detailing. This strategy reduced the complexity of the model and optimised its computational performance, while simultaneously promoting semantic enrichment. The proposed structure also ensures adaptability, allowing continuous data updates without the need for remodelling, preserving traceability throughout the entire building lifecycle.

2.4 Hierarchical Coding and Identification System for HBIM Elements

To ensure traceability, standardization, and interoperability with Computerized Maintenance Management Systems (CMMS), a hierarchical coding system was developed that articulates two levels of identification:

Main Code (Assembly ID): identifies a logical grouping of components, which may correspond to a single system or integrated systems. It is used to associate recurring cleaning, inspection, and preventive maintenance routines, as well as general work orders. Its composition includes a prefix referring to the type of assembly (e.g., BAS for toilet) and a sequential numerical suffix that functions as a unique identifier (e.g., BAS01-005).

Sub-code (Element ID): individualizes each component within the assembly, allowing for the recording and control of element-specific information. It is formed by the main code plus a letter for each component (e.g., BAS01-005A for the toilet bowl, BAS01-005B for the seat, BAS01-005C for the flexible hose). When there is more than one identical element, a number is added after the identifying letter. Figure 4 illustrates the implementation of this hierarchical identification system within the model interface.

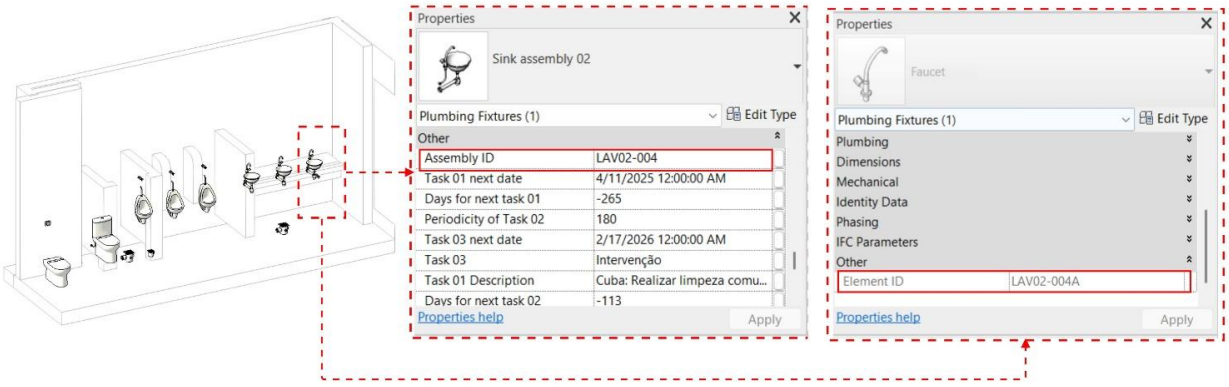

Figure 4 – Implementation of the hierarchical identification system in the model, highlighting the Assembly ID (group level) and Element ID (component level) parameters.

This system guarantees the unambiguous identification of both individual families (components that make up an assembly) and grouped families (the functional assembly as a whole). The structure facilitates data extraction for generating tables and reports, allows direct association with work orders, and enables integration with Excel spreadsheets through Dynamo.

Inserting information into the grouped elements contributes to reducing the informational load of the model, since data related to periodic maintenance, such as cleaning and inspection, is associated directly with the assembly. In practice, these procedures are applied simultaneously to all elements that make up the group, eliminating the need to replicate the same information in each individual component. This approach reflects the actual operations and maintenance flows more faithfully.

Concurrently, the parameters were organised according to their operational purpose, distinguishing information associated with the functional assembly (such as inspection frequency) from that linked to individual components (such as technical specifications and asset data). This organization strengthens the informational logic of the model and expands its compatibility with external management flows, allowing both the visualization of information for a specific element and the monitoring of cleaning routines applied to the group as a whole.

2.5 Hybrid Information Management Strategy

Considering that the BIM environment is not ideal for the extensive storage of voluminous documentation, a hybrid information management strategy was adopted. In this arrangement, only identification, classification, and operational decision-support data remain incorporated into the HBIM model families, while extensive documents, such as technical manuals, detailed reports, photographic records, and complete maintenance histories, are stored in structured external repositories, linked to both the elements and the families depending on the information.

Information related to maintenance, such as cleaning and inspections, is linked to the model through the assembly ID, using routines developed in Dynamo integrated with Excel, according to an approach adapted from Bessa et al. (2025). Unlike conventional approaches, which associate this data with individual elements, in this work the information remains directly linked to the grouped families, reflecting real-world operation and maintenance practices more faithfully (see Figure 5).

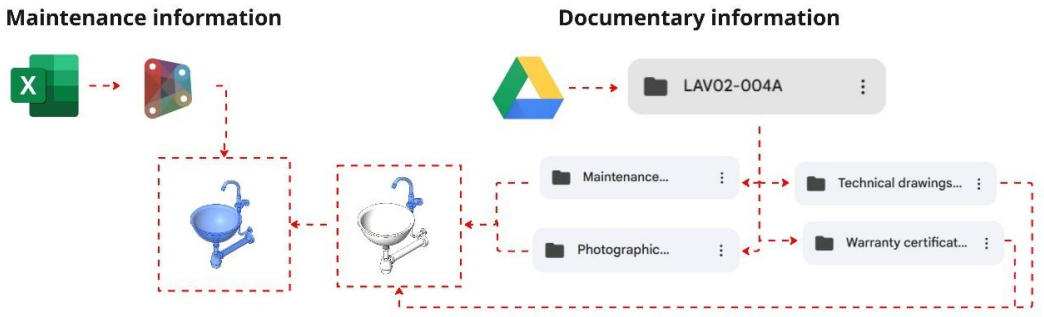

Figure 5 – Hybrid information management workflow: maintenance data integrated into the HBIM model via Excel and Dynamo (left), and documentary information stored in structured Google Drive repositories and linked to the model elements (right).

The connection between the elements represented in HBIM and externally stored documents is established through link parameters or coded references, ensuring a direct association between each element and its corresponding documentation. This approach keeps the model lightweight, navigable, and functional, favours dynamic updates, and expands the potential for interoperability with CMMS systems.

Thus, HBIM is conceived not as an absolute data repository, but as an organizing and visual interface for strategic information, oriented towards the effective support of operation and maintenance activities in historic buildings.

3. Results and Discussion

Regarding the survey of semantic information, this resulted in a considerable amount of data about the elements, such as type, location, colour, material, and manufacturer. However, some information could not be located, either because it was lost over time or because it was never recorded, such as serial number, warranty validity, and installation date. This gap is partly due to the fact that the building is in continuous use, which implies recurring replacements of components over time, whether due to the unavailability of original parts on the market or the need to adapt the system to the building's operation. In Figure 6, it is possible to observe these replacements of plumbing and drainage systems elements.

Figure 6 – Illustrates the replacement of plumbing and drainage system elements over time. (A) Original washbasin with a single operating handle, with the opposite side missing, indicating loss of components. (B) Washbasin after intervention, with the lateral holes sealed and a new faucet installed, demonstrating adaptation to current use conditions.

The installation dates of some elements could be estimated based on the set of characteristics, suggesting they belong to the last major renovation of the building, which took place in 1991. For the remaining elements, the corresponding fields were retained in the model's structure as fillable fields, even though they remained blank at the time of the survey.

Regarding modelling with a low Level of Development (LOD), nine grouped generic elements were developed, structured from grouped generic elements, comprising: one set of inlet valve, two distinct sets of toilets, four lavatories/sinks, one set of urinal, and one set of shower. Some elements remained isolated, bathroom drains, garden faucet, and bathroom valve, as they did not fit into the established grouping categories. For the infrastructure components, two sets of water tanks, thirteen sets of gutters, and seven sets of garden drains were modelled. In Figure 7, it is possible to observe the two generic modelling approaches adopted.

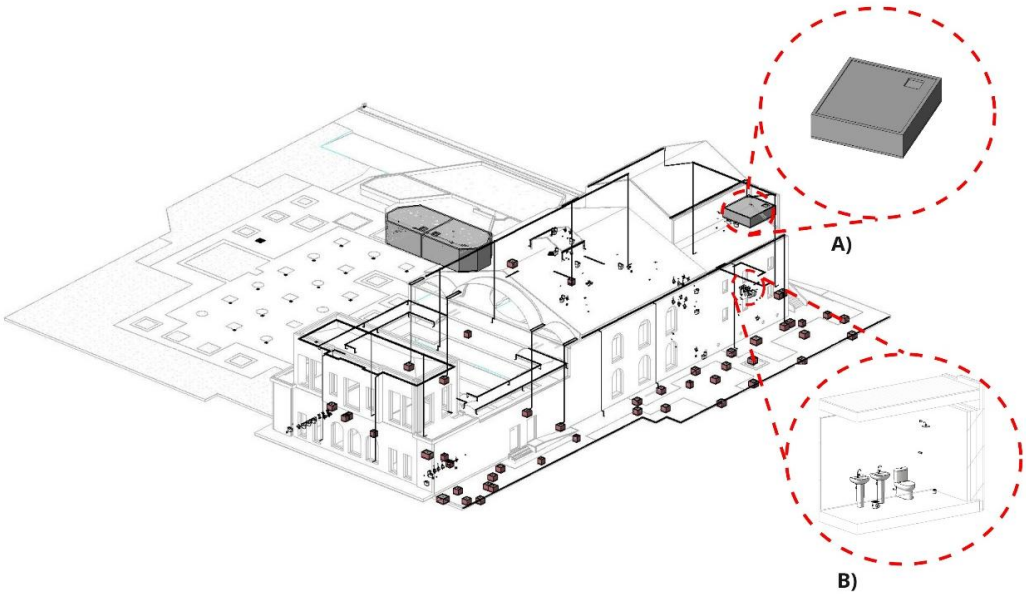

Figure 7 – Illustrates generic modelling approaches with a low Level of Development (LOD). (A) Simplified modelling approach based on minimal geometric representation of elements. (B) Modelling approach

based on aggregation of existing generic elements, which were cleaned, adapted, and combined into unified generic elements.

The strategy of adopting a low LOD associated with generic families allowed for eventual component replacements to be carried out by updating semantic information, without the need for geometric remodelling, an aspect particularly relevant for a building in continuous use, subject to modifications arising from operational needs and the unavailability of original parts on the market.

Regarding coding and integration with external tools, identifiers (IDs) were created for all model elements, enabling their integration with routines developed in Excel and Dynamo. A routine was implemented in Dynamo, as per Bessa (2025), applied to the plumbing and sanitation elements, allowing a maintenance spreadsheet, containing information on inspection, cleaning, and preventive maintenance based on current standards, to be integrated into the model. This integration enabled the functional assemblies to receive such information, as illustrated in Figure 8.

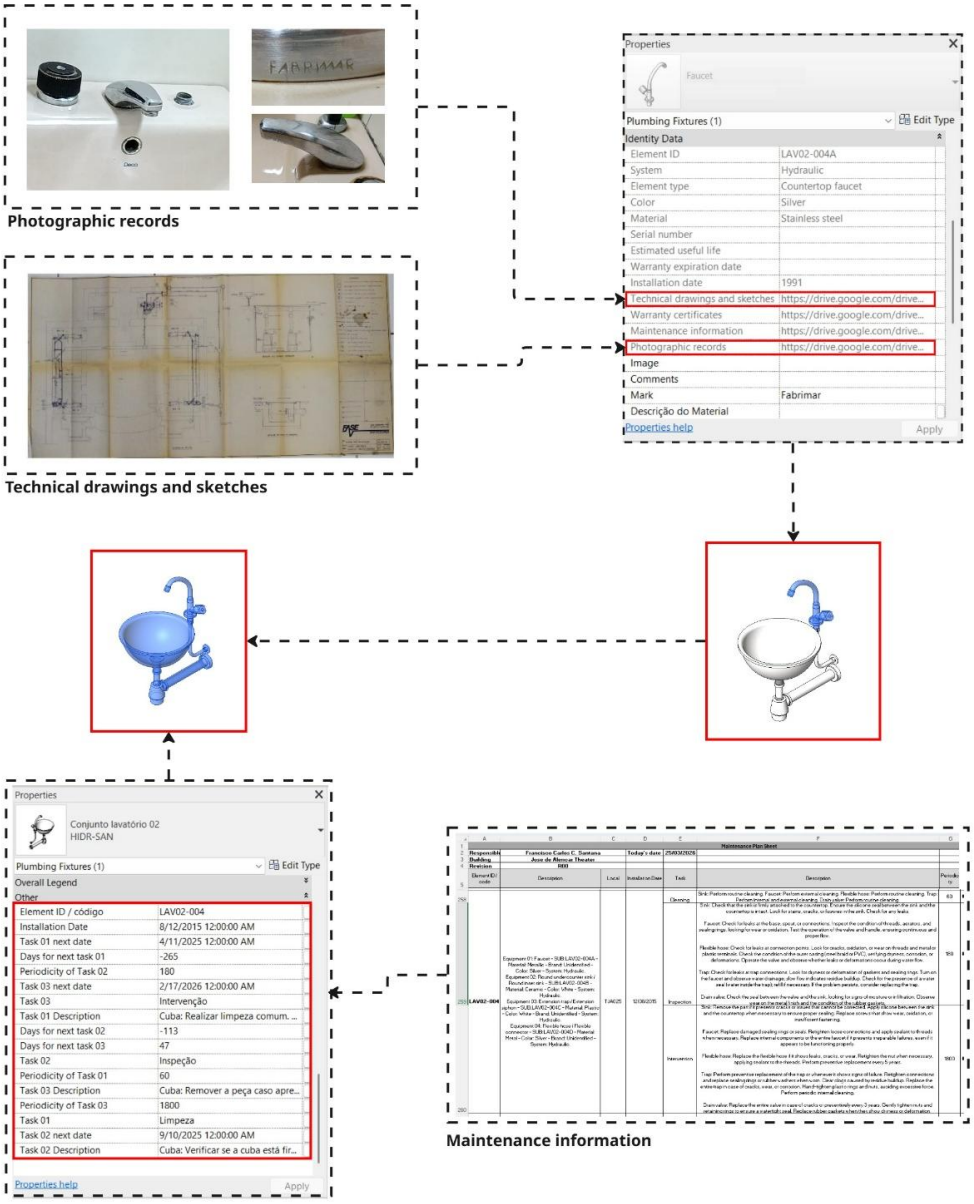

Figure 8 – Bidirectional information flow in the HBIM model. Top-down flow connects documentary and semantic information to the elements through external links and embedded data. Bottom-up flow integrates maintenance information from external spreadsheets into functional assemblies via Dynamo routines.

The coding of Element IDs was applied to a selected set of faucets in order to assess the feasibility of structuring this information. In these cases, both semantic information and the corresponding technical documents, organised in folders on Google Drive and linked to the HBIM model, were associated. This approach allows the maintenance information associated with the assembly (Assembly ID) to be linked with the specific and documentary data linked to the individual elements (Element ID).

Finally, regarding the model structure, the information fields were retained even when left unfilled, ensuring that future documentary discoveries or element replacements can be recorded without requiring a restructuring of the system. This approach gives the model flexibility and the capacity for continuous updating, aligned with the dynamic nature of the building in use.

4. Conclusions

This study presented a methodology for the development of HBIM models oriented toward the operation and maintenance of plumbing and drainage systems in historic buildings, based on the articulation between geometric simplification, hierarchical semantic structuring, and hybrid information management.

Unlike approaches traditionally centered on geometric detailing, the proposed methodology prioritized the informational value of the model, adopting a low Level of Development (LOD) associated with a high Level of Information (LOI). This choice proved adequate for building a lightweight, functional model aligned with real-world building maintenance practices in historic building contexts.

The two-level semantic structure, functional assembly and individual component, proved effective in articulating, within the same HBIM environment, the demands of preventive maintenance (associated with assemblies) and corrective maintenance (linked to individual components), ensuring traceability, standardization, and informational coherence. The hierarchical coding system and the organization of parameters according to operational purpose consolidated this logic, enabling the extraction of structured data and expanding the potential for integration with external management systems such as CMMS.

The adoption of a hybrid information management strategy reinforced the role of HBIM as an organizing hub for digital assets, avoiding model overload and expanding its practical applicability in real-world Facility Management contexts. Linking through identifiers proved sufficient to guarantee the association between modeled elements and extensive documentation stored externally.

The main contributions include: (i) the proposal of objective criteria for FM-oriented geometric simplification in historic buildings; (ii) the development of a two-level hierarchical semantic structure applicable to complex building systems; (iii) the implementation of a coding system that articulates assembly and component identifiers; and (iv) the integration between modeling and operational maintenance logic through routines in Dynamo and Excel.

Among the limitations of the research, it is noted that the model was developed but has not yet been validated under real use conditions with the theater maintenance team. Future work should focus on practical validation of the system through its application in a real context and the use of questionnaires with involved users (such as maintenance technicians and professionals), in order to assess usability, efficiency, and contribution to operational activities. This approach would enable an evidence-based evaluation grounded in real-world use, strengthening the empirical nature of the research.

Additionally, the application was focused on specific plumbing and drainage systems of the José de Alencar Theatre, although these systems are composed of multiple elements and functional interdependencies. Future studies may explore the development of more robust automated integrations between HBIM and CMMS for elements embedded in families; the correlation between technical data of components and cultural information, enabling the establishment of priorities for corrective maintenance based on integrated criteria; and strategies to improve information visualization for both functional assemblies and individual elements.

In summary, the work demonstrates that the effectiveness of HBIM for Facility Management does not lie in increasing geometric complexity, but in the strategic organization of information and its alignment with building operational practices. Thus, it reinforces the transition of HBIM from a predominantly representational tool to a strategic instrument for decision support and operational management, contributing to the consolidation of more efficient, sustainable digital models oriented toward the life cycle of historic buildings.

Resumo: Este estudo investiga o perfil tecnológico de chacotas de azulejos históricos datados dos séculos XVII e XVIII, provenientes de edificações religiosas localizadas no estado de Pernambuco, Brasil. A pesquisa concentra-se na caracterização das matérias-primas e das condições de processamento envolvidas na produção desses corpos cerâmicos, com ênfase na fração não plástica utilizada como tempero. A metodologia baseia-se na análise petrográfica por Microscopia de Luz Polarizada (MLP) em lâminas delgadas, técnica amplamente empregada em laboratório para a identificação mineralógica e textural de materiais silicáticos. A fração arenosa foi analisada segundo critérios análogos à classificação de rochas sedimentares, permitindo avaliar parâmetros morfológicos como dimensão dos grãos, esfericidade e grau de arredondamento, além da frequência relativa, distribuição e natureza das fases minerais presentes na matriz cerâmica. Os resultados evidenciam a ocorrência de seis perfis tecnológicos distintos entre as amostras analisadas, sugerindo variações nas escolhas de matérias-primas e nas práticas de preparação da pasta cerâmica, independentemente do período estilístico dos azulejos. Entre as fases cristalinas identificadas destaca-se, a presença de akermanita**,** mineral cuja formação é compatível com temperaturas de queima superiores a aproximadamente 950 °C, indicando regimes térmicos relativamente elevados para produções cerâmicas históricas. Do ponto de vista microestrutural, a análise morfológica dos grãos revela predominância de partículas angulares e de baixa esfericidade. Em observação microscópica, esses grãos atuam como concentradores de tensões na matriz vítrea parcialmente sinterizada, favorecendo o desenvolvimento de microfissuras. Tal característica contribui para aumentar a suscetibilidade das chacotas a processos de deterioração, especialmente em ambientes caracterizados por elevada umidade e intensa ação de sais solúveis, condições frequentemente observadas em edificações históricas situadas em áreas litorâneas.

Palavras-chave: Patologia das Construções; Azulejaria Histórica; Microscopia de Luz Polarizada; Petrografia Cerâmica; Perfil Tecnológico.

1. Introdução

A azulejaria histórica em Pernambuco representa um desafio para a patologia das construções devido à sua exposição a ambientes de extrema agressividade (alta salinidade e umidade ascendente) em cidades como Recife e Olinda. Além disso, os perfis tecnológicos revelam que esses azulejos são produto de trabalhos individuais de pequenos grupos, embora houvesse a intensão em controlar a produção manufatureira das Corporações de Ofício em Portugal através das *Casa dos Vinte e Quatro* e historicamente se estabelecessem, em cada período, padrões de tamanhos, cores e temáticas dos vidrados. Levando em consideração que o emprego de revestimento azulejar no interior de edificações religiosas foi uma prática importada de Portugal durante o Período Colonial, deve-se observar que as condições ambientais do país de origem são bem distintas das encontradas no litoral do Nordeste do Brasil, em especial nas cidades de Recife e Olinda, onde se concentram a maioria das igrejas estudadas. e essa circunstância de ordem natural ocorre em todos os edifícios estudados nesta pesquisa. Assim, a proposta de classificação através dos *perfis tecnológicos* possui uma aplicação prática. Isso devido às condições locais extremamente agressivas às peças azulejares, decorrentes do excesso de umidade do solo e do ar, da alta salinidade solúvel e da ineficiência do sistema de drenagem ao redor dos prédios. Essa situação ocorre porque o Recife localiza-se ao nível do mar e é recortado por rios e canais. Caso, por exemplo, da elevada umidade que existe nas paredes do Convento de Santo Antônio, infiltrando-se entre os painéis azulejares. De modo semelhante, Olinda situa-se no alto de uma colina com diversos nascedouros de água. As duas cidades, portanto, possuem situações bem mais agressivas das que se encontram nos países de origem de produção dos azulejos, e são justamente nelas onde se localização a maioria das edificações religiosas com azulejos no interior.

2. Materiais e Métodos

O procedimento analítico por Microscopia de Luz Polarizada (MLP) foi realizado em seis fragmentos cerâmicos previamente selecionados com base em critérios de preservação microestrutural. Foram priorizadas as amostras que apresentava degradação na camada vítrea superficial e integra toda a seção transversal da chacota, para a observação contínua da interface esmalte–corpo cerâmico e para a avaliação integrada da matriz argilosa e da fração arenosa ao longo da espessura do material.

Como suporte metodológico para a aplicação da MLP, adotaram-se como referências clássicas os trabalhos *Pottery Analysis: A Sourcebook*, Rice (1987) e *Ceramic Petrography*: The Interpretation of Archaeological Pottery & Related Artefacts in Thin Section Quinn, (2013).

Essas obras constituem referências consolidadas na literatura ao sistematizarem os procedimentos de análise por microscopia de luz polarizada aplicada a cerâmicas arqueológicas. Além da fundamentação teórica, apresentam estudos de caso que demonstram a eficiência da microscopia com luz polarizada na identificação de matérias-primas, tecnologias de produção e processos de transformação mineral durante a queima.

As amostras utilizadas na preparação das seções delgadas na ordem de 0,03 mm, foram fragmentos de chacotas provenientes das três igrejas localizadas em Recife e Olinda e que são representativas de distintos períodos históricos e estéticos do século XVII e XVII, 0.

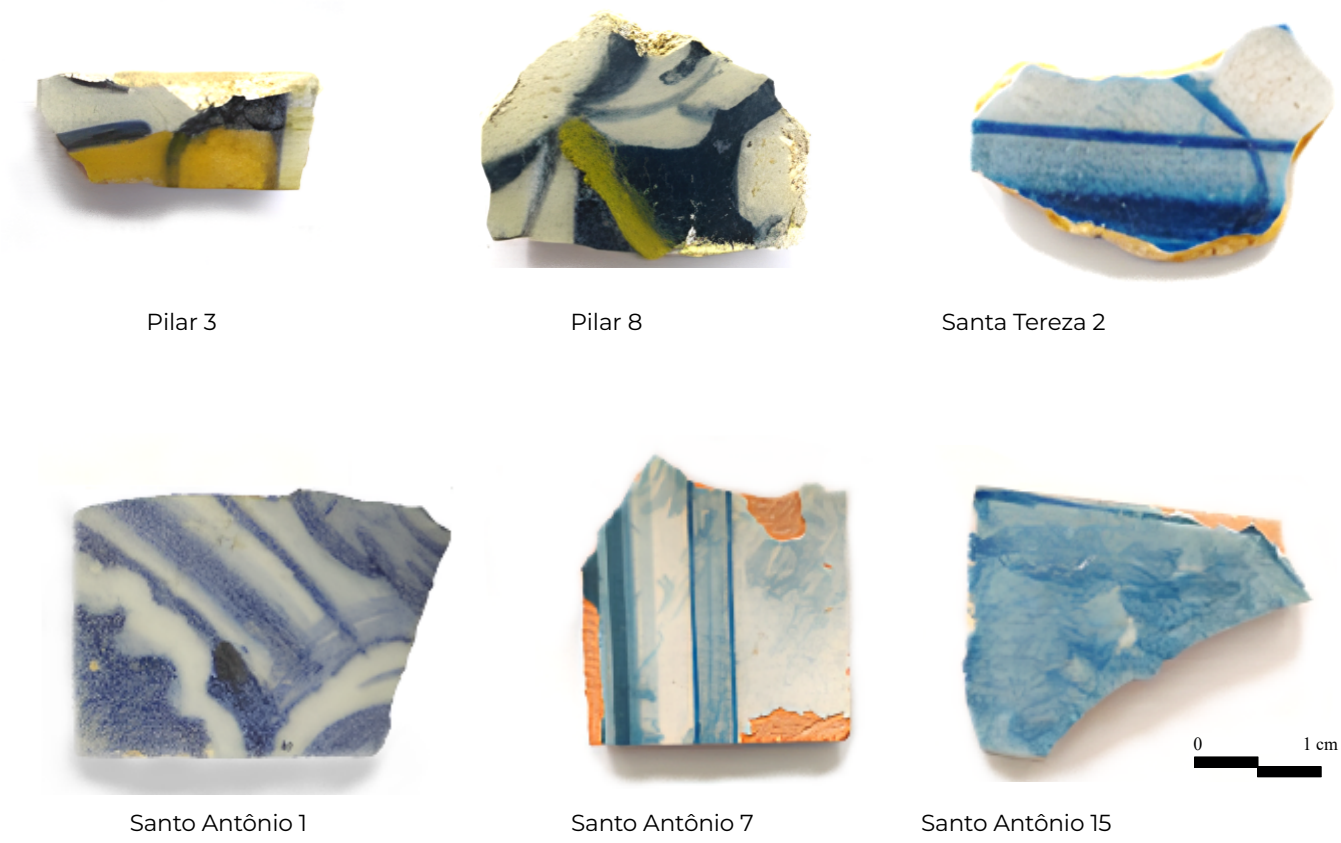

Figura 1 - Conjunto de 6 fragmentos azulejares. Do final da segunda metade do século XVII, proveniente da Igreja Nossa Senhora do Pilar em Recife, (Pilar 3 e 8). Da Primeira Metade do século XVIII, proveniente do Convento e Igreja de Santo Antônio em Igarassu (Santo Antônio 1, 7 e 15) e da metade do século XVIII, proveniente da Igreja Santa Tereza em Olinda.

A metodologia consiste inicialmente em determinar o contexto mineral das chacotas históricas, para tal os seguintes aspectos observáveis são: Morfologia, Fase mineral e Textura. São os dados as serem coletados com o uso da microscopia de luz polarizada. Como propriedades físicas da morfologia é analisado a granulometria, 0, a esfericidade e o arredondamento dos grãos minerais presentes de forma intencional e presentes de forma natural, 0.

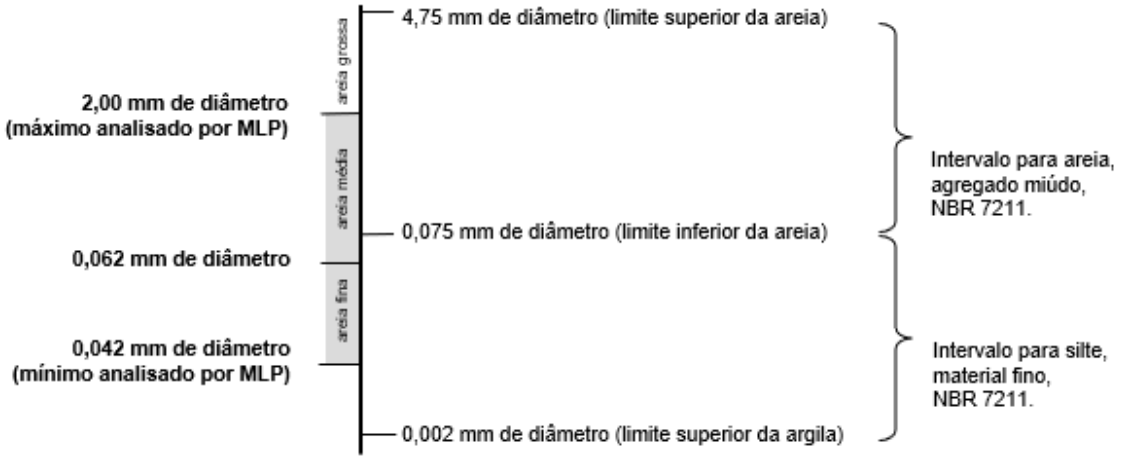

Figura 2 - Parâmetros de granulometria da NBR 7211 e a das rochas sedimentares, adotada para as análises por microscopia por luz polarizada (MLP) nas seções delgadas das amostras de azulejos históricos. O intervalo correspondente à fração areia (agregado miúdo) estende-se entre 0,075 mm a 4,75 mm segundo a norma. Entretanto, o limite inferior da areia fina foi ampliado para 0,042 mm em função da resolução analítica da MLP.

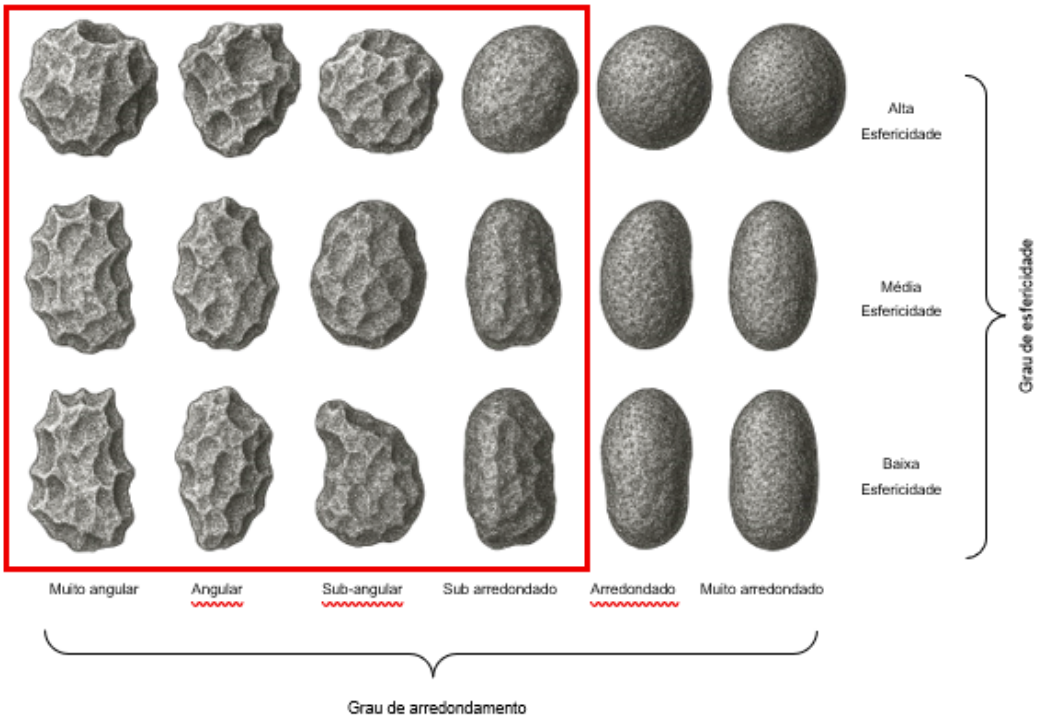

Figura 3 - A comparação visual da granulometria se baseia na medida do grau de agudez de cantos e arestas dos grãos arenosos. Para a esfericidade essa comparação analisa o quanto o grão se assemelha a forma de uma esfera. Uma chacota com grãos muito angulares e baixa esfericidade é mais suscetíveis a ocorrência de microfissuras.

O aspecto observável, fase mineral é definida pelas seguintes propriedades ópticas observáveis: cor, pleocroísmo, relevo, clivagem, partição, hábito, brilho, cor de interferência e ângulo de extinção. Nem sempre é necessário utilizar todas as propriedades, podendo ser escolhidas apenas algumas, 0.

Tabela 1 - Aspectos observáveis como elementos para determinar o contexto mineralógico da chacota, a morfologia e as fases minerais são os primeiros elementos que contribuem para o entendimento das causas das patologias de degradação das chacotas.

Aspectos observáveis	**Propriedades ópticas ou físicas**	**Condições Observáveis**	**Variação**
Morfologia do Tempero (areia)	Granulometria	Dimensão	Fração areia (grossa, média, fina) e fração (argila)
	Esfericidade	Forma	Esfericidade (alta, media, baixa)
	Arredondamento	Geometria das arestas	Angular, sub angular, sub arredondado, arredondado
Fases Minerais	Pleocroísmo	Aspectos da luz Visível	Mudança de cor
	Cor		Incolor, colorido
	Brilho	Refração	Metálico, vítreo, submetálico, adamantino

Já o aspecto observável, textura. permite inferir diretamente informações relacionadas à seleção de matérias-primas, ao preparo da pasta e ao desempenho microestrutural do material. Nesse contexto, a textura é definida neste estudo a partir de duas propriedades físicas: (i) a frequência dos grãos minerais (tempero) e (ii) a distribuição relativa entre a matriz argilosa e a fração areia, cuja interação resulta na organização da pasta cerâmica. A frequência corresponde à proporção volumétrica das fases minerais presentes, sendo um parâmetro fundamental para avaliar o grau de adição de tempero e sua influência na resistência mecânica do corpo cerâmico. Já a distribuição refere-se à forma como esses grãos se encontram dispersos na matriz homogênea ou heterogeneamente, fornecendo indicativos sobre o nível de preparo e homogeneização da pasta, além de sua influência na propagação de tensões e no desenvolvimento de microfissuras, **Error! Reference source not found.** .

Tabela 2 - A quantificação das fases minerais foi realizada por meio do método de contagem de pontos em grade, Stoops (2003). que permite estimativas confiáveis da frequência relativa dos constituintes. Complementarmente, a avaliação da distribuição entre matriz argilosa e tempero foi conduzida a partir da análise de imagens digitais obtidas em diferentes campos da mesma lâmina delgada, posteriormente processadas no software Image J.

Aspectos Observáveis	Subclasse	Condições observáveis	Variação
Textura	Frequência	Grãos minerais	Contagem de pontos em grade em porcentagem
	Distribuição	Concentração matriz argilosa e Tempero (areia)	Proporção entre matriz argilosa e areia (software Image J)

Na ausência de um sistema de referência específico para a classificação de contextos minerais em chacotas históricas, foi desenvolvido neste estudo um **modelo classificatório análogo**, derivado diretamente dos critérios utilizados na classificação de rochas sedimentares. Boggs (2006), Tucker (2001), Winkler (2005).

A adoção desse referencial se justifica pela similaridade estrutural existente entre esses dois materiais no que se refere à presença de uma fração detrítica mineral (areia) dispersa em uma matriz mais fina (argila). Embora as rochas sedimentares sejam produtos de processos naturais de intemperismo, transporte e deposição, enquanto as chacotas resultam de processos antrópicos de preparação de pasta e queima, ambos apresentam organização textural comparável em escala microscópica, o que permite a adaptação dos mesmos parâmetros descritivos. Com base nessa compatibilidade estrutural, os critérios clássicos empregados na sedimentologia particularmente aqueles relacionados à morfologia dos grãos, às fases minerais e às características texturais foram adaptados para a classificação das chacotas históricas 0.

Tabela 3 - Comparativo entre as características básicas utilizadas na classificação de rochas sedimentares e sua analogia para uma classificação das chacotas de azulejos históricos.

Classificação de Rochas sedimentares		**Classificação Análoga de chacotas**
Sandstone Pettijohn et al, (1987)	Areia > 80% granulometria entre 0,062 a 2 mm Esfericidade baixa e alta Arestas subângulosas e subarredondadas	Não identificada nas seções delgadas analisadas.
Quartzo Sandstone Pettijohn et al, (1987)	Quartzo > 90% Granulometria entre 0,042 e 0,062 mm Esfericidade alta Arestas arredondadas	Quartzo entre 80% e 50% da fração areia Granulometria + ou - 0,042 Esfericidade entre média a alta Arestas arredondadas e subarredondadas
Wacke Gilbert et al, (1954)	Argila > 15% Granulometria entre 0,042 a 0,062 mm Esfericidade baixa Arestas subangulosas	Quartzo e feldspato entre 50% e 75% na fração areia Granulometria entre 0,042 a 0,062 mm Esfericidade média a baixa Arestas angulosas a subangulosas
Lithic Sandstone Dott, (1964)	Fragmentos líticos ≥ 25% Granulometria entre 0,042 a 0,062 mm Esfericidade média Arestas subangulosas a subarredondadas	Fragmentos líticos ≥ 10% Areia com cerca de 50% de quartzo e 10% feldspato (tempero) Granulometria + ou - 0,042 Esfericidade entre média a baixa Arestas angulosas

A comparação sistemática das seções delgadas revelou simultaneamente semelhanças e contrastes nos contextos minerais, permitindo reconhecer distintos arranjos tecnológicos associados às matérias-primas empregadas na produção das chacotas. Considerando que um dos objetivos centrais da pesquisa é a definição de perfis tecnológicos capazes de indicar

potenciais manifestações patológicas nos revestimentos cerâmicos, tornou-se necessário extrair informações mineralógicas e texturais confiáveis das matérias-primas.

3. Resultados

Tabela 4 - Comparativo das propriedades físicas ópticas para classificação das amostras de chacotas da igreja do Pilar, da segunda metade do século XVII.

Amostra e classificação análoga	**Morfologia**			**Fases minerais**			**Textura**	
	Granulometria	Esfericidade	Arredondamento	Birrefringência	Cor	Brilho	Frequência	distribuição
Pilar 3: Wacke	Areia média a fina	Grãos subanguloso Esfericidade baixa		Quartzo, feldspato, argila (calcita + dolomita), akermanita			49,5 a 80% de fração argila e 20% a 50,5% de fração de areia	
Pilar 8: Lithic Sandstone	Areia média	Grãos anguloso Esfericidade baixa a média		Quartzo, feldspato, mica, fragmento de rochas, argila (calcita+ óxido de ferro), akermanita			80% a 56% de fração argila e 20% a 444% de fração de areia	

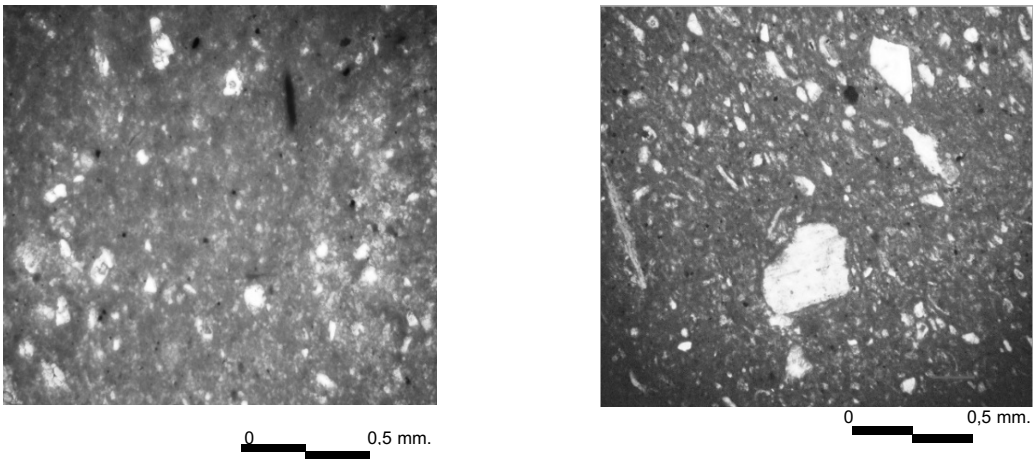

Figura 4 - A esquerda apresenta-se, á imagem micrográfica da amostra Pilar 3, da segunda metade do século XVII. No qual constatou-se que a chacota possui um contexto mineral análogo a classificação Wacke. A direita apresenta-se a imagem micrográfica da amostra Pilar 8, de mesmo período histórico, no qual constatou-se um contexto mineral análogo a classificação Litichic Sandstone.

Tabela 5 - Comparativo das propriedades físicas ópticas para classificação das amostras de chacotas da Igreja Santo Antônio, da primeira metade do século XVIII.

Amostra e classificação Análoga	**Morfologia**			**Fases minerais**			**Textura**	
	Granulometria	Esfericidade	Arredondamento	Birrefringência	Cor	Brilho	Frequência	Distribuição
Santo Antônio 1: Wacke	Areia média a fina	Grãos subanguloso Esfericidade baixa		Quartzo, feldspato, argila (calcita + dolomita), akermanita			75% a 48,5 de argila e 25% a 51,5% de areia	
Santo Antônio 7: Lithic Sandstone	Areia média	Grãos angulosos Esfericidade média		Quartzo, feldspato, fragmento de rocha (biotita) Argila (calcita, óxido de ferro), akermanita			80% a 69% de argila e 20% a 31% de areia	
Santo Antônio 15: Lithic Sandstone	Areia média	Grãos anguloso Esfericidade baixa a média		Quartzo, feldspato, fragmento de rochas (biotita, hematita) argila (calcita+ óxido de ferro), akermanita			60% a 48% de argila e 40% a 52% de areia	

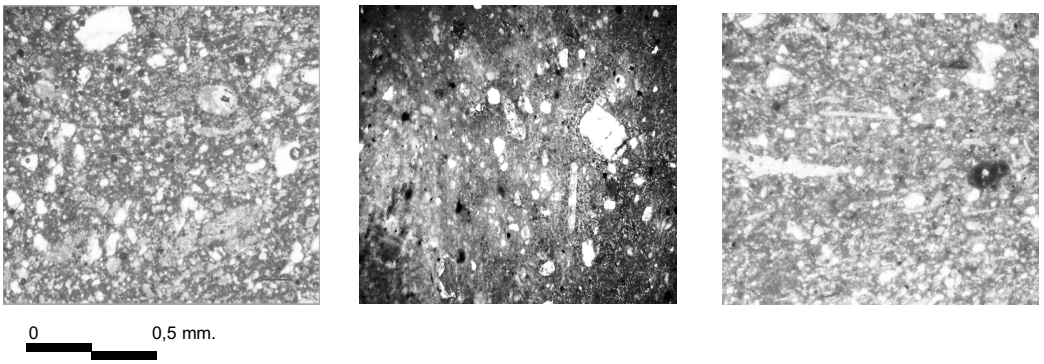

Figura 5- Imagem micrográfica das Amostra da primeira metade do século XVII, Na imagem à esquerda, apresenta-se a amostra Santo Antônio 1, onde constatou-se um contexto mineral análogo a classificação Wacke. Já as Imagens no centro e a direita, apresenta-se as amostras Santo Antônio 7 e Santo Antônio 15, onde constatou se um contexto mineral análogo a classificação Lithic Sandstone.

Tabela 6 - Comparativo das propriedades físicas ópticas para classificação da amostra de chacotas da Igreja Santa Tereza, da segunda metade do século XVIII.

Amostra e classificação Análoga	Morfologia			Fases minerais			Textura	
	Granulometria	Esfericidade	Arredondamento	Birrefringência	Cor	Brilho	Frequência	distribuição
Santa Tereza 2: Lithic Sandstone	Areia média	Grãos anguloso Esfericidade baixa		quartzo, feldspato, fragmentos de rocha (biotita + moscovita +piroxênio), argila (calcita + óxido de ferro), akermanita.			70% a 54% de fração argila e 30% a 46% de fração de areia	

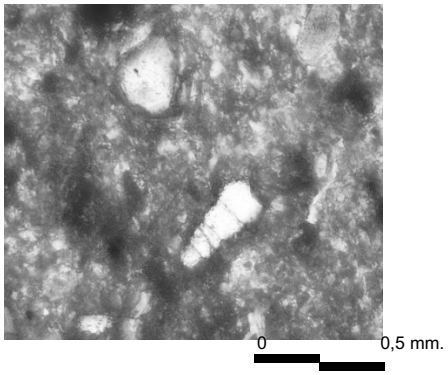

Figura 6- Imagem micrográfica da amostra, da segunda metade do século XVIII, no qual identificão-se um contexto mineral análogo a classificação Litichic Sandstone.

4. Discussão

A singular contribuição deste trabalho reside na aplicação do modelo classificatório análogo baseado em Pettijohn *et al*. (1987), Boggs (2006) e Tucker (2001). Ao classificar as chacotas, mobilizamos conceitos de maturidade textural e empacotamento que são essenciais para prever o comportamento do material frente às patologias de degradação. Essas questões são abordadas de forma intensas nas pesquisas de Mimoso *et al* (2016) especialista em caracterização química, mineralógica e conservação de chacotas e vidrados de azulejos históricos. Uma pasta cerâmica ao se aproxima do padrão análogo wacke, em termos tecnológicos, aponta para uma matriz argilosa pouco depurada e controle limitado do tempero. Do ponto de vista do desempenho, ocorre forte influência da matriz na mecânica do material. Em campo, isso se traduz em peças mais suscetíveis a retração diferencial, microfissuração, difusa e elevada absorção hídrica. Em condições de enterramento ou exposição, essas chacotas tendem a apresentar mobilização de sais, desagregação granular progressiva e perda de coesão superficial. A resistência mecânica, embora suficiente para uso cotidiano, é tipicamente baixa a moderada, com ruptura controlada pela matriz. Por quando uma pasta cerâmica se aproxima do padrão análogo Lithic Sandstone, o cenário muda de forma significativa. Aqui, ainda que a matriz argilosa permaneça presente, há uma participação mais efetiva dos clastos no suporte estrutural. Do ponto de vista tecnológico, o resultado material é uma chacota cerâmica com melhor distribuição de tensões, menor tendência à retração concentrada, acompanhada de vulnerabilidades: microfissuras localizadas, e a heterogeneidade composicional que pode favorecer diferenciais de dilatação térmica, sobretudo em ciclos de aquecimento/resfriamento

contribuindo para desintegração granular e abertura de microcavidades ao longo do tempo. Além disso, a identificação do termômetro mineralógico (akermanita) como marcador térmico superior a 950 °C revela um rigor técnico que remete às discussões de PAULO, B. Lourenço, CARLOS Maia, ARNALDO Sousa Melo, CLARA Pimenta do Vale(2023) , sobre a história das técnicas construtivas e o papel das Corporações de Ofício. Embora os azulejos analisados apresentem variações individuais em seus perfis tecnológicos, eles refletem uma tentativa de controle manufatureiro que atravessou o Atlântico a partir de Portuga.

5. Conclusões

A interpretação dos resultados obtidos para as chacotas de azulejos históricos de Pernambuco fundamenta-se em uma sólida base metodológica que transpõe conceitos da geologia para a arqueometria, ao fazer uso da Microscopia de Luz Polarizada (MLP). Os resultados obtidos neste estudo embora pertencente a uma pequena quantidade de amostras pode servir de ponto de partida para análise de outros conjuntos de chacotas maiores. A analogia com sistemas sedimentares permite mobilizar conceitos consolidados como empacotamento, suporte estrutural e maturidade textural para interpretar materiais antrópicos complexos. Isso eleva o nível de análise da simples descrição microscópica para uma leitura integrada entre tecnologia de produção, desempenho físico e trajetória de degradação. Em resumo, enquanto o padrão análogo **Wacke** foca na relação entre a matriz argilosa e um tempero arenoso rico em quartzo e feldspato, o padrão análogo **Lithic Sandstone** é identificado pela inclusão deliberada ou acidental de fragmentos de rocha e outros materiais complexos que alteram a resistência e a porosidade da cerâmica. O termômetro mineralógico, akermanita funciona como um registro fóssil do rigor térmico e das soluções técnicas aplicadas pelos artesãos nos séculos XVII e XVIII para garantir a durabilidade e a estética dos azulejos. Os critérios de esfericidade, arredondamento e granulometria que definem a morfologia da fração areia (tempero), são indicadores fundamentais para prever a vulnerabilidade de chacotas cerâmicas a manifestações patológicas. A principal patologia desenvolvida em função desses critérios é o surgimento de microfissuras. Enquanto a baixa esfericidade e o arredondamento mais angular promovem a durabilidade ao diminuir espaços vazios, o arredondamento mais arredondado a alta esfericidade agem como gatilhos para falhas estruturais e percolação de fluidos. Dessa forma, o trabalho contribui para a área ao utilizar as técnicas analíticas não apenas como ferramentas de catalogação, mas como indicadores de decisões tecnológicas tomadas pelos artesãos dos séculos XVII e XVIII, preenchendo lacunas sobre a gênese desses materiais e sua trajetória de deterioração no contexto agressivo de Recife e Olinda.

Agradecimentos

Gostaríamos de expressar nossos agradecimentos ao INAPAS (Instituto Nacional de Arqueologia, Paleontologia e Ambiente do Semiárido) pelo financiamento deste projeto, sem o qual esta pesquisa não teria sido possível. Agradecemos também a UFPE (Universidade Federal de Pernambuco) disponibilidade da utilização dos laboratórios e equipamentos utilizados nesta pesquisa, cuja contribuição foi essencial para o desenvolvimento e a conclusão deste estudo.

Argumentación en contra del uso de revoques texturados plásticos en fachadas patrimoniales. El caso del Museo Provincial de Bellas Artes de Santa Fe (Argentina)

Manuel Alfredo MINA[1]

[1] Universidad Católica de Santa Fe, Santa Fe, Argentina, manuelmina@ucsf.edu.ar

Resumen: Pese a los enormes avances científicos en el campo de la conservación de edificios de valor patrimonial en general y de sus fachadas en particular, subsisten algunas prácticas erróneas que menoscaban su originalidad, atentan contra su imagen histórica y producen incompatibilidades desde el punto de vista tecnológico que favorecen el surgimiento de lesiones. En este sentido, cabe detenerse en el tratamiento de fachadas provenientes de las primeras décadas del siglo XX, resueltas con revoques conocidos como símil piedra o piedra París que, en oportunidad de su restauración, son intervenidas mediante la aplicación de revoques texturados plásticos. Esta práctica, muy frecuente en la década de 1990 y 2000, favorecida por la novedad de la aparición de estos revestimientos formulados en base a resinas acrílicas, cargas minerales y pigmentos, motivada por su facilidad de aplicación y con las expectativas de impermeabilidad y vida útil, extendió su uso a obras, tanto del patrimonio monumental, como modesto, generando innumerables pérdidas en fachadas de gran valor. Aunque toda la argumentación teórica y los resultados puestos a la vista por el paso del tempo demuestran lo erróneo de este criterio, la práctica no ha sido desterrada por completo y subsiste en intervenciones algunas de ellas sobre ejemplares valiosos del acervo patrimonial de nuestras ciudades. El caso de estudio corresponde a la restauración del Museo Provincial de Bellas Artes Rosa Galisteo de Rodríguez de Santa Fe, fachada construida en 1922 y posteriormente ampliada en 1940, cuyas especificaciones de intervención requieren la aplicación de revoque texturado plástico. El presente trabajo establece la argumentación necesaria para revisar este criterio de actuación, reseña la investigación desarrollada para exponer la constitución original de la fachada y establece lineamientos para intervenir acordes a las buenas prácticas en restauro.

Palabras clave: Patrimonio, fachada, símil-piedra, restauro

1. Introducción

A partir de la necesidad de intervenir en la fachada del Museo Provincial de Bellas Artes Rosa Galisteo de Rodríguez en el contexto de la obra de restauración integral que se está llevando a cabo desde septiembre de 2025, se plantea la oportunidad de basar los criterios y las decisiones técnico - proyectuales en sólidos argumentos que la naturaleza patrimonial del edificio amerita.

En este sentido, existe un vasto marco de actuación referenciado en toda la literatura mundial del restauro, según el cual, previo a cualquier acción de restauración caben ineludibles tareas de investigación y reflexión que garanticen un adecuado criterio que respete el valor patrimonial del edificio o monumento a ser intervenido.

La Carta de Venecia (ICOMOS 1964) constituido en el documento fundante de la restauración moderna, abre su texto señalando en qué punto se ubica el valor de la conservación de los monumentos históricos.

> "Portadoras de un mensaje espiritual del pasado, las obras monumentales de cada pueblo son actualmente el testimonio vivo de sus tradiciones seculares. La humanidad, que cada día toma conciencia de la unidad de los valores humanos, las considera como un patrimonio común, y pensando en las generaciones

futuras, se reconoce solidariamente responsable de su conservación. Ella aspira a transmitirlas con toda la riqueza de su autenticidad." (ICOMOS 1964)

Ahora bien, la misma Carta expresa algunos lineamientos que es imprescindible tener en cuenta a la hora de decidir criterios de intervención. El objetivo de la restauración es salvaguardar tanto la obra de arte como el testimonio histórico que ella constituye y ese cometido se logra, fundamentalmente, basándose en el respeto por el material original y en documentos auténticos.

Por otra parte, cabe señalar que, a lo largo del tiempo, los edificios históricos van siendo objeto de intervenciones, muchas de las cuales no se basan en criterios de consenso internacional y ven menoscabada su imagen a partir de la inclusión de técnicas incompatibles con su originalidad, con su naturaleza técnica y con los criterios estéticos propios del edificio.

Será tarea, por tanto, del restaurador, intentar desandar el camino y devolver al edificio sus valores de originalidad y autenticidad que pudieron perderse (u ocultarse) a lo largo del tiempo.

Centrando específicamente la problemática de la conservación en la cuestión de las fachadas y haciendo foco en los revoques del tipo símil piedra o Piedra París, esta técnica se ha visto, en muchos casos, menoscabada en su tratamiento por criterios desacertados. Las malas decisiones técnicas han desechado las posibilidades de conservar el revoque símil piedra mediante cuidadosas prácticas de limpieza, consolidación y restitución y han optado por recubrirlo con materiales ajenos a la configuración original que han desmerecido gravemente su aspecto estético y han acelerado procesos de deterioros. El caso más elocuente lo constituye la aplicación de pinturas, sean estas a la cal o posteriormente al látex, sobre la superficie del material de frente, técnica que ofrecía una "renovación" del aspecto de la fachada a costa de una irreversible pérdida de originalidad, color, textura y realce de las formas y siluetas de la ornamentación. Esta técnica fue aplicada, tanto sobre fachadas monumentales, como también en obras del patrimonio modesto y reiterada, capa a capa, a lo largo del tiempo tal como se advierte en la Figura 1

Figura 1 – Tratamiento de pintura sobre fachada patrimonial

En las últimas décadas, la aparición en el mercado de un material innovador para el tratamiento de muros exteriores, el revoque texturado plástico, no tardó en desembarcar como técnica de intervención sobre fachadas de valor patrimonial favorecido por una cierta similitud en la textura y coloración y promocionado por su facilidad de aplicación. Este material se difundió con gran rapidez sin que se advirtiera convenientemente sobre su irreversibilidad y sobre una serie de incompatibilidades técnicas tal como se advierte en la Figura 2 y que se abordarán en apartados siguientes.

Figura 2 – Revoque texturado plástico sobre fachada de símil piedra

2. Criterio de intervención en el caso de estudio

2.1 El Museo Rosa Galisteo de Rodríguez

El Museo Provincial de Arte Rosa Galisteo de Rodríguez de la ciudad de Santa Fe (Argentina) constituye un bien de altísimo valor patrimonial por tratarse de un edificio enclavado en la zona fundacional de la ciudad, por ser un referente arquitectónico de la primera mitad del siglo XX de noble factura y rigor estilístico y por ser un referente social del arte pictórico y escultórico para la región. En su interior aloja una valiosísima colección de obras de arte que constituyen un tesoro cultural invaluable para los santafesinos. El museo es también una referencia nacional por sus Salones Anuales, por muestras, conciertos y eventos de renombre en la agenda cultural.

La fachada principal del museo sobre la calle 4 de enero (ver Figura 3) refleja en su configuración las dos etapas de construcción del edificio, el pórtico Norte (sobre la izquierda de la foto) correspondiente a su fundación en 1922 y el resto del frente correspondiente a la ampliación de 1940.

Figura 3 – Revoque texturado plástico sobre fachada de símil piedra

2.2 Análisis del criterio de intervención en fachada

En septiembre de 2025 dieron comienzo las tareas de restauración del edificio del museo en el marco de la licitación pública N° 00601-0056080-6 llevada a cabo por el gobierno provincial sobre un proyecto de la Dirección Provincial de Arquitectura e Ingeniería (DIPAI) con un presupuesto oficial de $ 1.504.159.725,79, lo que representa aproximadamente USD 1.500.000.-

El punto 12-13 del Pliego de Especificaciones Técnicas Particulares PETP titulado “Revestimiento de Material Plástico en Fachadas” (DIPAI 2024) indica la tarea de revestir las fachadas del edificio con el citado material, criterio posiblemente basado en que, en alguna intervención reciente el producto fue aplicado y quizás también en cierta fama de durabilidad e impermeabilidad del material.

Sabido es que los revoques texturados plásticos (“Quimtex” por citar la marca referenciada en el Pliego) son materiales formulados en base a resinas acrílicas (polímero sintético), cargas minerales y pigmentos y cuyo uso se popularizó en nuestra zona en los albores de la década de 1990. Importantes ventajas en su método de aplicación y ciertas expectativas de durabilidad e impermeabilidad hicieron que este material, no solo liderara en poco tiempo las terminaciones de fachadas en arquitecturas nuevas, sino que irrumpiera también en fachadas patrimoniales, en su gran mayoría tratadas con revestimientos símil piedra, dada su similitud cromática y (a cierta distancia) en la textura.

De una lectura temporal del edificio, se sabe que el bloque fundacional del edificio data de 1922 y la ampliación de 1940, datos que hacen descartar, de sentido común, que las fachadas hubiesen tenido en su tratamiento original revoque texturado plástico.

Ahora bien, la pregunta a resolver es cuál fue entonces el tratamiento original del edificio y para esto la tarea debe basarse en tres fuentes: una interpretación epocal en función de las técnicas disponibles y las costumbres al momento de la construcción; una investigación documental y de rescate de información oral y por último el trabajo de campo basado en cateos sobre diversos sectores del muro. Ninguna de las fuentes ha de tener un resultado absolutamente conclusivo por sí sola, sino que, complementándose unas a otras permitirán reconstruir con mayor fidelidad argumental la situación perdida.

En este caso en particular, las tres fuentes de información son absolutamente contundentes y permiten concluir que el Museo fue revestido con revoque símil piedra, técnica que se abordará en el siguiente apartado.

3. La investigación

3.1 Investigación histórica

En las últimas décadas del siglo XIX, una serie de factores se conjugaron para que se ejecutaran en nuestras ciudades los ejemplares edilicios más significativos de nuestro patrimonio arquitectónico. La prosperidad económica devenida del modelo agroexportador imperante, las ideas del iluminismo expresadas en términos estilísticos a través del neoclasicismo, el gusto por los modelos europeos (de Francia e Italia principalmente) y el arribo de numerosos operarios fundamentalmente italianos a partir de las fuertes corrientes inmigratorias del cambio de siglo constituyeron la base sobre la cual se configuró una manera de construir y por tanto una manera de la acabar las fachadas.

Las arquitectas Tarchini y Elías, investigadoras de la Facultad de Arquitectura, Diseño y Urbanismo de la Universidad Nacional del Litoral sostienen:

> "En América Latina, y en Argentina en particular, los revocos de terminación en fachadas históricas son un recurso material indispensable para la interpretación y conservación del patrimonio edificado. Las arquitecturas del academicismo eclecticista realizadas en ciudades tales como Buenos Aires, Rosario y Santa Fe, entre finales del siglo XIX y mediados del siglo XX, recurrieron a la aplicación de revocos y estucos que simulan piedras, debido a la escasez de rocas naturales adecuadas para la construcción, así como por la economía, rapidez y versatilidad que este sistema de revestimiento ofrece y que fue ampliamente difundido por los artesanos y albañiles italianos en la región. Estos morteros y revocos, elaborados a base de cal calcítica aérea y áridos naturales como arenas silíceas, además de rocas metamórficas como mármoles y rocas magmáticas como granitos, aportan no solo textura y coloración, sino también mejoran las características técnicas de las fachadas." (Tarchini y Elías 2024)

Así mismo, el arquitecto e historiador Mario Buschiazzo, considerado el padre de la preservación del patrimonio arquitectónico en la Argentina afirma:

> "Como es sabido, la piedra no es un material que se utilizó para construir en Buenos Aires, salvo como revestimiento o para ejecutar ciertas terminaciones. No obstante su ausencia física, podemos decir que tuvo una amplia presencia visual, ya que el grueso de los edificios académicos ostenta fachadas cuyo revoque imita piedra, de la cual efectivamente estaban hechos los modelos originales que sirvieron para inspirar los detalles estilísticos de aquellos; pero, por supuesto no se trataba en última instancia de piedra sino de argamasa. La auténtica piedra se colocaba en placas de pequeño espesor adheridas al muro de ladrillos, y eso sólo en ciertos lugares, por ejemplo, en los zócalos ejecutados de granito martelinado, que fueron frecuentes a principios de siglo, tanto en obras de importancia como en aquellas carentes de especial lujo..." (Buschiazzo 1971)

Tabla 1 – Composición clásica de los morteros símil piedra de principios del siglo XX

Componente	Función principal	Notas históricas
Cal	Aglomerante	Usada ampliamente antes de la popularización del cemento; aportaba plasticidad y trabajabilidad.
Cemento	Aglomerante	Introducido por inmigrantes italianos; daba mayor resistencia y durabilidad.
Arena	Árido	De granulometría variada; definía textura y compactación del mortero
Mica	Mineral molido	Aportaba brillo superficial y variaciones cromáticas
Dolomita	Mineral molido	Contribuía a tonalidades claras y resistencia.
Calcita	Mineral molido	Generaba tonos ocres y grises

Por otra parte, vale realizar un recorrido imaginario por las obras del patrimonio monumental de la época en la ciudad de Santa Fe y la resolución tecnológica de las fachadas siempre será la misma, revoque símil piedra, también llamado “Piedra París” o más recientemente “Material de Frente”. La Casa de Gobierno, el Teatro Municipal Primero de Mayo, la Escuela Industrial Superior, el Rectorado de la UNL, la Basílica del Cármen y el Hospital Italiano son solo algunos ejemplos que abarcan el abanico de época del museo y exhiben este tratamiento en sus fachadas según puede apreciarse en el collage de fachadas de la Figura 4.

Figura 4 – Edificios emblemáticos de la ciudad de Santa Fe construidos entre 1890 y 1940

En todos los casos, el acabado de los frentes se caracteriza por el uso del símil piedra como material de terminación, generalmente monocromo y la articulación de las superficies mediante el trazado de rehundidos (falsas juntas de distinto ancho y espesor) habitualmente tomadas con un mortero cementicio para enfatizar la idea de mampostería de sillares (bloques) de piedra. En algunas fachadas el material de frente se termina sin más textura que la propia del frataz que utiliza el obrero y en algunos casos más singulares se le da una terminación “peinada” o rayada imitando la impronta que la gradilla dejaba a la piedra natural cuando esta era labrada (Ver Figura 5).

Figura 5 – Texturas al frataz y “peinada”

En el caso de la ornamentación, se combinan dos criterios: por un lado, los ornatos directos, ejecutados sobre la superficie misma de la fachada tal es escaso de molduras, cornisas, guardapolvos y dentículos y por otro, los ornatos aplicados, piezas de molde, elegidos generalmente de catálogos de la época y fijados a la facha con pernos metálicos y mortero (Ver Figura 6). Es habitual que los elementos de molde no coincidan en coloración y textura con el Piedra París de la fachada, situación que en pocas oportunidades se dejaba expuesta componiendo fachadas bitonales, pero que en la mayoría de los casos se resuelve mediante una veladura de las piezas con el símil piedra usado para unificar cromáticamente el conjunto.

Figura 6 - Ornamentación directa y de molde

3.2 Investigación documental

A nivel documental no se han hallado pliegos ni reseñas técnicas de la construcción del edificio de ninguna de sus dos etapas y la fuente más cercana la constituye una escasa cantidad de fotos de épocas que revelan algunos datos útiles.

El documento más antiguo lo constituye una fotografía del acto inaugural del museo ocurrido el 25 de mayo de 1922 y que se reproduce en la Figura 7. La imagen solo aporta la confirmación de que el cuerpo norte de la fachada cuenta con una configuración volumétrica y ornamental idéntica a la actual.

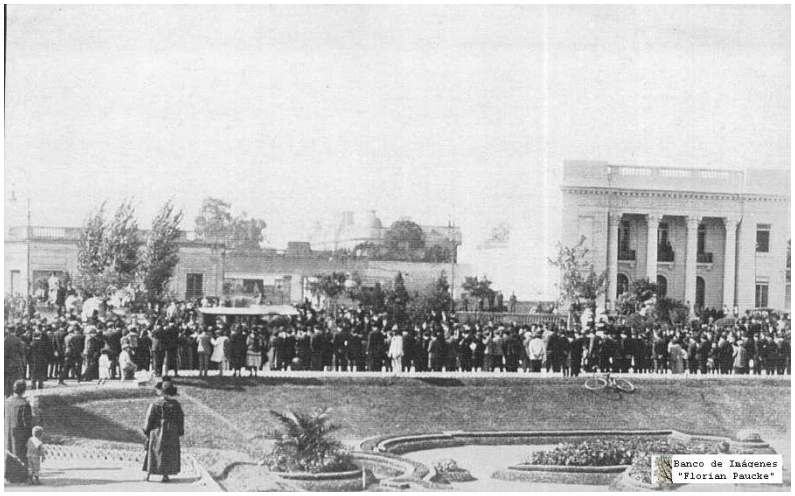

Figura 7 - Inauguración de 1922 – Obtenido de Banco de Imágenes “Florián Paucke”

Otro documento valioso lo constituye la Figura 8 que reproduce una fotografía de 1930 tomada específicamente de la, por entonces, fachada del museo. En la imagen se puede advertir que las columnas de orden corintio y el frontis que aloja las letras labradas “MUSEO ROSA GALISTEO DE RODRIGVEZ” parecen tener un tratamiento cromático diferente al resto de la fachada que amerita ser estudiado en profundidad. Los zócalos evidencian una materialidad diferente al resto de la superficie coherente con las placas de granito gris martelinado que luce actualmente.

Figura 8 - La fachada del Museo en 1930 – Obtenido del Banco de Imágenes Florian Pauke

Observando la foto publicada en la portada del Salón Anual de 1931 (Figura 9) se mantiene la presunción de que las columnas y el frontis pudieron tener un tratamiento cromático diferente al resto de la fachada, pero es evidente que el resto del sistema ornamental está tratado con el mismo criterio de color que los paños de muro.

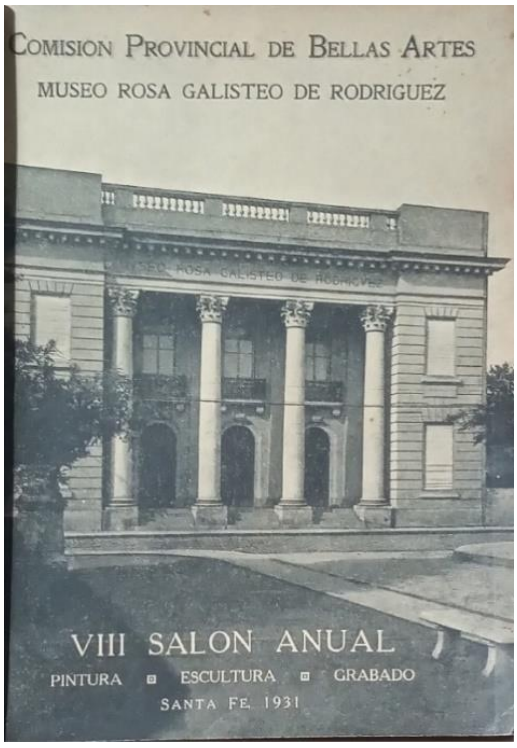

Figura 9 - La fachada del Museo en 1930 – Obtenido del Archivo del Museo Rosa Galisteo

El documento más revelador con el que se cuenta es el afiche de una muestra titulada “Colectivo de Aristas” basado en una fotografía de 1969, la imagen color más antigua que se pudo hallar (Figura 10). En el fondo de una toma familiar efectuada desde calle 3 de febrero se distingue la fachada del Museo, más precisamente el pórtico Sur y el muro de ochava que luce de un color ocre grisáceo característico del Piedra París.

Figura 10 - Afiche de "Colectivo de Artistas" (1969) – Obtenido del Archivo del Museo Rosa Galisteo

Leonardo Scheffer, un destacado miembro del staff del museo, actualmente a cargo del archivo, refirió su constante preocupación por la originalidad del color del edificio, aportando un dato significativo:

"Taverna Irigoyen, director de la Institución durante muchos años, me manifestó que la fachada fue pintada por primera vez a principios de la década de 1980 debido a los numerosos grafitis con leyendas políticas que habían sido estampados con motivo de la agitación de esos años y la cercanía del edificio con la legislatura provincial. El color que se eligió fue rosado, pero antes de eso el edificio fue gris." [1] (Ver Figura 11)

Figura 11 - El frente del Museo pintado de rosado (1981) – Obtenido del Banco de Imágenes Florian Paucke

Reforzando la teoría de que el edificio fue pintado, un artículo periodístico publicado en 2013 en el diario Uno, en oportunidad a las obras de refacción recientemente inaugurados por aquel entonces, refiere que la vuelta a la tonalidad ocre grisáceo de la fachada sería una vuelta a la originalidad de la misma afirmando que el tratamiento en tonos de rosa había sido una intervención de la década de 1980 basada en erráticos criterios de analogías al nombre de la institución o bien buscando similitudes con otros edificios tales como la Casa de Gobierno en la Ciudad Autónoma de Buenos Aires.

[1] Leonardo Scheffer, entrevista personal con el autor, Santa Fe, 6 de febrero de 2026

"Quizás la Intervención que más resalte es el cambio de color del rosa viejo que lucía desde 1982 a este nuevo gris que recupera el verdadero tono que tuvo al ser construido. Es que en una fallida intervención se lo había pintado como tomando a pie juntillas al poema El Golem, en el que Jorge Luis Borges decía *Si (como afirma el griego en el Crátilo) / el nombre es arquetipo de la cosa / en las letras de "rosa" está la rosa/ Y todo el Nilo en la palabra Nilo". Así, creyendo que con ese color se rendía homenaje a la madre del fundador a la vez que se refería directamente al Museo ensimismo, se incurrió en un error histórico. Otros dicen que se hizo para que se pareciera a la Casa Rosada[2] y no para aludir directamente al nombre de pila". (Redacción Diario Uno 2013)

3.3 Investigación de campo

A partir de la realización de cateos en la fachada del Museo, tanto sean en el segmento correspondiente a 1922 como al de 1940, se advierten signos evidentes del tratamiento original de la fachada ejecutada, en ambos casos, con un mortero símil piedra de coloración ocre grisáceo absolutamente congruente con las otras fuentes abordadas en apartados precedentes.

Las calicatas más reveladoras son las ejecutadas en el atrio norte (Figura 12), correspondiente a 1922, en el que asoma nítidamente el símil piedra (aunque con una coloración excesivamente amarronada por estar el tramo afectado por humedades ascendentes por capilaridad) pero dejando expuesto el clásico tratamiento de falsas juntas entre los sillares tomados con mortero de coloración oscura y alta dureza que refieren al uso de cemento portland. El tratamiento de falsas juntas se encuentra tanto en los sillares menores del interior del atrio como tratamiento de superficie, como así también en el fondo de las profundas buñas que configuran el almohadillado a ambos lados del pórtico.

Figura 12 - Calicatas realizadas por el autor en el pórtico de 1922

Dos estratigrafías realizadas en el muro Oeste (Figura 13) revelan datos que vienen a confirmar mucho de lo recabado en la investigación teórica y documental. Por un lado, en la calicata de la figura 11, se puede establecer con precisión la conformación del sistema de revoques previo a las intervenciones de pintura iniciadas entre los ´70 y los ´80. Se advierte la siguiente secuencia:

Mampostería de ladrillos cerámicos macizos / revoque impermeable: de gran dureza y coloración característica del cemento portland como ligante / revoque grueso a la cal: de baja compacidad y evidente presencia de una combinación de arena de sílice y polvo de ladrillo como agregados finos / material de frente: de gran compacidad, en un espesor promedio de 3 a 4mm

[2] Casa Rosada: nombre coloquial con el que se conoce a la Casa de Gobierno de la República Argentina ubicada en la Ciudad Autónoma de Buenos Aires

Figura 13 - Calicatas realizadas por el autor en el muro Oeste de 1940

La cala de la Figura 14 demuestra la presencia del símil piedra como material previo a las intervenciones de pintura (1). Si bien se hace muy difícil establecer la secuencia de al menos, 5 intervenciones de coloración rosa (2), es evidente que la primera intervención sobre el símil piedra fue en esa coloración y que después de sucesivas capas se aplicó un revoque texturado plástico de tonalidad manteca (3) y finalmente un látex más agrisado como tratamiento que hoy exhibe la fachada (4).

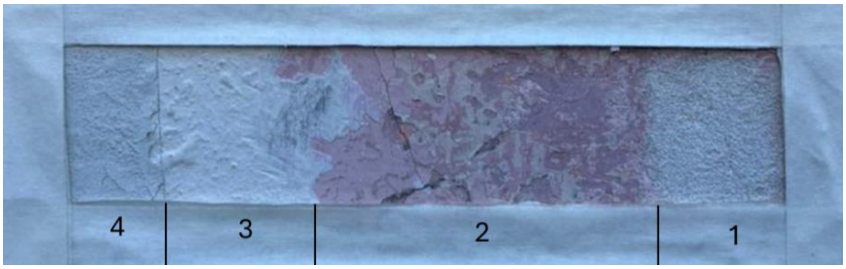

Figura 14 - Estratigrafía de colores realizada por el autor

4. Conclusiones

La coherencia detectada en las tres fuentes de investigación abordada permite afirmar indubitablemente que la fachada del Museo Rosa Galisteo de Rodríguez fue tratada originalmente con mortero símil piedra, tanto en su segmento de 1922 como en el de 1940, con algunas diferencias que se detallaron oportunamente y con un tratamiento monocromo que deberá confirmarse en investigaciones subsiguientes. Cualquier tratamiento de los aplicados sobre la fachada, sean estos de pintura o de revoque texturado plástico han sido intervenciones posteriores y distorsivas tanto de la materialidad del edificio como de su estética.

En un texto de referencia para la disciplina, el reconocido arquitecto restaurador Marcelo Magadán sostiene: que la alteración de los símil-piedra se da masivamente por malas intervenciones de restauración y/o conservación, estas se ejecutan con materiales inadecuados, técnicas incompatibles y al margen de los principios más elementales aceptados en el campo de la restauración. Uno de los errores más frecuentes es la aplicación de pinturas que hace perder irreversiblemente el color y la textura del material original. (Magadán 1999)

Un desacierto muy común es el "re-revocado" de los paramentos mediante la aplicación de una suerte de "enduido" que, modificando la textura, el color y las formas primigenios, transforma negativamente la imagen de los edificios. Existe además una técnica ubicada a mitad de camino entre ésta última y la pintura: se trata de los recubrimientos con carga, que comparten con ambas, no sólo el impacto negativo del que se habló, sino también las deficiencias de comportamiento por fallas en el anclaje entre estos materiales y el sustrato original. Además, no son reversibles mientras que toda intervención con materiales no originales debe poder ser retirada, la naturaleza de anclaje de los texturados plásticos no lo permite, o al menos si lo permite, lo hace a costa de un daño significativo al sustrato. Por otra parte, otorgan una impermeabilidad

excesiva al paramento y sellan los poros a partir de los cuales, estas mamposterías evaporan y eliminan excesos de humedad de distinta procedencia, los texturados plásticos configuran películas que actúan como barreras que favorecen la retención de humedad lo cual redunda en acelerado envejecimiento del símil piedra por la acción de la cristalización de sales solubles que no pueden ser eliminadas por no tener contacto con la atmosfera. La retención prolongada de agua en la masa del mortero endurecido comienza a solubilizar sales consolidantes de los aglomerantes y los disgrega. En algunos casos, la evaporación retenida por detrás del acrílico genera presiones que originan aglobamientos y el posterior decapado del texturado. Esto no solo desmerece largamente la condición estética, sino que abre puntos para el ingreso de humedad al muro tal como se advierte en la Figura 15.

Figura 15 – Diversas patologías desarrolladas por los revoques texturados plásticos

Resuelta la cuestión de la no pertinencia de la aplicación de revestimientos ajenos a la materialidad de la fachada, el desafío es cómo intervenirla para devolver las notas de originalidad perdidas a lo largo del tiempo.

Un criterio absolutamente consensuado a nivel de la literatura de la disciplina y avalado por virtuosas intervenciones de restauro, tanto en el mundo como en Argentina y Santa Fe, establece la necesidad de la vuelta a los materiales originales del edificio. La destacada investigadora Arq. Felicidad Paris Benito de la Universidad Nacional de Mar del Plata sostiene:

"En la restauración, el nuevo material debe cooperar con el original. Esta cooperación sólo está garantizada cuando los materiales son similares. En la reconstrucción del mortero hay que considerar el efecto de envejecimiento que ha sufrido el material original, de manera de poder lograr una imagen semejante. La intervención debe incluir la limpieza del sector, la extracción de sales solubles, la consolidación, la hidrofugación y la reconstrucción de partes perdidas. En cuanto al mortero de reposición, además de ser de similares características del original, se deben cuidar especialmente las técnicas de ejecución, para determinar el color definitivo del revoque. La muestra debe estar totalmente seca, por tanto, es muy importante la ejecución de las muestras en obra y en las diferentes orientaciones que tuvieran las fachadas del edificio."

Abstract: Onsite diagnostic investigation related to construction materials and components, including their condition and performance over time, plays a well-established role in knowledge-based management of historic buildings. However, in many practical applications, information is still addressed through traditional approaches based on fragmented data storage, isolated handling, and static representation of outputs. In this context, Historic Building Information Modelling (HBIM) provides an effective framework as an integrative environment capable of structuring and processing diagnostic data beyond their conventional use as supporting documentation. This paper presents a proof of concept for an HBIM-driven framework to diagnostic information management, with specific reference to sonic testing and video-endoscopic inspections applied to masonry structures. The proposed workflow is designed to operate across three complementary levels of integration: (i) incorporation of experimental measurements into the HBIM model by defining parametric diagnostic entities spatially and semantically linked to building elements; (ii) data processing and visualization, implemented via computational workflows based on Visual Programming Language (VPL), in which diagnostic values are filtered, normalized, and elaborated to generate interpretative outputs, including color-coded mappings and parametric representations of masonry stratigraphy; and, (iii) automated extraction and organization of diagnostic reports, conceived as an extension of the HBIM environment to support record-keeping and information reuse. The methodology is validated through its application to a test-bed simulating masonry elements characterized by different orientations, to which stratigraphic configurations and sonic velocity distributions derived from real-case diagnostic investigations were assigned. The proof of concept demonstrates the feasibility and adaptability of HBIM-driven workflows to support structured management of diagnostic information and provides a foundation for future developments toward integrated assessment and control digital strategies.

Keywords: HBIM, VPL, diagnostic testing, masonry structures, historic buildings.

1. Introduction

Onsite diagnostic investigation related to construction materials and components, including their condition and performance over time, plays a well-established role in knowledge-based management of historic buildings (Bolborea et al. 2025; Tejedor et al. 2022; Garrido et al. 2022). However, in many practical applications, information is still addressed through traditional approaches based on fragmented data storage, isolated handling, and static representation of outputs. In this context, Historic Building Information Modelling (HBIM) provides an effective framework as an integrative environment capable of structuring and processing diagnostic data beyond their conventional use as supporting documentation (Fattore et al. 2025; De Fino, Galantucci, and Fatiguso 2023).

As highlighted by a recent comprehensive review on HBIM-based information management (Parente, Bruno, and Ottoni 2025), different approaches can be identified for integrating data derived from diagnostic investigations into BIM environments.

A first approach, commonly referred to as Properties of Elements (PoE), consists in incorporating the results of diagnostic tests directly as properties of the investigated construction components. Within this strategy, numerical outcomes are stored as entity attributes, while images, graphs, and technical reports are generally linked as external documents. Representative examples include the assignment of mechanical resistance derived from double flat jack tests to masonry walls (Croce et al. 2022), as well as the association of resistance drilling profiles with timber beam objects to evaluate the effective resistant cross-section (Santos et al. 2022). In these cases, the precise spatial location of individual tests is not explicitly represented, and the approach proves more suitable for investigations whose results can be meaningfully referred to entire structural components.

A second strategy, known as Symbolic Modeled Objects (SMO), relies on the introduction of custom objects that symbolically represent diagnostic investigations within the HBIM model. These objects are enriched with structured information, such as test typology, execution date, instrumentation, quantitative results, interpretative notes, and links to related documentation. SMO-based solutions have been applied to direct sampling and constructional observations (De Falco et al. 2024), as well as to extensive datasets including reality-based surveys, microscopic analyses, and destructive and non-destructive tests (Garcia-Gago et al. 2022). By decoupling diagnostic information from the construction element, this approach allows for an accurate spatial localization of investigations and facilitates comparisons among multiple tests performed on the same component. However, the semantic integration between symbolic objects and building elements is often implicit, which may limit interoperability at the level of the information model.

A third approach, referred to as Realistic Modeled Objects (RMO), is based on modeling diagnostic investigations through objects that reproduce the actual extent of the investigated area rather than relying on abstract markers. This strategy is particularly suited to diagnostic techniques producing raster-based outputs, such as thermographic images and radargrams, which can be associated with extended surfaces (Cardinali et al. 2023; Coli et al. 2022). In some implementations, diagnostic images are projected directly onto wall objects, not as additional geometries but as new material layers whose properties encode the diagnostic data (Solla et al. 2020). This last solution enables an immediate three-dimensional correlation between investigation results and surface degradation patterns, enhancing visual coherence and supporting element-level contextualization of processed diagnostic outputs, when compared to representations that are limited to reproducing the spatial extent of the investigated area.

Against this background, the paper presents an HBIM-driven proof of concept that advances current SMO-based approaches by shifting the focus from the representation of diagnostic investigations to the computational management of diagnostic information, including its structuring, elaboration, and reuse, while selectively integrating RMO-inspired visualization strategies to project processed results onto building elements and support their direct correlation with surface-related information, particularly conservation conditions. The methodology, demonstrated through sonic testing and video-endoscopic inspections applied to masonry structures, is organized across three complementary levels of integration: (i) the incorporation of experimental measurements into the HBIM model through the definition of parametric diagnostic entities spatially and semantically linked to building elements; (ii) the computational processing and visualization of diagnostic data via Visual Programming Language (VPL) workflows, generating interpretative outputs such as color-coded mappings and parametric representations of masonry stratigraphy; and (iii) the generation and organization of diagnostic outputs within and beyond the HBIM environment, including integrated model-based visualizations and the automated extraction of structured reports to support record-keeping and information reuse.

Accordingly, the paper is structured as follows: Section 2 describes the proposed materials and methods, detailing the testing techniques, the HBIM test-bed, the definition of diagnostic entities, and the computational workflows adopted for data processing and visualization; Section 3 presents the results of the proof of concept, illustrating the implementation of the three levels of integration and the derived diagnostic outputs. Finally, Section 4 discusses the main findings, and current limitations of the approach,

outlining perspectives for future developments toward integrated digital strategies for the assessment and management of historic buildings.

2. Materials and Methods

The proposed proof of concept for an HBIM-driven framework for diagnostic information management is developed on a typological test-bed, conceived as a controlled environment to verify the feasibility and adaptability of the approach prior to its application to real case studies. The test-bed is based on a simplified HBIM model comprising masonry elements with different orientations, each assumed to be investigated through sonic testing and video-endoscopic inspections.

Sonic tests are typically performed by defining two corresponding grids of regularly spaced measurement points on the opposite faces (≈ 1 m^2) of the investigated element. For each homologous pair of points, the time of flight of low-frequency (< 20 KHz) mechanical waves propagating from the emitting probe on one surface to the receiving probe on the opposite surface is measured. Given the known thickness of the element, these measurements allow the calculation of sonic wave velocities, which are commonly used as indicators of material compactness, internal heterogeneity, and the presence of voids or discontinuities. A typical test report includes general information on the building, the execution and processing dates, the name(s) of the operator(s), planimetric localization, the description of the test operating principle and set-up, and the technical specifications of the equipment, a matrix of the acquired velocity values. These data are commonly presented either in point-based form or, by interpolation, as area-based false-color maps.

In parallel, video-endoscopic inspections are carried out through the execution of a transverse micro-drilling (≈ 3 cm diameter) through the masonry element, followed by the insertion of an endoscopic probe equipped with an integrated lighting and recording system. The probe acquires continuous video footage of the internal stratigraphy of the wall, after the introduction of a metric reference that enables the identification and localization of interfaces between adjacent layers. This technique provides qualitative and semi-quantitative information on masonry texture, construction technique, and the thickness and arrangement of internal layers, complementing the results obtained from sonic investigations. In this case as well, the test report includes the previously mentioned general information, together with a sequence of representative frames extracted from the video recording and a stratigraphic section drawing indicating the thickness, material type, and state of conservation of the identified layers.

The proposed BIM-based approach is grounded in the idea that diagnostic information can be treated as structured information entities, semantically and spatially linked to the investigated building elements, according to a logic consistent with the principles of information modelling and with the semantic structure of the IFC (Industry Foundation Classes) data schema. From this perspective, the modelling of diagnostic entities can be interpreted as a process of ontology-based structuring of diagnostic knowledge, in which the results of investigations are formalized as semantic information associated with the objects of the information model. The IFC schema indeed provides an explicit ontological structure based on entities, properties, and relationships, which makes it possible to formally represent knowledge related to the built environment by distinguishing between physical objects (IfcProduct), descriptive properties (IfcProperty), and informative relationships (IfcRelationship). The integration of diagnostic data through Property Sets and semantic relationships therefore makes it possible to enrich the HBIM model through a process of semantic enrichment, in which the information derived from experimental investigations becomes an integral part of the model knowledge base. This approach makes it possible to treat diagnostic data as components of the BIM model knowledge graph (Pauwels, Zhang, and Lee 2017), making them queryable, updatable, and reusable within interoperable information workflows based on open standards.

The methodology adopted in this study is structured into three interrelated operational levels, which define the following workflow:

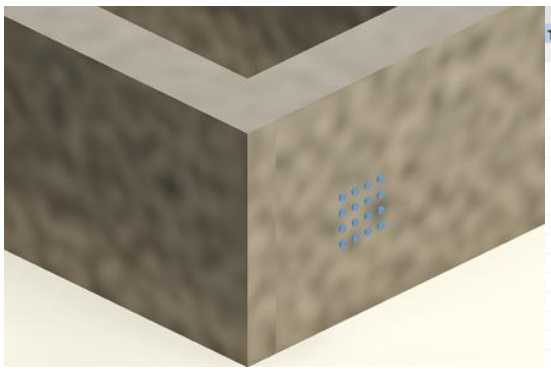
i. definition and integration of diagnostic entities within the HBIM model through the modelling of parametric information objects associated with the investigated building elements;

ii. computational processing of diagnostic datasets through VPL-based workflows aimed at querying, filtering, and transforming the data contained in the model;

iii. generation and structured extraction of derived information outputs, organized as forms of representation and reusable datasets for the documentation and analysis of diagnostic investigations.

The first level (i) concerns the transformation of experimental measurements into HBIM information entities through the creation of specific parametric families designed to represent the individual diagnostic tests carried out on masonry elements. These entities are configured with parameters capable of recording the main attributes of the test, including, in addition to the general information already mentioned, the numerical values recorded during measurement. From an informational point of view, these data are organized according to a structure consistent with the logic of Property Sets (Psets) provided by the IFC data schema, in which descriptive information is modelled as IfcProperty entities, grouped into IfcPropertySet and associated with model elements belonging to the IfcProduct hierarchy (e.g. IfcWall) through explicit IfcRelDefinesByProperties relationships. The investigated building element is thus interpreted as a product entity (e.g. IfcWall) belonging to the IfcProduct hierarchy, while diagnostic information is structured as informative properties linked to that entity through specific property sets. In this way, the experimental datum is not represented as a simple graphic annotation, but as structured information associated with the investigated building element, while maintaining the distinction between the physical object of the model and the set of properties describing the test results. In addition, each diagnostic entity is characterized by three-dimensional coordinates (X, Y, Z), which make it possible to precisely locate the measurement point on the surface of the investigated masonry element. These coordinates can be manually entered by the operator within the informational parameters, according to a chosen reference system, mainly for descriptive purposes and to support data interpretation. In the subsequent processing phases, these coordinates are automatically acquired and reinterpreted in relation to the geometry of the investigated masonry element through the analysis of the orientation of its axis and its thickness. This makes it possible to reconstruct local spatial relationships that keep explicit the connection between the investigation points and the masonry element under analysis. This approach preserves the relationship between the experimental datum and its position within the three-dimensional space of the building, ensuring the traceability of the measurement within the information model and making explicit the relationship between diagnostic information, building element, and spatial context.

The second level (ii) concerns the computational processing of diagnostic datasets. At this stage, the HBIM model is used not only as an information container, but also as a computational environment capable of supporting processes of querying, processing, and transformation of the data associated with the model objects. To this end, a VPL-based workflow was developed, enabling direct access to the information parameters of the diagnostic entities contained in the model and operations on the datasets associated with the BIM objects. The computational phases first include a model querying stage, in which diagnostic entities are selected by category and their related information parameters are extracted through operations that read the parameters associated with the elements. Subsequently, the data are subjected to a logical filtering stage, which makes it possible to isolate the relevant datasets according to the type of test and the investigated building element, thus allowing different diagnostic investigations contained in the model to be separated and managed distinctly. In the case of sonic testing, once the relevant data have been isolated, the workflow proceeds with the extraction and reorganization of the measured velocity values, which are collected into data structures and subjected to a process of normalization and ordering in order to make them comparable and prepare them for the subsequent visualization and analysis procedures. At the same time, the geometric information related to the position of the different diagnostic points constituting the measurement grid is also extracted, based on the position of the elements within the model coordinate system. Starting from the spatial coordinates of the diagnostic points, the workflow generates a series of



new parametric geometric entities used to support data visualization, by assigning a color coding derived from the recorded values. Similarly, in the case of video-endoscopic inspection, the workflow integrates the generation of parametric entities based on masonry stratigraphic analysis. In this case, the VPL script queries the parameters associated with the diagnostic entities related to the endoscopic test, extracting information on the thickness and type of the different layers identified along the investigated section. These data are subsequently organized into parametric structures, taking into account the position of the diagnostic point and the information related to wall orientation and thickness. The workflow then generates a sequence of appropriately dimensioned three-dimensional geometries representing the different layers detected by the investigation. The resulting geometries are finally integrated into the model as derived information objects, maintaining the association with the original diagnostic entity and making it possible to explicitly visualize the stratigraphic configuration of the investigated masonry within the BIM environment. It is important to emphasize that these representations are not modelled as static objects within the information model. Rather, they are generated dynamically as outputs derived from data processing, thus avoiding the creation of independent geometric objects and maintaining a close relationship between the diagnostic dataset and its visualization. In this sense, diagnostic representation is understood as the result of a computational process applied to the data contained in the model, rather than as a manually modelled element.

The third level (iii) concerns the generation and organization of information outputs derived from the computational workflow. The developed system provides the possibility of automatically extracting the results of the processing steps and organizing them into a series of structured reports, such as false-color maps and summary tables, which can be used for subsequent analyses or documentation.

3. Results

The application of the methodology described was carried out on a simplified parametric model developed in the Autodesk Revit® environment, consisting of perimeter masonry walls and internal partitions. In particular, two orthogonal perimeter walls were used as a simulated test-bed, to which sonic velocity values and stratigraphic configurations derived from real diagnostic investigations carried out by the authors on historic masonry structures were assigned. This choice allowed the workflow to be tested on realistic datasets, producing meaningful diagnostic representations and outputs. In the case of the sonic test (Figure 1), acquisitions on regular grids of points were considered, arranged in a 4×4 pattern, for a total of 16 points distributed over the wall surface, with a constant spacing of 20 cm. In order to integrate sonic velocity data into the model in a structured way, in accordance with the first level of operational integration (i), a dedicated parametric family was developed, conceived as a point-based information object capable of simultaneously representing the spatial position of each measurement within the grid and containing the parameters associated with the test.

Figure 1 – Real-case sonic test set-up, BIM modelling, and velocity values in the Revit schedule

The parametric structure of the family was defined by introducing a set of custom informative attributes, including both quantitative data (such as sonic velocity and spatial coordinates) and descriptive and management-related information (point ID, test type, associated wall, dates, operators, test operating principle and set-up, and the technical specifications of the equipment used). This configuration made it possible to transform each diagnostic point into a queryable and manageable element within the model, thus supporting the organization, filtering, and subsequent processing of the data.

This initial phase was followed by a sequence of steps (Figure 2) aimed at implementing the second level of operational integration (ii).

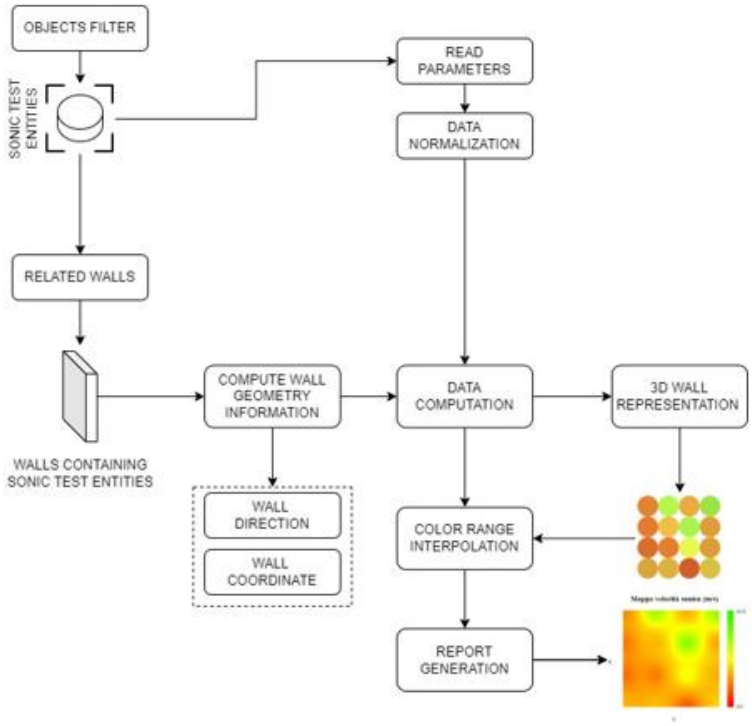

Figure 2 – Sonic test data processing workflow

First, the data filtering phase was performed through the development of a script in Dynamo (Figure 3), a visual programming environment in which users build graphs by connecting nodes, each of which performs a specific operation, while the graph defines the workflow used to read, process, or write data in Revit. More specifically, through the script, all elements belonging to the diagnostic point category were extracted and subsequently filtered according to the parameters Test type and Associated wall. The combined application of these criteria made it possible to obtain a consistent dataset, free from interference, containing only the information entities corresponding to the tests carried out on a specific wall. The sonic velocity values were then extracted and normalized within a user-defined range - 500–2000 m/s in this case, according to the dataset to be represented - thus making them dimensionless and comparable. A continuous red–yellow–green colour scale was then assigned to these values through a Color Range function, in order to progressively highlight variations in the parameter and improve the readability of transitional areas. In addition, the integration of a Python script (Figure 3), based on the Revit API and embedded directly within the VPL workflow, made it possible to automate the association of each diagnostic point with its corresponding wall by exploiting relationship properties and solid intersection checks between the geometric entities (IfcWall and test entity). Subsequently, starting from the wall localization data, the directional vector of the wall face was computed, thus identifying its prevailing orientation within the

workspace. This information proved essential for correctly defining the geometric plane on which the interpolation of the test data was to be performed. Finally, the coordinates of the diagnostic points were used to generate elementary geometries (circular surfaces) positioned in space consistently with the wall orientation. A colour was assigned to each surface according to the normalized sonic velocity value, resulting in a georeferenced point-based representation that is immediately interpretable. Moreover, in order to overcome the discrete nature of the data, an IDW (Inverse Distance Weighting) spatial interpolation was implemented on a regular grid (0.01 m spacing), defined on the plane of the wall according to its orientation (XY or YZ). The interpolated values were calculated as the weighted average of the known points, with weights inversely proportional to distance. The results, normalized within the same reference range, were then converted into a continuous false-colour map, subsequently represented in the model through surfaces and, in parallel, exported in PNG format. Finally, the sonic map can be reintroduced into the model by generating a geometric panel positioned in correspondence with the measurement grid, to which a material using the PNG image as a texture can be assigned. In this way, the visualization could also be extended into the three-dimensional space of the model, allowing for a direct reading of the distribution of values in false colors within the Revit environment.

In the case of the endoscopic test, by contrast, the first level of operational integration (i) involved the creation of an information entity corresponding to a parametric diagnostic point, simulating the video-endoscopic inspection hole (Figure 4). This element acts as an information container including both the test metadata (e.g. ID, investigation type, associated wall, coordinates, etc.) and the stratigraphic parameters resulting from the investigation (layer thicknesses and materials). In this way, the data are structured in a form that is both queryable and integrable within the BIM model. For this purpose, reference was made to the results of a real test performed on masonry investigated through a 20 mm diameter hole to a depth of 90 cm and characterized by an alternation of calcarenite blocks and mortar joints.

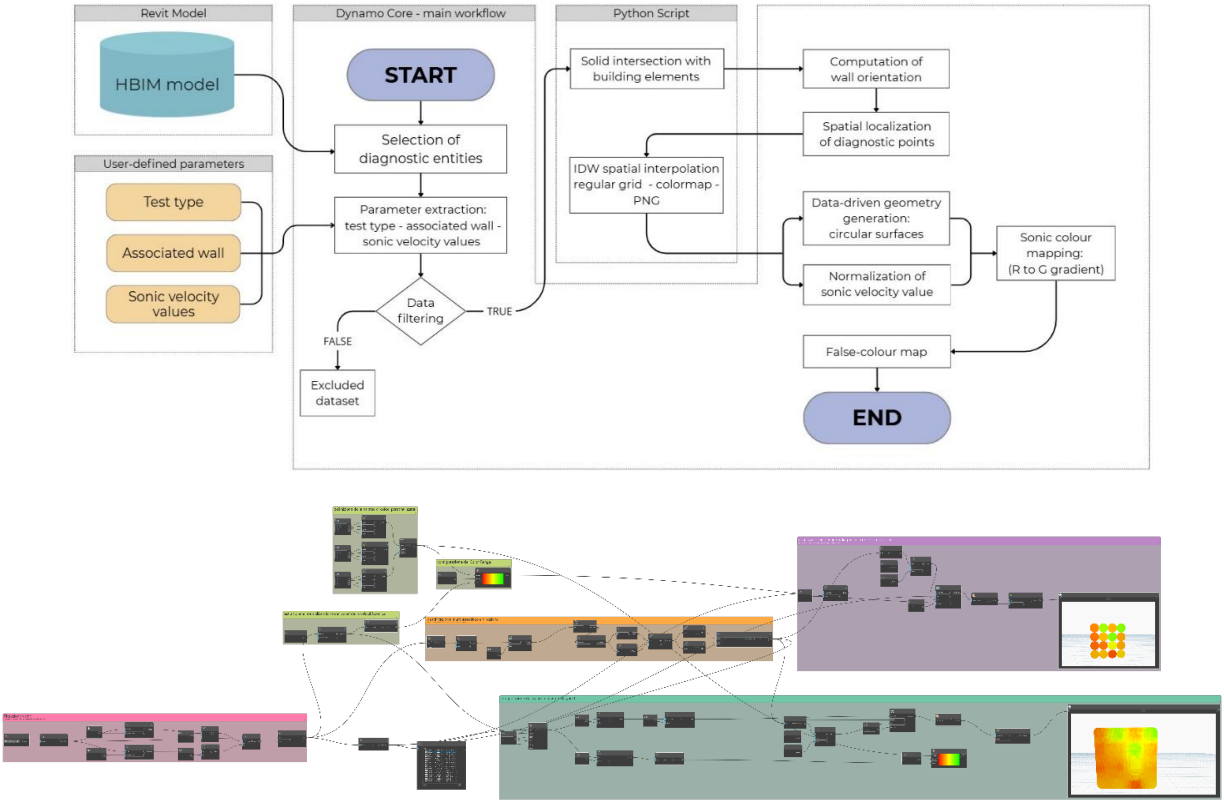

Figure 3 – Integration of the Revit model with user input, Python processing, and Dynamo management: pipeline (top) and script (bottom – full-size version available at: https://github.com/3DMauLAB/HBIM_Diagnostic)

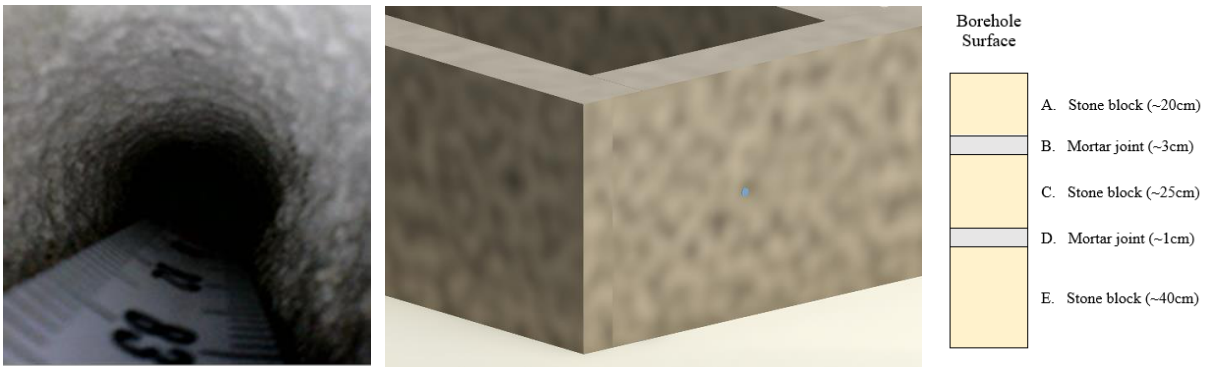

Figure 4 – Real frame from the video-endoscopic investigation, BIM modelling, and stratigraphic scheme

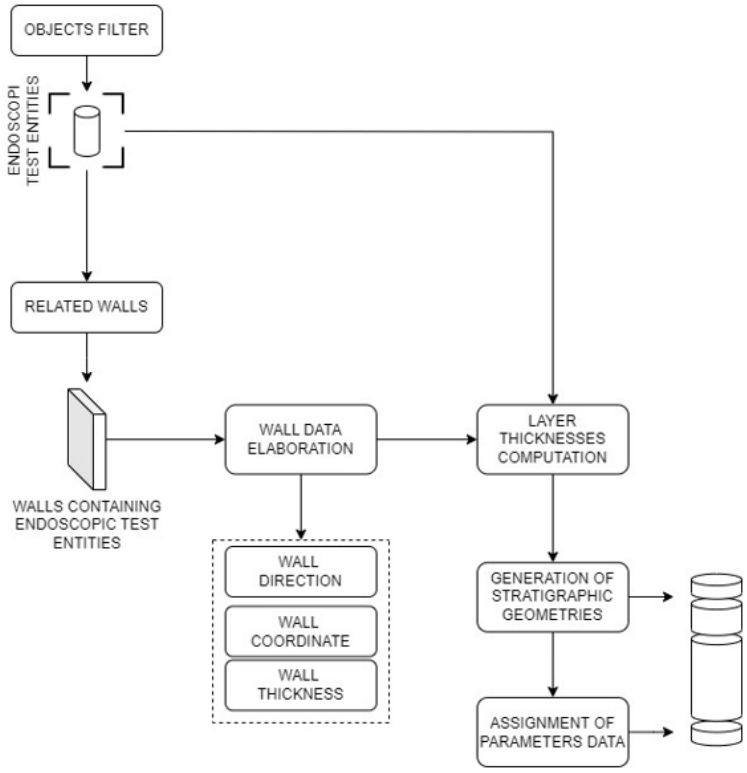
In this case as well, a sequence of phases (Figure 5) corresponding to the second level of operational integration (ii) was implemented through Dynamo (Figure 6).



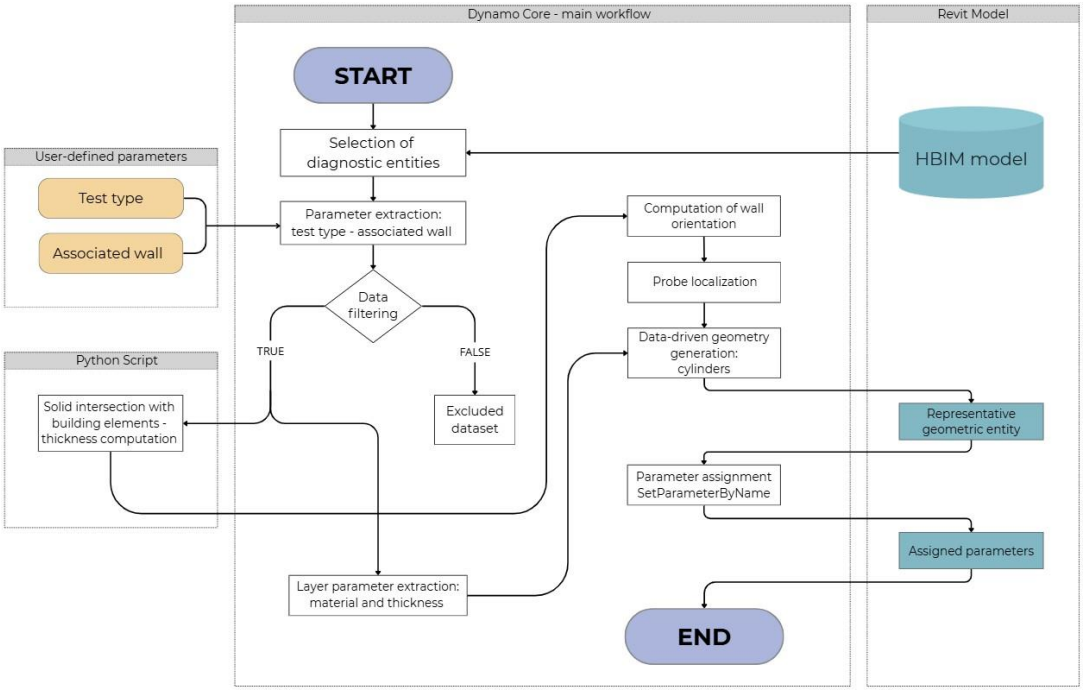


Figure 5 – Videoendoscopy Inspection data processing workflow

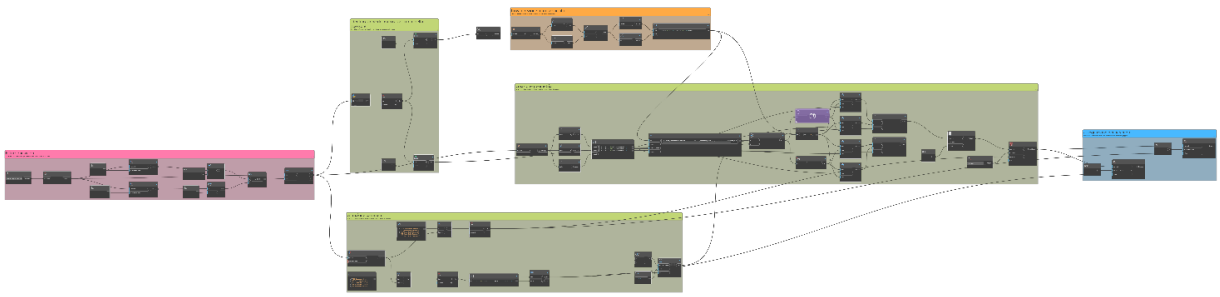

First, the diagnostic points were filtered according to the parameters Test type and Associated wall, thus isolating only those relevant to the endoscopic test. The workflow then proceeded with wall identification and wall data calculation through a Python script, by which each point was associated with the corresponding wall through a geometric intersection check between the diagnostic entity and the IfcWall element. At the same time, the fundamental parameters of the masonry element were extracted, in particular wall thickness and prevailing wall direction. This information is necessary to correctly position the

stratigraphic geometries in space. This was followed by the computation of layer thicknesses, through the extraction and validation of the stratigraphic parameters. The parameters related to the individual layers (materials and thicknesses) were extracted from the diagnostic points in Dynamo through a filtering process designed to exclude null or invalid values, thereby allowing the algorithm to automatically detect the actual number of layers present and correctly assign the corresponding properties to each of them. The stratigraphic data were then translated into three-dimensional geometries in the form of cylinders, each representing a masonry layer. These geometries were generated from the position of the diagnostic point and oriented according to the wall direction, while also taking into account the overall wall thickness in order to reconstruct the correct sequence of layers along the wall section. Finally, the workflow proceeded with the generation of stratigraphic geometries and the assignment of parameter data within the BIM model.

The generated geometries were represented in Revit through the DirectShape function and subsequently enriched with information parameters, including thickness, material, and a representative frame extracted from the video-endoscopic inspection. In this way, each test entity becomes an informative BIM element, directly queryable and consistent with the data acquired in situ.

Figure 6 – Integration of the Revit model with user input, Python processing, and Dynamo management for video-endoscopy inspection: pipeline (top) and script (bottom – full-size version available at: https://github.com/3DMauLAB/HBIM_Diagnostic)

Finally, for both tests, starting from the outputs of the processing stages - namely the sonic map reprojected onto the masonry surface and the stratigraphic entity integrated into the model (Figure 7) - and with reference to the third level of operational integration (iii), a process of automated extraction was implemented to generate structured diagnostic outputs directly from the model. This procedure relies on the interrogation of the parameters associated with the diagnostic entities and on their reorganization into coherent information layouts, including summary tables of recorded values, graphical representations, and exportable datasets. Through the implementation of a Python script, the generation of diagnostic reports from a predefined template was automated. The document is populated by automatically retrieving both the information already embedded in the model and the outputs generated during the processing stages, thus avoiding manual data transcription. The generated report therefore maintains a direct relationship with the BIM model and the queried diagnostic entities, including both descriptive test information and graphical representations derived from the computational workflow (Figure 8). In this way, the correspondence between the information embedded in the model and the derived documentation is preserved, reducing the risk of inconsistencies and ensuring alignment between data processing and output production. Moreover, the parametric nature of the system allows any update in the input data or processing stages to be consistently reflected in the extracted outputs, supporting an incremental and updatable documentation framework. Within this perspective, report generation is not treated as a separate phase, but as a direct extension of the computational workflow, contributing to the consolidation of a structured and reusable information base.

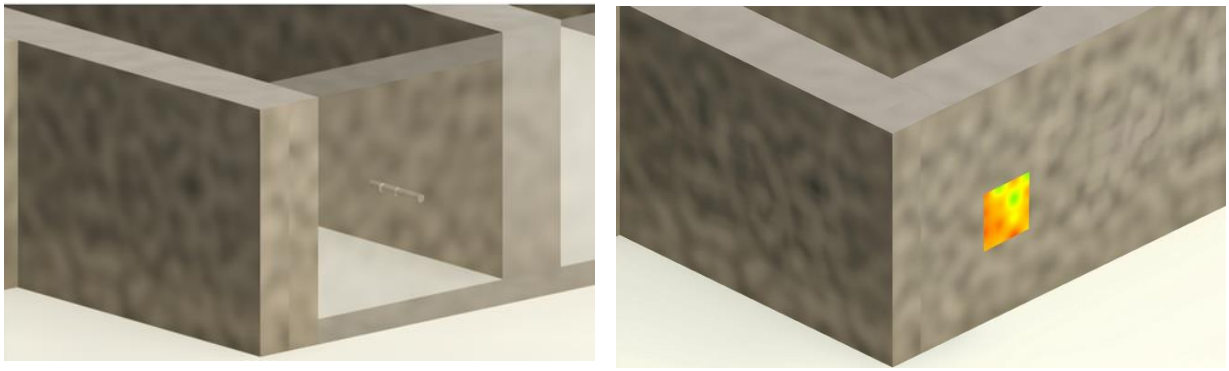

Figure 7 – Output integration in the model

4. Discussion and Conclusions

The proposed demonstration confirms the feasibility of the proof of concept concerning the integration of diagnostic data into BIM models. The resulting information model does not merely represent the geometry and constructional configuration of the building, but also incorporates knowledge related to the materials and performance characteristics of the investigated components. In this sense, the study shows how HBIM can be used not only as a digital repository for survey and documentation purposes, but also as an operational environment for structuring, processing, and reusing diagnostic knowledge.

More specifically, the proposed approach combines the semantic rigour of property-based information structures with the explicit representation of the spatial localization of measurements. This makes it possible to overcome the limitations of approaches that treat diagnostic results either exclusively as attributes of building elements or, conversely, as graphical entities without a formalized semantic structure. The outcome is a model-based environment in which different types of experimental investigations can be consistently associated with individual building components, with clear advantages in terms of information systematization, centralization, and traceability. In this context, a relevant implication lies in the possibility of establishing more structured correlations among diagnostic datasets. The proposed framework supports the comparison of different and complementary investigations performed on the same element, repeated

tests conducted over time on the same component, and equivalent investigations carried out on different elements within the same building. In the case presented here, this means, for example, relating the sonic response - typically associated with material compactness, internal heterogeneity, and the presence of voids or discontinuities - to the localized verification of material consistency and conservation conditions provided by direct endoscopic observation on the same masonry. From this perspective, future developments may exploit the proposed framework to support comparative assessments based on repeated diagnostic acquisitions over time, for example before and after structural consolidation interventions. Likewise, its application to more extensive diagnostic campaigns could enable the comparison of sonic responses across multiple building elements, supporting the investigation of spatially distributed pathologies and more complex deterioration patterns.

With regard to data processing and visualization, the results also demonstrate the usefulness and feasibility of performing interpretative procedures within the same environment used to collect and structure the original information. The automated generation of false-colour maps of sonic velocity distribution and volumetric entities representing masonry stratigraphy shows that the HBIM environment can support not only data storage, but also the production of derived outputs that make diagnostic evidence more immediately readable. This has evident benefits in terms of workflow harmonization, reduced fragmentation of analytical procedures, and a lower risk of operator error, particularly in contexts where users may be experienced in BIM modelling but not necessarily in diagnostic investigation and vice versa.

Another significant outcome concerns the automated extraction and organization of outputs. Integrating diagnostic report production directly into the BIM workflow, in formats such as raster maps, parametric tables, and reusable datasets, facilitates information sharing and promotes continuity between the investigation phase and subsequent phases of interpretation, assessment, and heritage management. In this way, the model can provide a stable and shared reference framework for different operators, different temporal stages, and different categories of data, while also supporting the progressive enrichment of the building knowledge base over time.

Overall, the proposed methodological workflow enables the integration within the HBIM model of three complementary dimensions of diagnostic information management: the semantic structuring of data through parametric entities, their computational processing through VPL-based workflows, and the automated generation of organized information outputs. This integration allows the information model to function not only as an archive of acquired data, but as an operational platform for the management and interpretation of diagnostic knowledge on the built heritage, in line with the principles of interoperability and semantic modelling underpinning the IFC schema.

At the same time, the study presents some limitations that should be acknowledged. The workflow has been tested on a typological test-bed developed as a controlled environment, and the proof of concept has been limited to two diagnostic techniques applied to masonry elements. Although this choice was appropriate for verifying the internal coherence and adaptability of the methodology, further validation on real case studies will be necessary to assess its robustness in relation to more complex geometries, heterogeneous construction conditions, larger datasets, and broader diagnostic campaigns, as well as to support a systematic evaluation of computational performance, scalability, and processing times. In addition, future developments should further investigate the interoperability of the proposed information structure in openBIM environments and its transferability across different software ecosystems.

In all, the proposed framework should be regarded as a starting point that will require further validation before wider generalization can be established, by the integration of additional destructive and non-destructive investigation methods, the implementation of more advanced data querying and comparison procedures, and the connection of diagnostic information with monitoring, assessment, and maintenance-oriented processes. In this broader perspective, the study provides a foundation for the development of integrated digital workflows capable of supporting diagnosis, interpretation, and intervention planning in the knowledge-based conservation and management of historic buildings.

DOCUMENT CODE:	PS/03

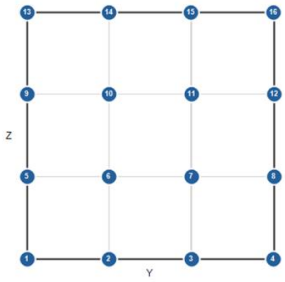
EQUIPMENT:	Digital ultrasonic detector, model CMS V3HLF-P, with a nominal transmitter frequency of 20 kHz

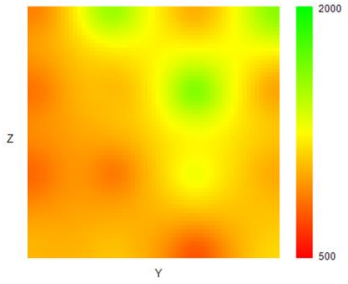
DIAGNOSTIC REPORT
SONIC TEST

TEST LOCATION (PHOTO):



TESTING METHOD:

The sonic investigation was carried out on a ground-floor masonry wall after marking two corresponding grids (4 × 4 nodes with a 20 cm spacing) on the opposite faces of the element. For each pair of corresponding points, five repeated measurements of the sonic wave travel time were acquired and subsequently converted into sonic velocity values based on the known path length. The measurements were then averaged for each node and represented as false-color maps through linear interpolation over the entire grid surface.



GRID DIAGNOSTIC VALUES:

ID	Sonic Velocity
1	1037 m/s
2	1074 m/s
3	755 m/s
4	1136 m/s
5	808 m/s
6	863 m/s
7	1282 m/s
8	1005 m/s
9	844 m/s
10	1050 m/s
11	1612 m/s
12	992 m/s
13	886 m/s
14	1541 m/s
15	1019 m/s
16	1595 m/s

ACQUISITION GRID LAYOUT:

SONIC MAP:

RESULTS

The grid associated with test PS/03 consists of 16 diagnostic points located on Wall 1. The recorded sonic velocity values range from 755 m/s to 1,612 m/s, with an average value of 1,093.69 m/s. The standard deviation of the measured values is 275.88 m/s.

Abstract: The preservation of historic buildings for cultural use requires rigorous and up-to-date information on their building systems and technical installations, particularly when the aim is to develop maintenance plans aligned with contemporary management practices. Within this context, Heritage Building Information Modeling (HBIM) has gained prominence due to its capacity to integrate geometric, material, functional, and historical data. However, the application of HBIM to listed heritage buildings faces significant limitations related to the availability and quality of existing information. This paper discusses the challenges encountered during the survey and data acquisition processes required to update the HBIM model of the Theatro José de Alencar, a important cultural facility and listed heritage site in Brazil. The employed research methodology encompasses a literature review, documentary research, semi-structured interviews, and on-site surveys. Consequently, this study provides an analysis of the capture precision levels of the surveying methods utilized within the theater, alongside a critical assessment of the challenges in acquiring data related to building services. Ultimately, a protocol for surveying this specific information is proposed. This protocol structures the data collection activities for building systems, focusing on maintenance management integrated into the heritage asset's HBIM model. This research contributes to the ongoing debate regarding the demand for advanced surveying tools in the built heritage sector, underscoring the necessity for specialized protocols tailored to the assessment of building services in historical structures.

Keywords: Architectural survey; survey protocols; building heritage; maintenance management; HBIM;

1. Introduction

The preservation of historical buildings intended for cultural use demands management frameworks that go beyond episodic restoration interventions. When operational, these assets face intensive and regulatory demands. Under these circumstances, maintenance management assumes a central role, as continuity of use depends on the reliability of the structural systems and building services. Conservation becomes a permanent process, structured by maintenance plans grounded in robust and up-to-date technical information.

The effectiveness of these plans depends on the quality of the available data of the building. In this context, Building Information Modeling (BIM) and Heritage Building Information Modeling (HBIM) integrate geometric, historical, and functional data into a single platform. (Brumana *et al.* 2017; Dore and Murphy 2017; Banfi and Liu 2026; Penjor *et al.* 2024).

However, despite methodological advancements, the application of HBIM to the operation and maintenance (O&M) remains in an emergent stage, exhibiting significant gaps in the structuring of facility

management (FM) data (Oliveira *et al.* 2024; Wojciechowski *et al.* 2024). Most studies focus on capturing and modeling architectural and structural geometry, building services remains underdeveloped (Parente *et al.* 2025).

Technologies such as Terrestrial Laser Scanning (TLS), digital photogrammetry, Unmanned Aerial Vehicle (UAV) imagery, and historical documentary surveys have proven highly effective in documenting the building "envelope" (Froner *et al.* 2024; Vieira et al. 2023). These methods enable high geometric precision and formal detailing, being extensively documented in recent studies. Nevertheless, these methodologies do not automatically capture building services, particularly those embedded within walls, floors, and ceilings. Elements such as plumbing, electrical conduits, cabling, HVAC ducts, drainage networks, and fire protection systems (FPS) are rarely represented in point clouds or models derived exclusively from geometric data. Even when certain components are exposed (e.g., electrical panels, light fixtures, grilles, or exposed pipes), the extraction of relevant technical information is not automatic. The point cloud records their shape and spatial position but does not identify their function, capacity, materiality, conservation status, or connections to other systems. Converting these geometric records into semantically structured data requires technical interpretation, on-site verification, and often, consultation of supplementary documentation. Consequently, both concealed systems and visible elements demand specific procedures for identification, categorization, and informational structuring to be effectively incorporated into the HBIM model.

Current literature reveals that the structuring of specific protocols for the acquisition and modeling of building services data within an HBIM environment remains still in early stages. Studies dedicated to modeling historical architecture (Ribeiro *et al.* 2026), reconstructing construction phases (Castellano-Román and Pinto-Puerto 2019), and analyzing materials predominate (Oliveira Magalhães *et al.* 2025), while building services remain underrepresented or entirely absent from digital models. This limitation underscores the necessity for on-site data collection through targeted inspections, interviews with maintenance teams, analysis of scattered technical documentation, and the application of complementary non-destructive methods, strategies that still lack systematization in recent scientific output.

In light of this scenario, this paper seeks to address the following research question: what are the main challenges in collecting building installation data for the development of maintenance plans in operational historical buildings? This study is based on the hypothesis that current surveying methodologies tailored for HBIM do not systematically encompass building services, thereby requiring the development of specific protocols for their identification, recording, and modeling.

To explore this issue, the Theatro José de Alencar is adopted as a case study. Although the building benefited from architectural surveys produced by the National Institute of Historic and Artistic Heritage (IPHAN) and a point cloud generated via laser scanning, a significant inadequacy in data pertaining to building services was identified. This condition highlighted the need for complementary surveying strategies to update the HBIM model with a focus on maintenance management.

By discussing the challenges encountered throughout this process, this article contributes to the contemporary debate on the digitalization of the built heritage, emphasizing the urgent need for methodologies that systematically integrate geometric data and technical information regarding building installation. Beyond merely amplifying the level of detail of digital models, the objective is to reinforce their role as effective instruments for the preservation and sustainable management of historical buildings intended for cultural use.

2. Data collection and HBIM for FM in built heritage

HBIM supports documentation, analysis, maintenance, and conservation through the integration of geometric and semantic data. Its development has progressively expanded toward facility management (FM) applications.

Several studies have explored HBIM integration in maintenance and conservation processes (Jordan-Palomar et al. 2018; De Fino et al. 2019; Piselli *et al.* 2020; Mora et al. 2021; Khan *et al.* 2022; Matrone *et al.* 2023). Despite this evolution, a critical limitation persists: most HBIM applications remain predominantly focused on geometric and historical representation, while building services systems are systematically underrepresented. This imbalance directly affects the applicability of HBIM in the Operation and

Maintenance (O&M) phase, where decision-making depends on accurate, up-to-date technical information regarding system performance, configuration, and condition.

Maintenance management in heritage buildings assumes particular relevance due to the absence of a demolition phase and the need to ensure the continuity of use (Pishdad-Bozorgi *et al.* 2018). In this context, the Asset Information Model (AIM) becomes a central component, as it integrates geometric, alphanumeric, and documentary data required for lifecycle management.

The distinction between these data types is not merely classificatory but operational. Geometric data enable spatial representation and model construction; alphanumeric data define the technical and functional properties of elements; and documentary data provide contextual and procedural information that cannot be reduced to parametric attributes (Figure 1). The absence of any of these layers compromises the integrity of the AIM and, consequently, the reliability of maintenance planning. This is particularly critical for building services systems, whose performance depends on accurate, detailed, and up-to-date information.

In practice, heritage buildings are often managed through fragmented systems (Tsay *et al.* 2022), limiting interoperability and restricted access to information. This condition reinforces that the main limitation of HBIM for FM is not technological, but informational. Therefore, the effectiveness of HBIM for facility management depends fundamentally on the establishment of systematic data collection processes capable of integrating both geometric and technical information.

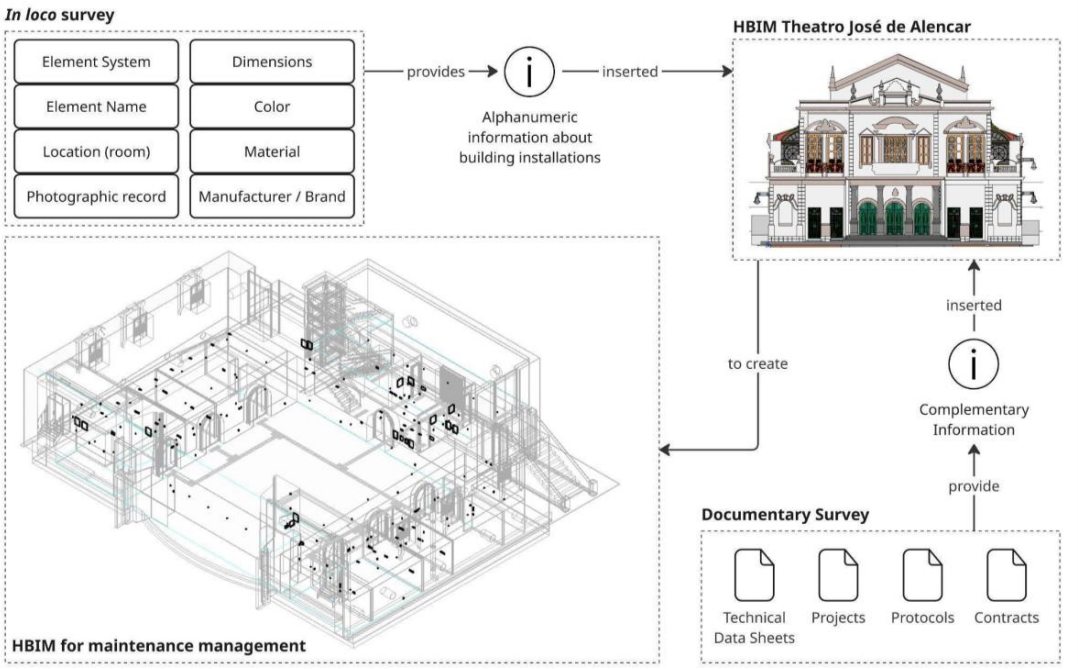

Figure 1 – Workflow for Maintenance Survey.

3. Survey methods and challenges in historic buildings

Survey protocols require alignment between data acquisition methods and the type of information required (Alshawabkeh and Baik 2023). In heritage contexts, four main approaches are typically employed: laser scanning, photogrammetry, documentary research, and visual inspection.

Laser scanning and photogrammetry provide high geometric accuracy and enable detailed three-dimensional representation of the built asset. However, both methods are limited to visible surfaces and are therefore unable to capture embedded building systems. In addition, they do not provide semantic or operational information, which restricts their use in maintenance-oriented applications.

Documentary research contributes to understanding the historical and technical evolution of the building but depends on the availability and reliability of records, which are often incomplete or inconsistent in

heritage contexts. Visual inspection, in turn, enables the identification of materials, construction techniques, and technical systems that cannot be captured digitally, although it depends on accessibility and expert interpretation.

In historic buildings, these limitations are amplified by the absence of reliable “as-built” documentation, the invisibility of embedded systems, and restrictions on invasive inspection methods. As a result, data collection becomes an interpretative process, subject to uncertainty and dependent on multiple sources of information.

These conditions demonstrate that survey methods, when applied in isolation, are insufficient to capture the full range of data required for HBIM-based maintenance. Consequently, integrated approaches combining digital and manual techniques are necessary to bridge the gap between geometric representation and technical information.

4. Methodology

This study adopts a structured methodological approach to investigate the challenges associated with surveying building services systems in historic buildings and to support the development of maintenance plans integrated with HBIM models.

The research process is organized into five stages (Figure 2). The first stage consists of problem formulation based on a literature review, leading to the definition of the research hypothesis. The second stage involves the selection of the case study, the Theatro José de Alencar, based on its historical significance, continuous use as a cultural facility, and the institutional interest in applying HBIM for maintenance management.

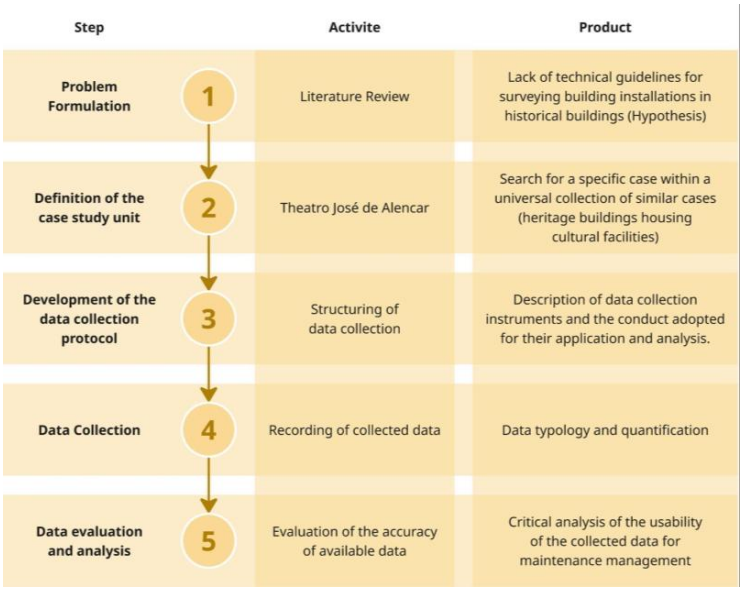

Figure 2 – Research methodology.

The third stage comprises the development of a data collection protocol, defining the procedures, instruments, and analytical strategies for data acquisition. The fourth stage involves data collection, combining documentary research, semi-structured interviews, and in situ surveys. Data were collected between May and July 2025, including ten site visits and the recording of 235 photographs to support system documentation. Finally, the fifth stage consists of evaluating the accuracy and quality of the collected data. This methodological structure ensures that data collection is treated as an analytical and iterative process, directly linked to the reliability and usability of HBIM models in maintenance management.

4.1 Data collection protocol

A multifaceted approach was adopted for data collection, combining different methods to ensure a comprehensive understanding of the building systems and their operational context. Data were collected between May and July 2025, a period during which the building management granted full access to the survey team. This temporal window was critical, as it enabled the observation of maintenance activities under real operating conditions.

The data collection strategy combined documentary research, semi-structured interviews, and on-site surveys of building services systems (Figure 3). Documentary research included the analysis of existing architectural drawings, historical records, point cloud data, a virtual tour of the building, and maintenance management documents. This stage provided a baseline for understanding the building's physical configuration and its documented interventions, although gaps in services-related information were already evident.

Semi-structured interviews were conducted in two formats. The first consisted of an interview with the maintenance manager, focusing on the organizational structure and operational processes of maintenance management. The second involved ten meetings with two maintenance technicians, aimed at documenting daily routines and identifying practical challenges in the execution of maintenance activities. The interview with the maintenance manager was recorded and transcribed. Open-ended questions were used throughout to encourage detailed responses, particularly regarding workflow organization, decision-making processes, and the execution of maintenance tasks.

In parallel, ten on-site visits were carried out to survey building services systems associated with maintenance activities. During these visits, a total of 235 photographs were taken, documenting selected installations and supporting the development of a structured database for system modelling. This empirical dataset played a key role in complementing the limitations identified in existing documentation and digital surveys.

Data collection method	Type of data collected	Data collected	Analysis of the usability of the collected data for FM
Documentary Research	Existing Projects and Surveys	153 digitized documents, including: · 77 related to air conditioning, · 30 to the electrical system, · 16 to the plumbing system, · 30 to the fire prevention system.	Extensive documentation, but outdated in relation to the reality of the building.
	Historical Documentation	Books and historical documents about the theater.	There is no record of the most recent interventions in the theater's building systems.
	Point Cloud and Virtual Tour	1 point cloud of the entire building	Although up-to-date, it does not capture all elements of building installations.
	Maintenance Control Documents	5 contracts with maintenance service providers and 1 maintenance control spreadsheet	Documentation under construction and lacking all the necessary information for each system.
Semi-structured Interviews	Maintenance Manager Maintenance Technicians	· 1 interview with audio recording and transcriptions · 10 interviews with 2 technicians	Provided necessary information for understanding building systems.
On-site Survey	Images of the building's installations and measurements	235 photographs and 47 digital scans of the drawings used in the survey.	Relevant and necessary information for the semantic enrichment of the maintenance model.

Figure 3 – Different methods and types of data collected.

5. Case study: Theatro José de Alencar - Existing documentation and building installations data

The Theatro José de Alencar, located in Fortaleza, Ceará, Brazil, is one of the most significant cultural, historical, and architectural heritage assets in the region. Inaugurated in 1910 and later listed by the Instituto do Patrimônio Histórico e Artístico Nacional (IPHAN) in 1964, the building represents a notable example of

eclectic architecture in Ceará. Its architectural composition is characterized by the integration of imported metallic structures with traditional construction systems, reflecting a combination of French stylistic influences and British structural contributions, particularly in the cast-iron elements fabricated in Scotland (Castro 2010). Beyond its architectural value, the theatre holds strong symbolic and cultural significance, functioning as a continuous space for artistic production, public engagement, and the preservation of collective memory.

Architecturally, the building follows the Italian theatre typology, with a clearly defined and integrated spatial organization. Its material composition, primarily metal, masonry, and wood, combined with the richness of ornamental elements across façades and interior spaces, results in a complex architectural system. This complexity is further intensified by successive maintenance and adaptation interventions carried out over time, reflecting both evolving functional requirements and changing construction practices. From a maintenance perspective, this layered transformation introduces significant challenges, as the current state of the building is the result of cumulative modifications rather than a single, coherent design phase.

The Theatro José de Alencar remains fully operational, hosting performances, events, and guided visits. Field surveys conducted as part of this research indicate that the building retains many of its original characteristics, while also incorporating adaptations driven by functional and regulatory updates. These interventions reveal a process of continuous negotiation between heritage preservation and contemporary use (Figure 4). In terms of building services, updated electrical systems were identified, adapted to meet current demands for lighting and sound. Mechanical systems, such as air conditioning, were introduced after the original construction, requiring integration with the historic structure, alongside fire protection systems. Hydrosanitary installations also show evidence of modernization, particularly in response to current accessibility standards.

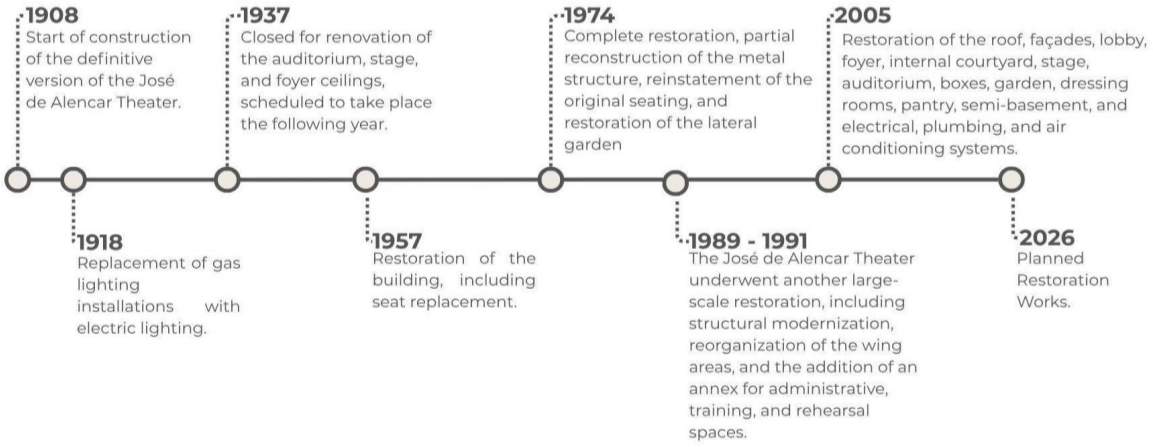

Figure 4 - Timeline of documented maintenance work at the José de Alencar Theatre.

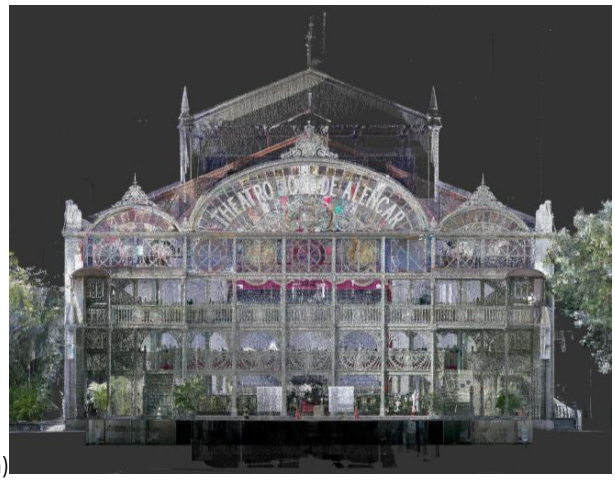
Although the building is supported by architectural documentation, including plans, sections, and elevations, and point cloud data, the analysis revealed substantial inconsistencies and gaps, particularly regarding building services systems. The available documentation reflects different phases of intervention but lacks a comprehensive and reliable record of modifications over time. In several cases, projects associated with renovation works were not executed, and there is no systematic documentation of maintenance interventions. This condition creates a disconnect between the recorded information and the current state of the building.

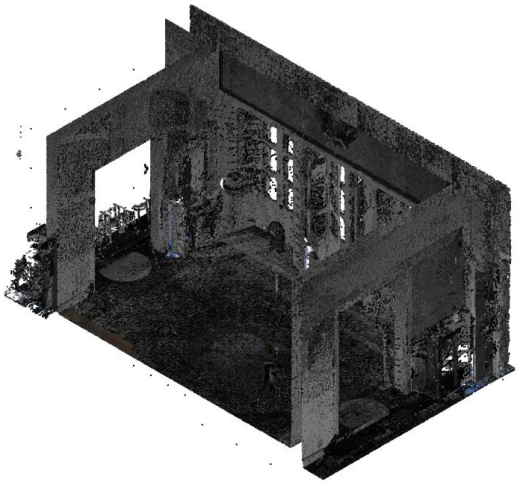
Point cloud surveys provide a highly accurate representation of visible geometry and support the updating of architectural documentation (Figure 5). However, they do not capture embedded systems, limiting their applicability for maintenance purposes. Consequently, the geometric accuracy of the model does not translate into informational completeness.

The in situ survey identified the presence of electrical, hydrosanitary, HVAC, and fire protection systems; however, no technical documentation was found describing their configuration, layout, or evolution. The

coexistence of obsolete and updated components indicates incremental and undocumented interventions. In several cases, even maintenance staff lacked precise knowledge of system functions and configurations.

This lack of documentation introduces significant uncertainty into maintenance planning, particularly regarding network layouts, system specifications, and intervention history. As a result, the HBIM model risks representing only the visible aspects of the building, without incorporating the infrastructure that supports its operation.





a)  b) 

Figure 5 – a) Point cloud visualization of the facade of the theater's auditorium. b) Point cloud visualization of an interior environment of the theater.

From the case study, it was possible to identify the main challenges in collecting building installation data in historical buildings (Figure 6), which lie not in the absence of geometric data, but rather the lack of structured and reliable information about building installations.

		Systems identified				
		Electrical	Hydrosanitary	Drainage	HVAC	FPS
Challenges in data collection	Difficulty in identifying electrical panels in operation	x				
	Difficulty in identifying inspection boxes that are unregistered and/or unidentified	x	x	x		
	Presence of elements from different eras that perform the same function	x	x	x	x	x
	Lack of plans identifying the elements present in the updated system	x	x	x		x
	Impossibility of identifying the layout of internal piping related to the system	x	x	x	x	x
	Lack of historical records of interventions carried out for system maintenance	x	x	x	x	x

Figure 6 – Summary of the challenges in collecting data from building systems.

Overall, the evidence indicates that interventions in the building systems have occurred progressively over time, responding to functional demands but without the establishment of a comprehensive technical archive encompassing all phases of the building's lifecycle. This fragmented evolution has direct implications for HBIM development. While point cloud data enable accurate geometric representation of visible elements, the absence of reliable technical information regarding embedded systems limits both the modelling process and the incorporation of non-geometric data. As a result, the HBIM model risks remaining

a predominantly geometric representation, failing to adequately capture the infrastructure that supports the building's operation.

From a maintenance planning perspective, the lack of knowledge regarding network layouts, installed components, and intervention history increases uncertainty in decision-making processes. This condition may lead to interventions that are incompatible with the actual state of the building, potentially compromising both its performance and its heritage value. In historic buildings, technical documentation is therefore not merely supportive but essential to ensure user safety and the preservation of the asset.

Consequently, the absence of systematized data on building services in the Theatro José de Alencar constitutes a central challenge for the implementation of integrated heritage management. It also reinforces the need for structured data collection protocols capable of bridging the gap between physical reality and digital representation, thereby enabling HBIM models to function as effective tools for maintenance management rather than as purely descriptive models.

6. Results

The analysis demonstrates that no single technique is capable of capturing the full range of information required for HBIM-based maintenance management (Figures 7 and 8). Instead, each method presents complementary strengths and limitations that directly affect the accuracy, completeness, and usability of the resulting data.

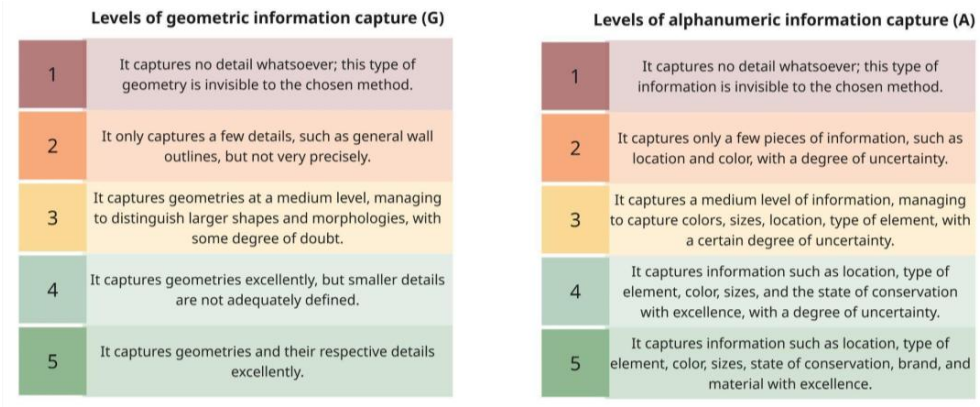


Figure 7 – Levels of precision of surveying methods.

		Elements Surveyed									
		Walls		Windows and Doors		Roofs		Building Systems		Internal Pipes	
	Type of Information Surveyed	G	A	G	A	G	A	G	A	G	A
Survey Method	Laser Scanner	5	4	5	4	1	1	3	4	1	1
	Aerial Photogrammetry	3	3	2	3	5	4	1	3	1	1
	Visual Inspections	4	5	4	5	1	5	4	5	1	1

Figure 8 – Table analyzing the accuracy level of data capture for surveying methods used in theater.

Laser scanning and photogrammetry provide accurate representations of the building. These techniques enable the capture of complex forms with high precision, supporting the development of detailed three-dimensional models. However, both methods are constrained by line-of-sight conditions, as they can only record visible surfaces. Consequently, they are inherently limited in their ability to capture embedded

building services systems. In addition, their capacity to acquire alphanumeric and descriptive information is minimal, restricting their usefulness for maintenance-oriented applications.

Conversely, manual survey methods, particularly visual inspection, play a critical role in capturing semantic and technical data. The in situ survey conducted in this study proved indispensable for identifying building services components located in inaccessible or concealed areas, such as installations beneath fixtures or within enclosed spaces. Moreover, the collection of alphanumeric data, including material, color, brand, and model, was essential for supporting maintenance actions, especially in the context of component replacement and lifecycle tracking. These findings demonstrate that manual surveying should not be regarded as an obsolete practice, but rather as a process of data curation, capable of providing the level of detail required for informed decision-making.

Within the HBIM framework, particularly in FM applications, the integration of geometric and semantic data is a fundamental requirement. Maintenance processes depend on access to reliable information regarding previous interventions, technical specifications, and system configurations. Without this information, maintenance decisions must rely on assumptions or repeated site inspections, reducing efficiency and increasing the risk of inappropriate interventions. In heritage buildings, this issue is further amplified, as replacement actions must be compatible with the original architectural language, preserving both material integrity and historical significance.

Despite the complementary nature of survey methods, significant limitations persist. A key limitation is the absence of systematic documentation over time. The gradual and often undocumented replacement of components, such as electrical fixtures and hydrosanitary elements, results in a heterogeneous accumulation of systems within the building. In such cases, the survey is limited to the observation of existing elements, while previous configurations remain unknown. This lack of historical traceability introduces uncertainty into both the modelling process and maintenance planning.

Another major limitation concerns the invisibility of embedded systems. In historic buildings, invasive inspection methods are generally not permitted, which prevents access to critical information about the layout, materials, and dimensions of internal networks.

To address these challenges, this study proposes a structured protocol for surveying building services systems in historic buildings (Figure 9). The process begins with a preliminary assessment, including the collection and analysis of existing documentation, point cloud data, and interviews with maintenance personnel. This stage establishes the baseline level of available information and identifies data gaps, ensuring that subsequent efforts are strategically targeted.

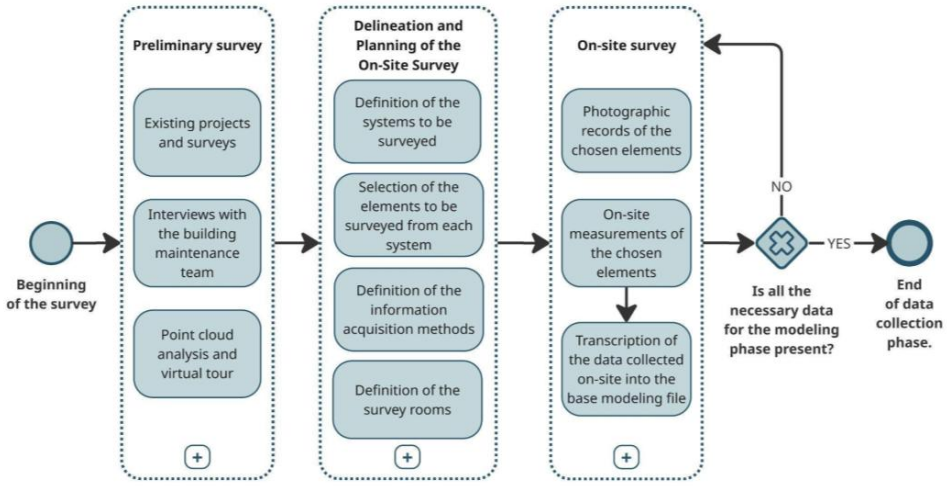

Figure 9 – Protocol for surveying building installation systems in historic buildings.

The second stage involves the planning of the in situ survey, where the systems to be investigated, the data acquisition methods, and the practical conditions for fieldwork are defined. This step is critical, as methodological decisions directly influence the scope and quality of the data collected. The third stage

consists of the survey itself, including measurement, descriptive recording, and photographic documentation of building components. The collected data are then organized and structured for integration into the HBIM model. Finally, a validation stage is conducted to assess data completeness and consistency, ensuring that the information meets the requirements for modelling and maintenance applications.

The proposed protocol addresses a key gap identified in this study: the lack of systematic procedures for collecting alphanumeric and operational data related to building services systems. By formalizing the survey process, the protocol reduces uncertainty, improves data consistency, and enhances the usability of HBIM models for maintenance management. More importantly, it shifts the focus of HBIM workflows from geometry-driven modelling to information-driven processes.

From an analytical perspective, the results indicate that the main challenges in data collection for historic buildings are not solely technical, but also informational and procedural. The absence of documentation, the limitations of non-invasive survey methods, and the lack of standardized workflows collectively hinder the development of reliable HBIM models. Therefore, improving data collection practices is not only a methodological issue but a prerequisite for enabling HBIM to function as an effective tool for Facility Management.

Finally, while the proposed protocol demonstrates potential for improving data collection practices, its applicability across different heritage contexts requires further validation. Future research will test the workflow in additional case studies, allowing for the assessment of its adaptability and robustness. Such validation is essential to ensure that the protocol can support a broader range of heritage assets and operational conditions.

Overall, the findings reinforce that the effectiveness of HBIM in maintenance management is directly dependent on the quality and completeness of the underlying data. Without structured and reliable data collection processes, particularly for building services systems, HBIM models risk remaining descriptive representations rather than operational tools capable of supporting informed decision-making in historic buildings.

7. Discussion and Conclusions

The findings derived from the Theatro José de Alencar case study demonstrate that, despite significant advances in geometric data acquisition through technologies such as laser scanning and photogrammetry, critical gaps persist in the collection and structuring of information related to building services systems. These gaps directly affect the capacity of HBIM models to function as reliable tools for maintenance management, particularly in heritage buildings that remain in continuous use and have undergone successive interventions.

The comparative analysis of survey methods confirms that, while each technique contributes valuable information, none is sufficient when applied in isolation. While laser scanning and photogrammetry provide reliable geometric representation, they fail to capture embedded systems and semantic information. Conversely, manual inspection enables the identification of technical attributes but lacks geometric precision. Therefore, the main challenge is not technological, but related to the integration and systematization of heterogeneous data sources.

From an operational perspective, the study highlights that the effectiveness of HBIM in FM is not determined solely by geometric accuracy, but by the completeness and consistency of the associated semantic data. In this sense, the absence of structured information on building services represents a key limitation, restricting the transition of HBIM models from descriptive representations to decision-support systems.

From a broader perspective, the findings indicate that the effectiveness of HBIM in Facility Management depends fundamentally on data quality and completeness. The transition from geometry-based modelling to information-based management requires a shift in focus from data representation to data acquisition.

As a central contribution, this study highlights the need for structured protocols specifically designed for the collection of building services data in heritage contexts. The proposed protocol addresses this gap by integrating multiple data sources and establishing a systematic workflow for data acquisition and validation. Future research should focus on validating the proposed protocol in different case studies to assess its

adaptability and scalability. Such validation is essential to consolidate its applicability and to support the broader implementation of HBIM in heritage maintenance management.

Abstract: The behaviour of historical masonry exposed to high temperatures represents a critical issue in the assessment and preservation of built heritage. Thermal loading can significantly alter the mechanical and physical properties of traditional construction materials, thereby affecting the structural integrity of historic buildings. This study focuses on the response of selected natural stones and fired clay bricks to elevated thermal exposure, with particular emphasis on changes in mechanical performance and material behaviour after cooling.

The investigated specimens were subjected to controlled heating followed by two different cooling regimes, allowing evaluation of the influence of cooling conditions on the resulting material properties. The experimental results revealed a pronounced dependence of mechanical behaviour on both the applied thermal load and the cooling method. Distinct differences were observed among the investigated materials, reflecting their individual mineralogical composition and structural characteristics.

The findings highlight that material response to thermal exposure cannot be generalized and must be assessed individually for each type of masonry. This study contributes to a better understanding of the behaviour of traditional building materials subjected to fire-related damage.

Keywords: Sandstone, fired brick, high temperatures, mechanical properties, colour change

1. Introduction

Historical buildings constitute a fundamental component of cultural heritage, as they embody societal development through their architectural form, construction techniques, and material composition, while frequently holding significant historical importance by virtue of their association with notable figures or events. Masonry has historically represented the predominant construction method, with commonly employed materials encompassing sedimentary rocks such as marlstone, sandstone, and limestone, as well as igneous and metamorphic rocks including granite and trachyte, complemented by fired and unfired clay bricks. Material selection was governed principally by local availability, durability, and workability (Witzany et al. (2024)). Despite their considerable cultural and structural value, these materials are inherently susceptible to fire, which may originate from natural phenomena, human negligence, or ageing infrastructure, and whose severity is exacerbated by high building occupancy and limited firefighting access (Kincaid (2022), (Petrini et al. (2022)). Exposure to elevated temperatures induces water loss, chemical transformations, and microstructural damage in masonry assemblies, resulting in progressive reductions in mechanical strength (Witzany et al. (2024)). Visible post-fire manifestations, including surface blackening, spalling, decomposition, and oxidation, further compromise both the aesthetic integrity and structural performance of stone elements (Dimes (2007)). Although the effects of fire on historical masonry have been the subject of extensive research, the combined influence of material type, construction technique, and thermal exposure on mechanical and physical properties remains insufficiently characterised. This deficiency underscores the necessity for systematic experimental investigations to inform preservation strategies and mitigate risks to cultural heritage assets.

2. State-of-the-art

The effects of elevated temperatures on rock materials of selected lithological types have been previously investigated. High-temperature exposure alters rock microstructure, porosity, mineral composition, and mechanical properties, with important implications for the stability and safety of engineering structures.

Rong et al. (2018) studied the influence of specimen size and temperature on fine-grained marble from Fujian Province, China. Cylindrical specimens (25–100 mm diameter; height-to-diameter ratio 2:1) were heated to 200–600 °C. P-wave velocity decreased significantly with temperature, reaching an approximately 80% reduction at 600 °C due to progressive microcracking. Compressive strength and Young's modulus declined with increasing temperature, with the largest specimens exhibiting the greatest strength reduction. Conversely, deformation at peak stress increased, indicating enhanced ductility.

Guo et al. (2023) investigated sandstone heated to 200–1000 °C. Microcrack development led to a substantial decrease in ultrasonic velocity, which dropped to 29.7% of its initial value at 1000 °C. Bulk density decreased by about 4 %, particularly between 800 °C and 1000 °C.

Franzen et al. (2023) analysed sandstone from Pirna-Neundorf, Germany, exposed to temperatures up to 1250 °C. Ultrasonic velocity remained nearly constant up to 400 °C but decreased progressively at higher temperatures, reaching about 40 % of its original value. Below 400 °C, wet specimens showed lower compressive strength than dry ones; above 500 °C, however, wet samples exhibited strength increases, especially between 600 °C and 800 °C. The highest post-heating strength at 1250 °C was recorded in wet specimens loaded perpendicular to bedding.

Shen et al. (2024) evaluated the combined effects of cyclic loading and elevated temperature on red sandstone. After preloading at different stress levels, specimens were heated to 200–800 °C. P-wave velocity decreased in all cases, most markedly in highly preloaded samples. Compressive strength declined with increasing preloading intensity, while strain capacity increased with temperature.

Wang et al. (2023) investigated fine-grained sandstone heated up to 1200 °C. Bulk density decreased approximately linearly, and mass loss followed a parabolic trend. A slight increase in P-wave velocity at 100 °C was attributed to microcrack closure, followed by progressive deterioration at higher temperatures. Mechanical properties declined significantly above 400 °C, particularly between 400 °C and 600 °C.

Srinivasan et al. (2022) examined granite from the Jalore region, India, subjected to heating (200–600 °C) followed by slow or rapid cooling. Rapidly cooled specimens developed surface cracks at lower temperatures (300 °C) than slowly cooled ones (400 °C). P-wave velocity decreased progressively under both regimes. Compressive strength and Young's modulus declined with temperature, more markedly in rapidly cooled samples; at 600 °C, compressive strength decreased to 38 % (slow cooling) and 21 % (rapid cooling) of the reference value. Tensile strength showed a consistent decrease under rapid cooling, while slowly cooled samples exhibited minor fluctuations. Higher temperatures accelerated fracture development in both cases.

Zhang et al. (2020) studied granite subjected to different cooling regimes. Rapid cooling up to 500 °C slightly increased compressive strength and Young's modulus due to thermal stresses, whereas higher temperatures caused significant reductions, particularly under rapid cooling. Porosity increased with temperature, more sharply in water-cooled samples above 500 °C. P-wave velocity decreased similarly under both cooling conditions.

Han et al. (2019) analysed sandstone exposed to heating up to 800 °C followed by rapid cooling. P-wave velocity decreased by approximately 66 %, and bulk density by about 2 %. Mechanical behaviour evolved in three stages: relative stability up to 200 °C, moderate degradation between 200 °C and 500 °C, and pronounced deterioration above 500 °C. All specimens failed in a brittle manner.

The influence of high temperatures on the mechanical properties of fired bricks was studied by Bošnjak et al. (2020), who investigated the effects of heating up to approximately 1100 °C on calcium–silicate bricks, ceramic bricks, and mortar. For calcium–silicate bricks, an initial increase in compressive strength was followed by a significant decrease after heating to 700 °C, including instances of spontaneous disintegration after cooling. In contrast, ceramic bricks showed minimal change up to 500 °C, after which strength

increased, reaching approximately 5.7 times the reference value at 1100 °C, accompanied by notable changes in volume, colour, and a transition to brittle failure behaviour. Mortars exhibited an approximately linear decrease in compressive strength with increasing temperature, consistent with the expected behaviour of cement-based materials under high-temperature exposure.

In addition to mechanical degradation, elevated temperatures induce visible colour changes due to mineralogical transformations. Iron-bearing minerals oxidize to ferric oxide or hematite Fe_2O_3, producing red to reddish-brown coloration (Ge et al. (2022)).

Pires et al. (2024) investigated two Portuguese limestones (Lioz and Ançã) subjected to elevated temperatures and rapid cooling. CIELab analysis showed temperature-dependent shifts in colour parameters (L*, a*, b*), attributed to mineral decomposition, oxidation, and organic matter transformation.

Hajpál et al. (2004) studied seven sandstones with varying initial hues. Increasing temperature generally led to higher a* values (reddening) and increased b* values (yellowing), although some lithology-specific deviations were observed. Mineral transformations, such as glauconite and chlorite alteration and hematite formation, controlled these colour changes, while lightness (L*) varied depending on mineral composition.

Overall, the reviewed studies consistently demonstrate that increasing temperature leads to progressive microstructural degradation of rock materials, primarily driven by microcrack initiation and propagation, mineral transformations, and thermally induced stresses. These processes result in significant reductions in ultrasonic wave velocity, compressive and tensile strength, and elastic modulus, particularly above critical temperature thresholds commonly observed between 400 °C and 600 °C. Cooling conditions, especially rapid water quenching, further intensify damage and mechanical deterioration. In addition to mechanical weakening, high temperatures induce measurable changes in density, porosity, and colour parameters, reflecting ongoing mineralogical and chemical transformations. Despite lithology-specific differences, the general trend indicates a transition from relatively stable behaviour at low temperatures to accelerated physical and mechanical degradation at higher thermal exposure levels.

However, the findings of individual studies are difficult to generalise due to pronounced variability in mineralogical composition, microstructural properties, and temperature-dependent phase transformations across different material types and provenances. This highlights the need for material-specific investigations, particularly for locally sourced historic building materials, for which systematic thermal characterisation data remain scarce.

3. Materials and methods

3.1 Experimental samples

The materials investigated in this study comprise Hořice sandstone and fired brick. Sandstone became progressively established as a primary construction material in Gothic architecture across the Czech lands from the late fourteenth century onwards, as attested by its prominent use in St. Vitus Cathedral in Prague (Figure 1a). Its application persisted throughout the Baroque period, particularly for sculptural elements and architectural components such as staircases, portals, and window frames. During the second half of the nineteenth century, sandstone was also extensively employed in historicist buildings in Prague, including the National Theatre (Figure 1b), the Rudolfinum, and the National Museum. Building sandstones encompass a range of lithological types, varying from fine- to coarse-grained, with quartz constituting the predominant mineral phase. Intergranular spaces are occupied by primary or secondary cement, which exerts a significant influence on cohesion, porosity, mechanical behaviour, and long-term durability (Kotlík (1999);Hošek (1996)).

For the purposes of the present study, Hořice sandstone was selected as the primary stone material. The quarried deposit is situated in eastern Bohemia, between the towns of Jičín and Hořice in the Podkrkonoší region. The rock is classified as a fine-grained sandstone with a grain size ranging from 0.05 to 0.25 mm,

occurring within the Cenomanian succession of the Bohemian Cretaceous Basin, specifically in the Peruc-Korycany Formation (Korycany beds). The deposits exhibit gentle to sub-horizontal dipping with platy to flaggy bedding and are characterised by sparse, regularly distributed fracturing. Petrographically, the sandstone comprises more than 90% quartz grains, with accessory minerals, including glauconite, feldspars, micas, and heavy minerals, present only in trace amounts. The cement phase consists of a kaolinite–illite mixture with subordinate quartz dust (Rybařík (1996)). A set of 18 cylindrical specimens with a nominal diameter of approximately 35 mm and a height of approximately 70 mm was prepared for mechanical testing (Figure 2a).

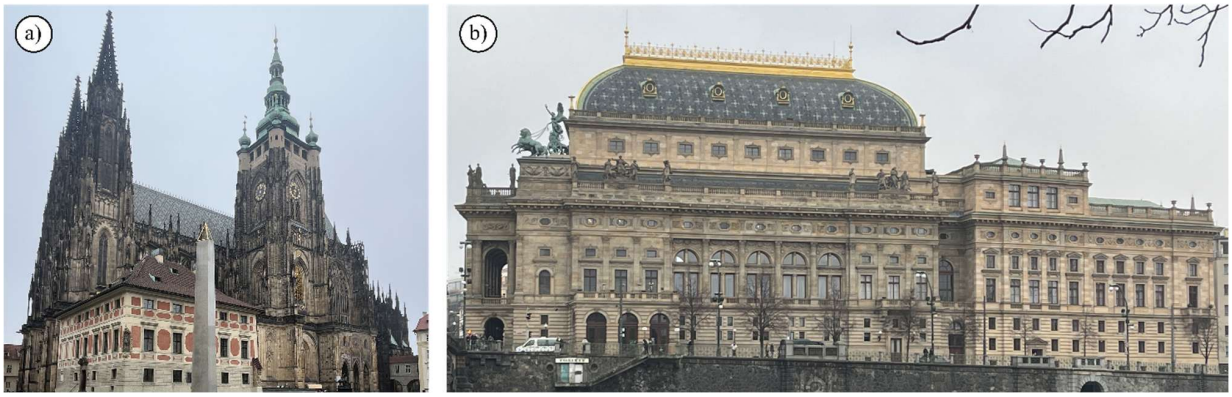

Figure 1 - a) St. Vitus Cathedral in Prague, **b)** The National Theatre in Prague.

Fired brick represents a traditional ceramic building material manufactured from clay rich in clay minerals such as illite, montmorillonite, and kaolinite, commonly containing accessory components including quartz, calcite, mica, and chlorite. During the firing process, clay minerals undergo dehydration at approximately 500–600 °C, followed by the transformation of aluminosilicates into a spinel-type phase and, at higher temperatures, into mullite, accompanied by the concurrent formation of a glassy phase. These mineralogical transformations exert a considerable influence on the microstructure and mechanical properties of the resulting material, the compressive strength of fired bricks typically ranges from approximately 5 MPa to 60 MPa (Witzany et al. (2024); Kotlík (1999)). In this study, a set of 20 cylindrical specimens with a nominal diameter of approximately 35 mm and a height of approximately 60 mm was used. (**Figure 2b**).

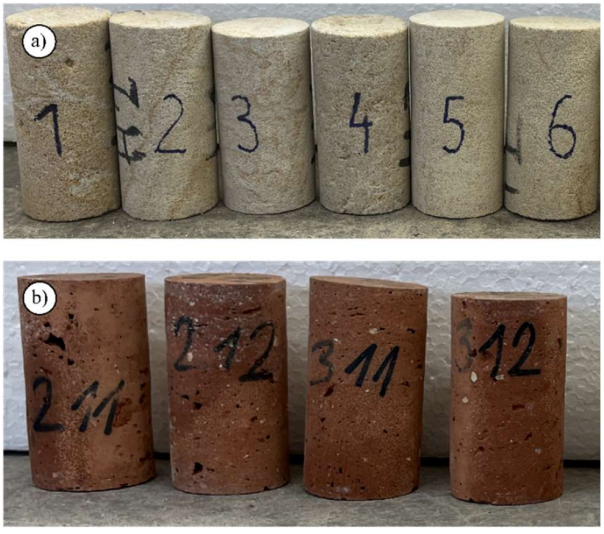

Figure 2 - a) Sandstone samples, **b)** Fired brick samples.

3.2 Experimental procedures and settings

Specimens were heated in an electric muffle furnace (**Figure 3a**) using a two-phase regime: heating to the target temperature at 13–16 °C/min, to minimize thermal shock, followed by a 60 minute isothermal dwell to ensure thermal stabilization Target temperatures were 690 °C, 850 °C, and 1100 °C for sandstone (**Figure 3b**), and 920 °C and 1100 °C for fired brick. After exposure, specimens were cooled either slowly in the furnace or rapidly by water quenching (≈20 °C, 120 s), with rapid cooling applied to samples heated to 850 °C and 1100 °C for sandstone samples and 920 °C and 1100 °C for fired brick samples. Furnace temperature was monitored using two thermocouples.

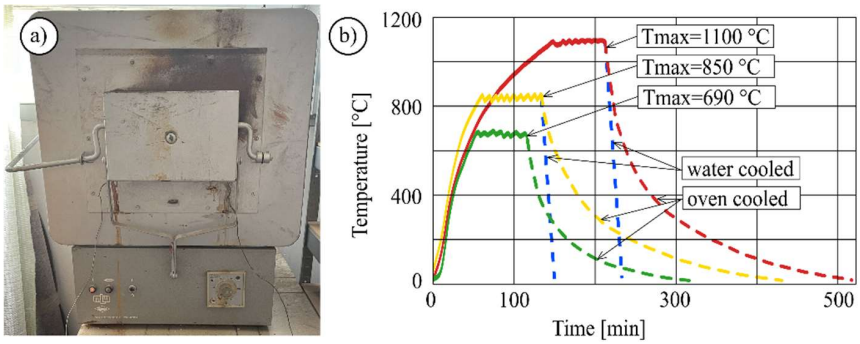

Figure 3 – **a)** Electric muffle furnace, **b)** Heating-cooling curves for Sandstone samples.

Uniaxial compression tests were conducted using a universal testing machine LabTest 4.100.SP1 (maximum load capacity 100 kN) at a loading rate of 0.25 mm/min (**Figure 4**). Stress and strain were derived from force–displacement data, and Young's modulus was determined from the linear elastic region.

Deformation was monitored by digital image correlation (DIC) using an optical extensometer with a 5 Mpx sensor and monochromatic blue illumination optimized for sensor sensitivity. The system included a LaborTech AOX-ONE camera equipped with a 5 Mpx (2448 px × 2048 px) Blackfly BFS-U3-51S5M sensor and a 16 mm lens, complying with EN ISO 9513 accuracy class 0.5 and ASTME 83: Class A. Blue monochromatic LED lighting matched the peak sensitivity of the camera chip used. Data were processed in Alpha® software (version 1.0.377).

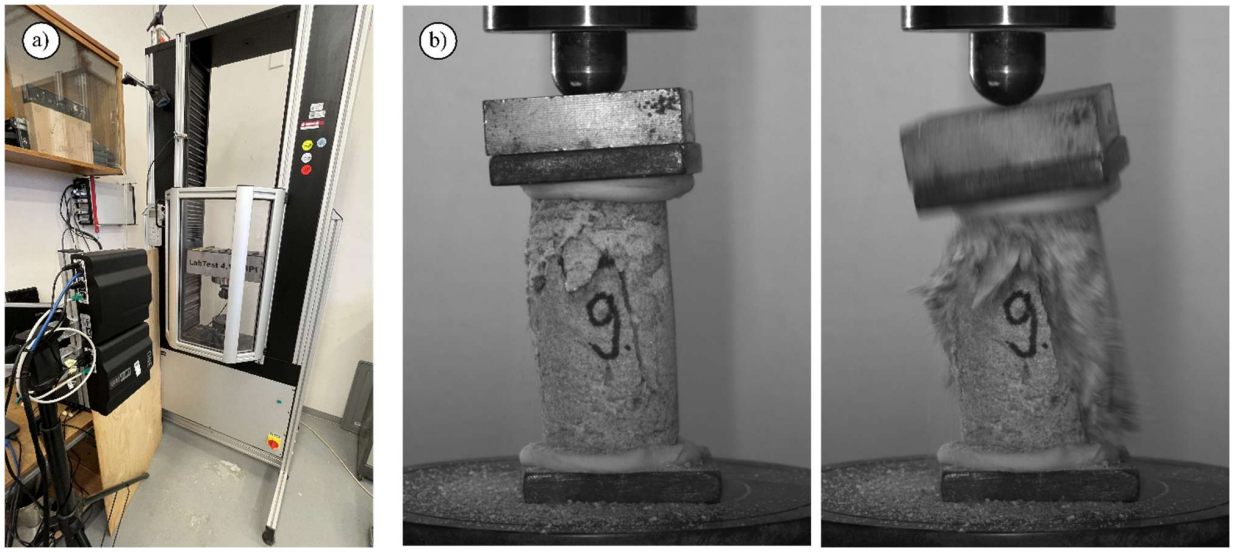

Figure 4 – **a)** Experimental setup, **b)** failure of test specimens under uniaxial compressive loading.

Colour changes were documented using a Canon EOS 60D camera under controlled lighting conditions (two reflectors with diffusers, 5000 K, neutral infinite background). Colour parameters (L*, a*, b*) were

evaluated in the CIELab space from four 100 × 100 px regions of interest per specimen, and the total colour difference (ΔE) was calculated as the Euclidean distance between reference and heated states.

Statistical analysis was conducted in RStudio, including descriptive statistics, Grubbs' test for outliers, and ANOVA followed by Tukey's HSD test ($p < 0.05$).

4. Results and discussion

4.1 Mechanical properties

4.1.1 Sandstone

The reference specimens attained a mean compressive strength of 21.83 MPa (100 %), with individual values ranging from 20.50 to 22.60 MPa (94–104 %). Following heating to 690 °C, mean compressive strength decreased to 19.40 MPa (89 %), with a range of 17.91–20.36 MPa (82–93 %). Specimens heated to 850 °C and cooled slowly in the furnace exhibited a further reduction to 17.66 MPa (81 %), with values between 16.49 and 19.57 MPa (76–90 %), while water-quenched specimens reached 12.30 MPa (56 %), ranging from 8.64 to 14.38 MPa (40–66 %). At 1100 °C, furnace-cooled specimens attained a mean compressive strength of 13.49 MPa (62 %), ranging from 11.43 to 16.79 MPa (52–77 %), whereas water-cooled specimens exhibited the lowest values, with a mean of 7.77 MPa (36 %) and a range of 5.88–10.13 MPa (27–46 %).

The mean strain of the unheated specimens was 0.00150 (100%), with values ranging from 0.00137 to 0.00162 (91–108 %). After heating to 690 °C, mean strain increased to 0.00451 (300 %), with values between 0.00432 and 0.00465 (287–309 %). At 850 °C, furnace-cooled specimens reached a mean strain of 0.00621 (413 %), ranging from 0.00504 to 0.00812 (334–540 %), while water-cooled specimens exhibited a higher mean value of 0.01040 (691 %), with a range of 0.00954–0.01169 (634–777 %). Following exposure to 1100 °C, furnace-cooled specimens exhibited a mean strain of 0.00830 (552 %), ranging from 0.00818 to 0.00853 (544–567 %), while water-cooled specimens attained a mean value of 0.01073 (714 %), ranging from 0.01033 to 0.01151 (687–766 %).

The mean Young's modulus of the unheated specimens was 16.13 GPa (100 %), with values ranging from 15.68 to 16.88 GPa (97–105 %). Following heating to 690 °C, the modulus decreased to 7.52 GPa (47 %), with a range of 6.70–9.03 GPa (42–56 %). At 850 °C, furnace-cooled specimens attained a mean modulus of 4.74 GPa (29 %), ranging from 3.43 to 6.30 GPa (21–39 %), while water-cooled specimens showed a further reduction to 2.42 GPa (15 %), with values between 1.52 and 2.88 GPa (9–18 %). At 1100 °C, the modulus of furnace-cooled specimens was 2.33 GPa (14 %), ranging from 1.79 to 2.84 GPa (11–18 %), and water-cooled specimens exhibited the lowest values, with a mean of 1.17 GPa (7 %) and a range of 0.82–1.70 GPa (5–11 %).

The stress–strain curves for Sandstone specimens are shown in **Figure 5**. Unheated specimens (blue) exhibited an almost linear increase in stress with increasing strain. In thermally exposed specimens, a progressive deviation from linear towards nonlinear, and ultimately exponential, behaviour was observed with increasing temperature. Specimens heated to 690 °C (green) displayed the steepest gradient among all thermally treated groups. For specimens heated to 850 °C (yellow) and 1100 °C (red), the influence of the cooling method was discernible. Furnace-cooled specimens exhibited steeper curve gradients compared to their water-cooled counterparts. Water-cooled specimens were characterized by more pronounced initial strain values and the lowest curve gradients overall.

The observed changes in the slope and shape of the stress–strain curves reflect progressive alterations in the microstructure of the sandstone induced by high-temperature exposure. These include phase and chemical transformations of thermally sensitive minerals, as well as the development of microcracks arising from differential thermal expansion and mineral decomposition, both of which contribute to the degradation of mechanical stiffness and the increasingly nonlinear mechanical response (Franzen et al. (2023); Shen et al. (2024)).

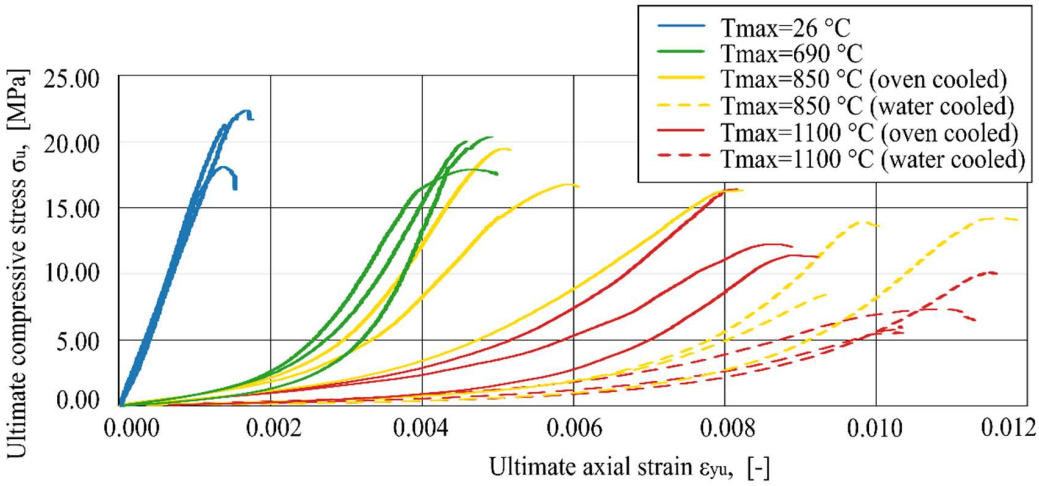

Figure 5 – Stress–strain relationship of Sandstone samples under uniaxial compression.

4.1.2 Fired brick

The unheated specimens exhibited a mean compressive strength of 17.99 MPa (100 %), with values ranging from 14.35 to 24.16 MPa (80–134 %). Following heating to 920 °C and slow furnace cooling, compressive strength decreased to approximately 9.84 MPa (55 %), with values between 8.40 and 11.48 MPa (47–64 %). Specimens subjected to rapid water quenching exhibited a more pronounced reduction, attaining a mean compressive strength of approximately 7.50 MPa (42 %), with values ranging from 6.25 to 9.44 MPa (35–53 %). After heating to 1100 °C and slow furnace cooling, compressive strength increased markedly to approximately 23.18 MPa (129 %), with values between 22.58 and 23.78 MPa (127–132 %). The increase was less pronounced in water-cooled specimens, which attained a mean compressive strength of approximately 12.88 MPa (72 %), with values ranging from 11.22 to 14.97 MPa (62–83 %).

The mean relative strain of the reference specimens was 0.00223 (100 %), with values ranging from 0.00168 to 0.00264 (75–118 %). Following heating to 920 °C and slow furnace cooling, the mean relative strain increased to approximately 0.00330 (148 %), with values between 0.00234 and 0.00493 (105–221 %). Specimens subjected to rapid water quenching exhibited a more pronounced increase, attaining approximately 0.00573 (257 %), with values ranging from 0.00553 to 0.00610 (248–273 %). After heating to 1100 °C and slow furnace cooling, the mean relative strain was 0.00426 (191 %), with values between 0.00325 and 0.00527 (146–236 %), while water-cooled specimens exhibited a mean relative strain of 0.00355 (159 %), ranging from 0.00256 to 0.00498 (115–223 %).

The mean Young's modulus of the unheated specimens was 9.88 GPa (100 %), with values ranging from 8.63 to 11.88 GPa (87–120 %). Following heating to 920 °C and slow furnace cooling, the mean modulus decreased to approximately 3.50 GPa (35 %), with values ranging from 1.88 to 4.83 GPa (51–65 %). In specimens subjected to rapid water quenching, a further reduction was observed, with a mean value of approximately 1.75 GPa (18 %) and a range of 1.28–2.50 GPa (13–25 %). After heating to 1100 °C and slow furnace cooling, the Young's modulus attained a mean value of 7.62 GPa (77 %), with values ranging from 5.22 to 10.02 GPa (53–101 %). Water-cooled specimens exhibited a mean value of 4.05 GPa (41 %), with values between 3.92 and 4.30 GPa (40–44 %).

The stress–strain relationships for Fired brick specimens are presented in **Figure 6**. The steepest curve gradients, characterised by an almost linear increase, were observed in the reference specimens (blue) and in specimens heated to 1100 °C and furnace-cooled (red). Specimens heated to 920 °C and furnace-cooled (yellow) also exhibited an approximately linear trend, however with a lower gradient compared to the reference specimens and those heated to 1100 °C. In the case of water-cooled specimens at both

temperature levels, the stress–strain response approached a nonlinear character, with specimens heated to 1100 °C displaying steeper curve gradients than those heated to 920 °C.

The variations in curve gradient and shape observed across the different thermal and cooling conditions can be attributed to microstructural and compositional changes induced by high-temperature exposure. In fired brick, these include the further sintering of the ceramic matrix, recrystallisation of clay minerals, and thermally driven phase transformations, all of which alter the pore structure and intergranular bonding ((Kotlík (1999); Witzany et al. (2024)).

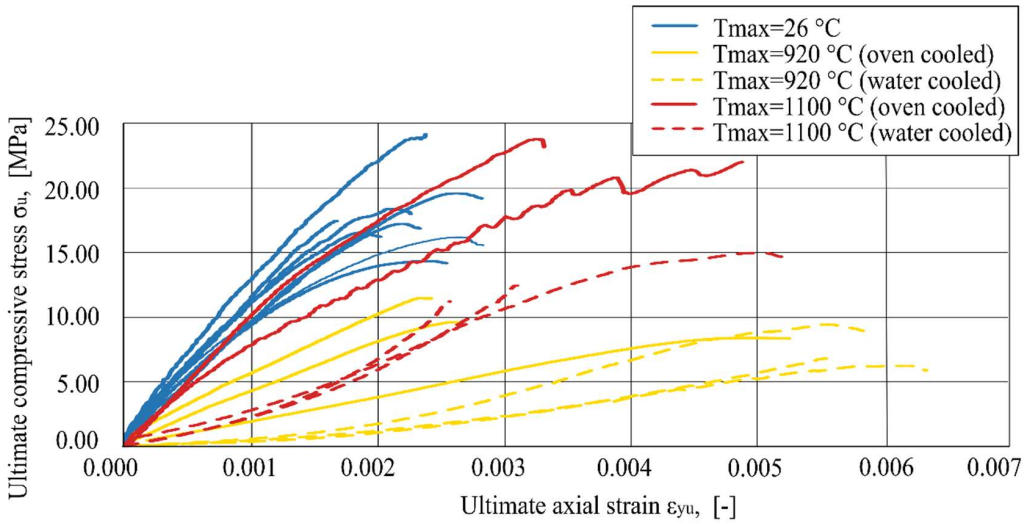

Figure 6 – Stress–strain relationship of Fired brick samples under uniaxial compression.

4.2 Colour change

For the sandstone specimens, colour changes were visible after every temperature treatment (**Figure 7**), chromatic changes were quantitatively evaluated within the CIELab colour space (**Figure 8**). Lightness (L*) decreased slightly with increasing temperature, from the reference value of 52.26 to 48.83 following heating to 690 °C. No statistically significant additional changes in L* were observed at 850 °C or 1100 °C, and the cooling method exerted no discernible influence on this parameter. The a* parameter (red–green axis) increased markedly after heating to 690 °C, from 5.74 to 12.41, indicative of pronounced specimen reddening. At 850 °C, furnace-cooled specimens exhibited a slight decrease to 11.08, while water-cooled specimens attained a value of 12.65. Following heating to 1100 °C, a* decreased under both cooling conditions, to 9.69 for furnace-cooled and 9.55 for water-cooled specimens. For the b* parameter (yellow–blue axis), no substantial change was observed at 690 °C (reference: 17.64; post-heating: 16.74). At 850 °C, furnace-cooled specimens exhibited a decrease to 14.88, whereas water-cooled specimens showed a marginal increase to 17.83. At 1100 °C, b* decreased under both cooling conditions, to 14.26 for furnace-cooled and 14.84 for water-cooled specimens. The total colour difference (ΔE) was 8.11 following heating to 690 °C. At 850 °C, ΔE increased to 8.93 for furnace-cooled specimens and to 8.75 for water-cooled specimens. After heating to 1100 °C, ΔE decreased to 8.08 for furnace-cooled and to 7.49 for water-cooled specimens.

The observed reddening, reflected in the marked increase in a*, is attributable to the oxidation of iron-bearing minerals and the formation of hematite at elevated temperatures. As documented by Hajpál et al. (2004), such mineral transformations, including the alteration of glauconite and chlorite, represent the primary controls on colour change in thermally treated sandstones.

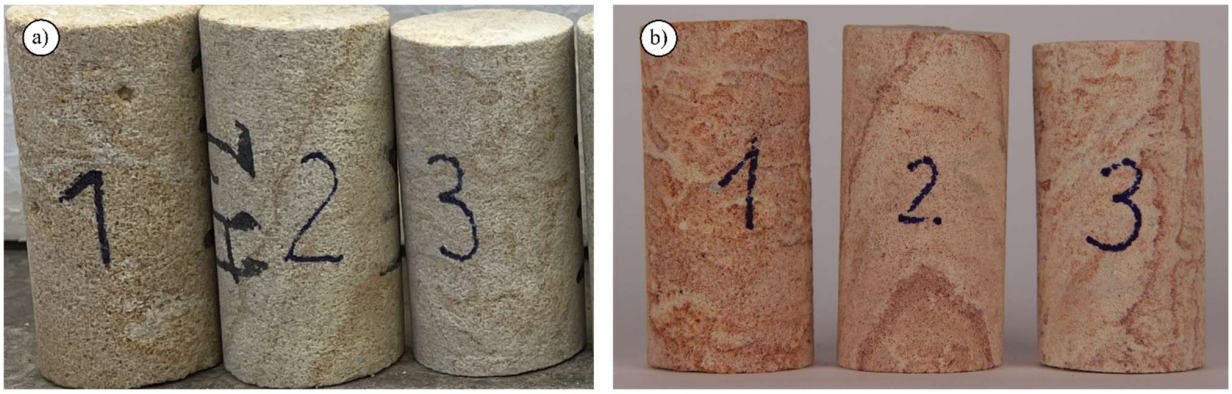

Figure 7 – Sandstone specimens: **a)** unheated reference, **b)** heated to 690 °C.

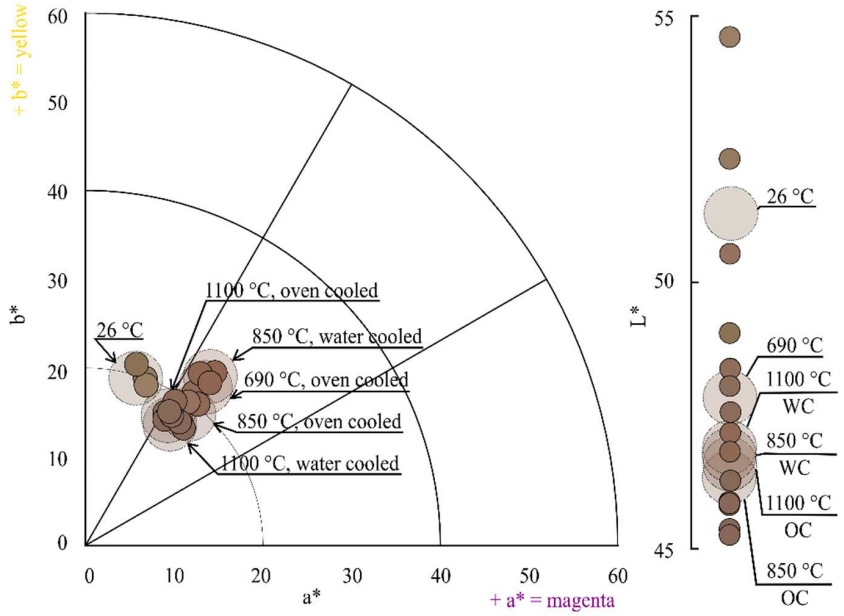

Figure 8 – CIELab colour parameters of Sandstone specimens subjected to elevated temperatures; OC - oven-cooled, WC - water-cooled.

For the fired brick specimens, systematic quantitative evaluation of colour parameters was not performed, owing to the pronounced non-uniformity of coloration across individual specimen surfaces. Specimens heated to 920 °C appeared slightly lighter in colour relative to the reference samples. Following heating to 1100 °C, a marked chromatic contrast was observed between the opposing faces of individual specimens. Rapidly cooled specimens displayed a brown-orange coloration on one face (side a, **Figure 9a**), while the opposing face (side b, **Figure 9b**) appeared dark brown with white spots. Furnace-cooled specimens were characterized by very dark coloration with white spots on side b (**Figure 9b**) and a lighter appearance on side a (**Figure 9a**).

Analogous chromatic changes following high-temperature exposure are reported by Cikrle et al. (2020), in which a markedly dark brown colour corresponds to firing temperatures of approximately 1150 °C, comparable to the appearance of side b in furnace-cooled specimens heated to 1100 °C, while a red-brown coloration is associated with firing temperatures of approximately 1100 °C. These colour shifts are primarily driven by thermally induced oxidation and recrystallisation of iron-bearing mineral compounds within the brick matrix, which produce progressive changes in hue towards red, brown, and dark brown tones as a function of temperature and local thermal conditions (Bošnjak et al. (2020); Kotlík (1999)).

Figure 8 – Fired brick specimens heated to 1100 °C: **a)** side a — first three specimens from the left are furnace-cooled, remaining specimens are water-cooled; **b)** side b — first three specimens from the left are furnace-cooled, remaining specimens are water-cooled.

4.3 Statistical analysis

For the Sandstone specimens, one-way ANOVA confirmed a statistically significant effect of temperature on all mechanical properties for both furnace- and water-cooled specimens ($p \leq 0.004$). Tukey's HSD post hoc test indicated that compressive strength was significantly affected primarily at higher temperatures, particularly at 1100 °C, while relative strain and Young's modulus were significantly influenced across all temperature levels investigated. Two-way ANOVA further demonstrated a statistically significant effect of both temperature and cooling method on compressive strength and Young's modulus, whereas relative strain was less markedly affected by the interaction of these factors. No statistically significant interaction between temperature and cooling method was identified.

For the Fired brick specimen set, one-way ANOVA indicated a statistically significant effect of temperature on all mechanical properties under both cooling regimes ($p < 0.05$). Tukey's HSD test revealed that differences were most pronounced at 920 °C for furnace-cooled specimens, while significant effects were identified at both 920 °C and 1100 °C for water-cooled specimens. Two-way ANOVA confirmed a statistically significant influence of both temperature and cooling method on compressive strength and Young's modulus, whereas relative strain was less consistently affected. A statistically significant interaction between temperature and cooling method was identified exclusively for compressive strength.

5. Conclusion

The present study investigated the effects of elevated temperature and post-exposure cooling method on the mechanical properties and chromatic characteristics of two traditional masonry materials, Hořice sandstone and fired brick, with relevance to the assessment and preservation of historical built heritage.

The experimental results demonstrate that thermal exposure induced progressive and statistically significant degradation of mechanical performance in both materials, albeit with material-specific trends. In sandstone, compressive strength, Young's modulus, and axial strain deteriorated consistently with increasing temperature, with the most pronounced reductions observed at 1100 °C. The cooling method exerted a substantial additional influence, rapid water quenching consistently produced more severe mechanical deterioration than slow furnace cooling at equivalent temperatures, reflecting the damaging effect of thermally induced stress gradients during quenching.

Fired brick exhibited a more complex thermal response. While mechanical properties decreased markedly following heating to 920 °C, specimens heated to 1100 °C and cooled slowly in the furnace displayed a notable recovery in compressive strength, exceeding the reference value by approximately 29 %, attributable to high-temperature mineralogical transformations including mullite formation and glassy phase development. Rapid cooling suppressed this recovery, highlighting the critical role of the cooling regime in governing the final mechanical state of thermally exposed ceramic materials.

Chromatic analysis confirmed measurable colour changes in both materials, most notably progressive reddening in sandstone attributable to iron mineral oxidation, and pronounced surface colour heterogeneity in fired brick at 1100 °C.

Statistical analysis confirmed the significance of both temperature and cooling method on compressive strength and Young's modulus in both materials, with a significant interaction between these factors identified for compressive strength in fired brick.

The findings provide experimentally grounded data to support post-fire damage assessment and conservation of heritage buildings. Future investigations will extend the range of materials and temperature levels examined and address the influence of pre-existing microstructural, mineralogical, petrographic and chemical variability on thermal response, in order to further refine predictive frameworks for the structural assessment of fire-affected heritage structures.

Abstract: Damage observed in recent earthquakes affecting historical unreinforced masonry (URM) buildings has revealed discrepancies between predicted structural performance based on established theoretical models and the behaviour of these structures in practice. These differences raise critical questions regarding the adequacy of current rapid seismic vulnerability assessment methods, particularly when applied to traditional and protected building stock. This paper addresses the gap between existing theoretical frameworks, practical post-earthquake observations, and the perspectives of professionals directly involved in the assessment and rehabilitation of URM buildings.
The study focuses on the role of expert judgment in evaluating the relative importance of parameters influencing the seismic response of historical URM structures. An international survey was conducted to collect expert opinions from professionals with diverse disciplinary backgrounds and regional experience.
The analysis highlights notable differences in parameter prioritization, reflecting variations in professional experience, exposure to real damage scenarios, and interpretative frameworks. These findings demonstrate that theoretical models may not fully capture the complexity of structural behaviour observed in practice and that expert knowledge provides valuable insights into damage mechanisms and vulnerability patterns.
The paper emphasizes the importance of integrating expert perspectives with theoretical foundations to improve the reliability and practical relevance of seismic vulnerability assessments. Such integration is particularly relevant for building pathology and construction repair, where informed decision-making relies on a balanced understanding of theory, observed damage, and professional experience.

Keywords: Expert opinion, Seismic vulnerability, Survey, Heritage, Masonry

1. Introduction

Seismic risk is typically described through three components: hazard, exposure, and vulnerability. Hazard - the likelihood of certain ground motions - depends on location and cannot be controlled, while exposure, tied to population and infrastructure, is also difficult to change. Vulnerability, however, can be reduced. It refers to the *likelihood* of damage at a given seismic intensity and depends on factors such as building age, structural system, materials, design codes, maintenance, and retrofitting, as well as site conditions like soil type and ground stability.
Because of this, assessing seismic vulnerability is essential for reducing risk and predicting potential damage and losses. There is a broad spectrum of assessment methods, which are often tailored to specific regions and building types (Moufid, Mohamed, and Noroozinejad 2020). Their differences reflect variations in construction practices and structural characteristics across countries, as well as specialized focuses on elements like façades or building aggregates. This highlights the need to adapt parameter selection to local conditions to accurately capture building behaviour - an issue that motivated this research. It must be emphasized that this paper presents only a part of the ongoing research, which, in addition to expert opinions, encompasses both empirical and analytical methods. However, this paper itself focuses solely on expert opinions and their significance. The research focuses on the Croatian building stock, specifically traditional unreinforced masonry (URM) buildings from the late 19th and early 20th centuries (Figure 1). These structures were built according to Austrian, German, and Hungarian practices, at a time when seismic

design was not considered. They typically consist of masonry walls with lime mortar, timber floors or shallow vaults at lower levels, and timber roofs. Although their vertical load-bearing capacity generally meets modern standards - evidenced by their long service life exceeding current design expectations - they remain highly vulnerable to earthquakes (Stepinac et al. 2021; Atalić, Novak, and Uroš 2019).

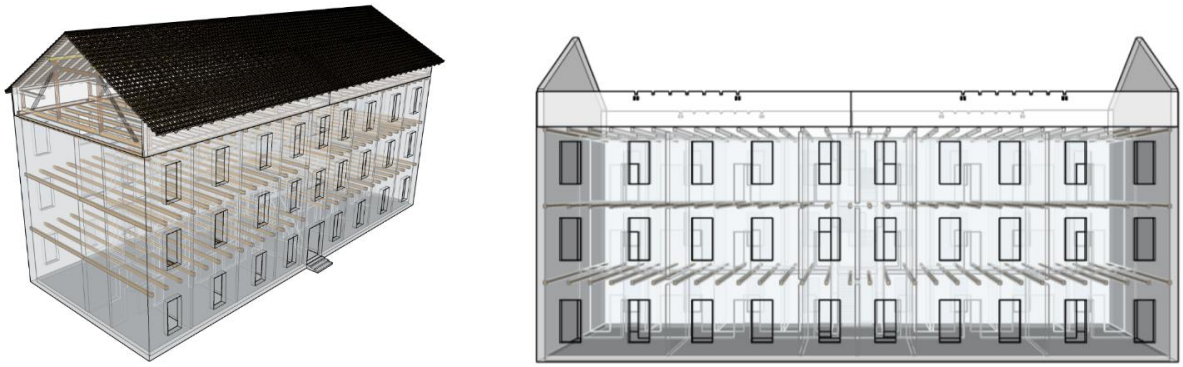

Figure 1 - Characteristic building in Lower Town, Zagreb

The buildings are commonly arranged in urban aggregates (Figure 2), which complicates their seismic behaviour. In Zagreb's Lower Town, these aggregates are fairly uniform in height, usually three to four storeys, but vary in layout. Typical patterns include L-shaped corner buildings, rectangular structures, buildings with plan offsets, and those without adjacent neighbours, alongside occasional reinforced-concrete structures. The interactions among the units lead to two effects: global, involving force redistribution across the whole aggregate, and local, related to pounding between adjacent units with different seismic responses (Torres-Olivares et al. 2024). Key influencing factors include height differences, position within the row, floor misalignment, structural variability, and façade openings (Angiolilli et al. 2021; Schiavoni et al. 2023).

Figure 2 - Aerial view of Zagreb – urban aggregates

A preliminary study of 66 historic masonry buildings in Zagreb's Lower Town, using an Italian-based method, indicated moderate vulnerability but showed notable mismatches with observed damage (Moretić et al. 2022). This highlighted the need to adapt vulnerability parameters to local building characteristics. To address this, a rapid assessment method for unreinforced masonry buildings has been developed, combining analytical models, empirical data, and expert judgment. This paper focuses on the role of expert input in defining parameter weights, which can also be compared with statistically derived values. Expert opinions were collected through a structured international survey, though a reduced number of questions was necessary to ensure participation. The Analytic Hierarchy Process (AHP) was used to convert subjective judgments into quantitative weights.

2. Survey design and data collection

A total of 111 experts in earthquake engineering and masonry structures participated in the survey, mainly based in Europe. The majority of respondents came from academia, including professors, researchers, PhD candidates, and Master's students, while 37% were professionals from the Croatian design and construction sector, contributing practical experience from post-earthquake assessments and reconstruction activities. Participants were also classified according to their professional experience; most had more than three years of experience, and 41% had over ten years, which supports the reliability of the collected responses. In addition, respondents were asked to self-assess their level of expertise on a scale from 1 to 5. The comparison between respondents' years of professional experience and their self-assessed level of expertise indicates a likely positive correlation between these two variables. The majority of respondents reported having between 3 and 20 years of professional experience, while most participants evaluated their expertise at a moderate to high level (levels 3–5). This distribution suggests that respondents with greater professional experience tend to perceive themselves as more knowledgeable and competent in the field of seismic vulnerability and seismic design. Furthermore, lower self-assessment scores (levels 1 and 2) were

represented by a relatively small proportion of respondents, which may indicate that limited expertise is less common among participants with longer professional engagement in the field.
Although most participants were from Croatia, the survey also included experts from other seismically active regions to provide broader perspectives on the seismic behaviour of traditional structures. The participant data is presented in Figure 3.

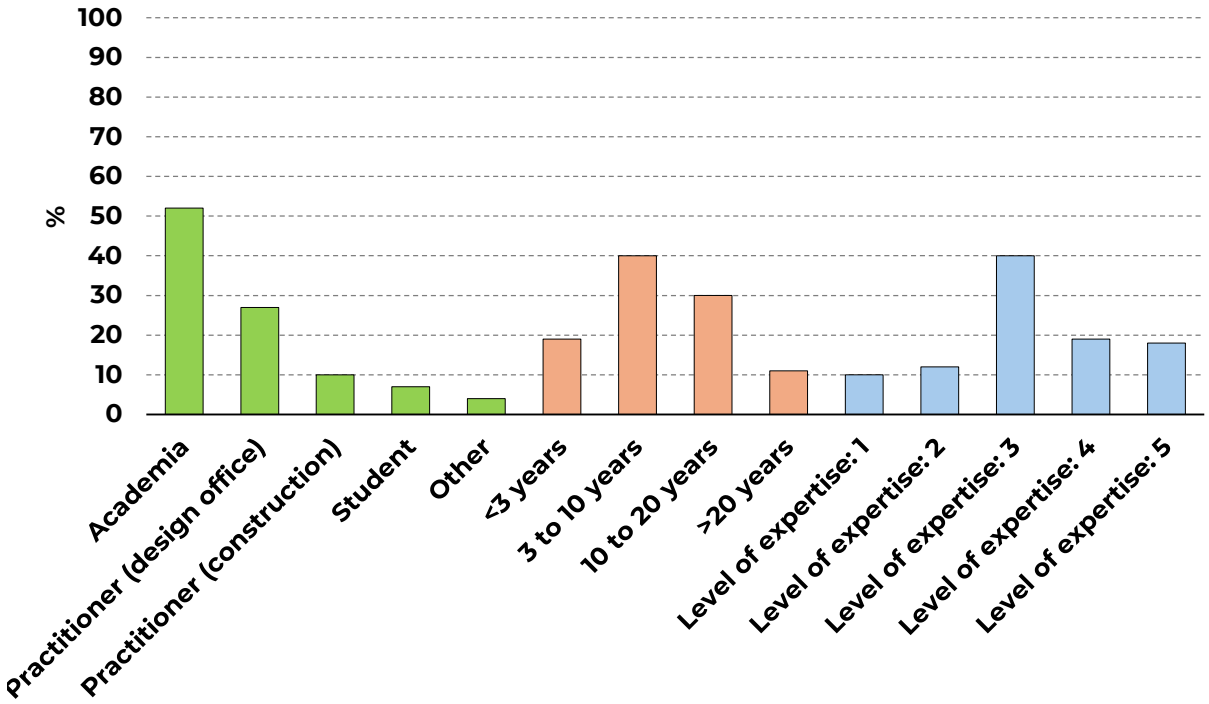

Figure 3 - Participants data

The survey was created using the online platform Fillout and distributed digitally to experts. It was shared through email contacts, direct communication with professionals, social networks such as LinkedIn, WhatsApp groups of post-earthquake building assessment specialists in Croatia, and among participants of the final conference of the ARES project funded by the Croatian Science Foundation.

The questionnaire, which required about 15–20 minutes to complete included the introductory section that collected general participant information and the technical section.

Since the survey included only a limited number of technical questions, the analysed parameters had to be carefully selected. Their choice was guided by damage patterns observed after the 2020 Zagreb earthquake (Novak et al. 2020; Uroš et al. 2021), which helped identify the factors considered most relevant for this study (Figure 4).

Figure 4 - Damage inspected in Zagreb in post-earthquake assessments in 2020

The survey contained three groups of questions. The first asked respondents to rank parameters affecting the seismic behaviour of masonry structures in Croatia and those influencing aggregate vulnerability from most to least important. This produced an average ranking score for each parameter together with qualitative explanations for the most and least influential factors. The second group of questions served as cross-validation. Participants evaluated groups of parameters on a 1–5 scale, where 5 indicated greater influence. The third group of questions also supported cross-validation. First, respondents performed pairwise comparisons, choosing which of two parameters they considered more influential. They then rated their relative importance on a 1–10 scale, where 1 indicated equal importance and 10 indicated extreme dominance of one parameter. These questions referred to both individual masonry buildings and aggregates.

Using different question formats for closely related topics had an important methodological role. It enabled verification of response consistency, reduced systematic bias, and improved data reliability. Varying the phrasing also helped reveal underlying attitudes, supported clearer interpretation by respondents, and reduced fatigue or automatic responses, thereby strengthening the reliability of the measurement scales used in the study.

3. Survey results

Figure 5 shows the results of the key survey question, in which participants ranked 15 parameters according to their influence on building behaviour. The average ranking reflects the mean score across all respondents, with lower values indicating greater influence. The parameters are ordered by perceived importance, with plan regularity identified as the most influential (average score 4.9) and type of roof structure as the least influential (11.5). In addition to the overall results, the respondents' answers were analysed according to their country of origin, as well as with respect to their professional experience and place of employment. These results were later used to calculate weighting factors, which were compared with factors derived from statistical methods (Ožić 2025).

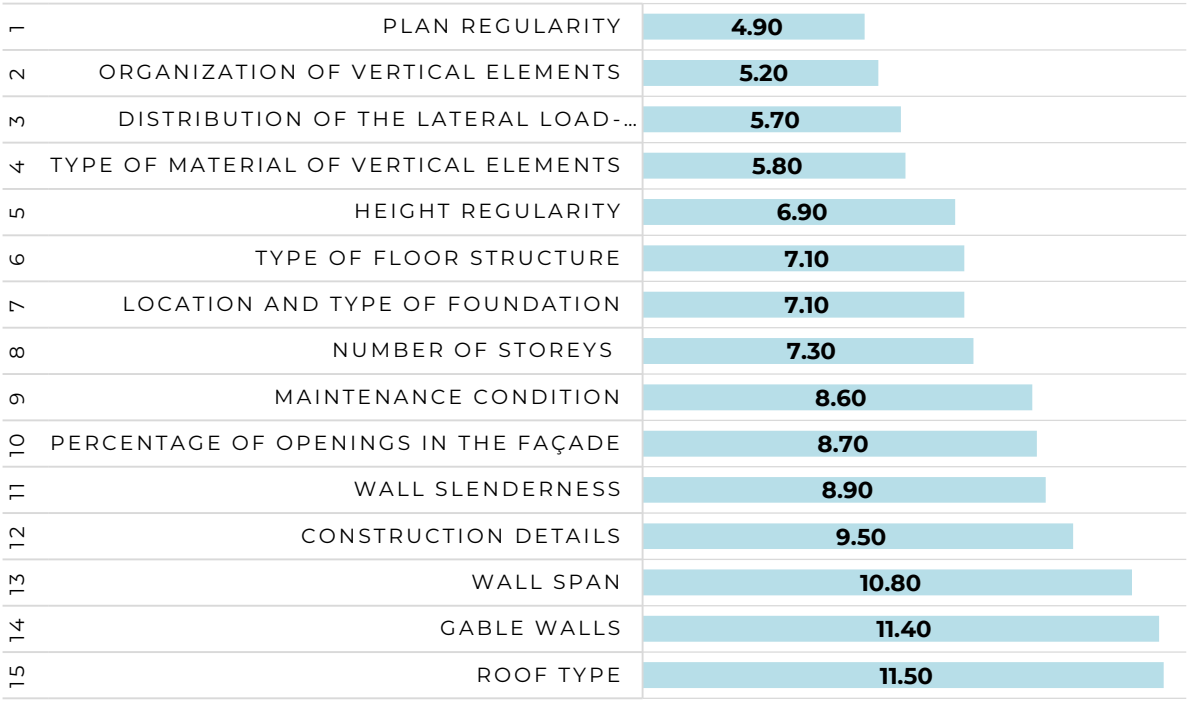

Figure 5 – Investigated vulnerability parameters and their rankings

The average ratings of individual parameters were compared between experts from Croatia and those from the rest of the world. This comparison was intentional, as the objective was to analyse the seismic behaviour of the Croatian building stock. Respondents from Croatia are naturally more familiar with the buildings under assessment, making their input particularly relevant. For most parameters, the ratings are relatively consistent; however, a notable difference is observed for the parameter related to foundation location and type. Croatian experts likely consider this parameter less important, which may be attributed to the relatively uniform soil and foundation conditions in the city of Zagreb. Interestingly, domestic experts assigned greater importance to parameters such as wall slenderness and wall span, both of which are associated with out-of-plane failure mechanisms. Although such mechanisms were not dominant during the Zagreb earthquake, this observation may reflect specific perceptions or experiences among Croatian experts regarding the potential vulnerabilities of masonry structures.

A comparison between academic and professional participants reveals a clear divergence in opinions. Academics tend to emphasise regularity and structural organisation, while practitioners prioritise practical aspects, such as wall span. A pronounced difference is observed for wall slenderness (parameter 11), which practitioners consider less influential, possibly because of the similar configurations of buildings in Zagreb.

Differences are also evident for the type of floor structure (parameter 6), indicating varying priorities in assessing its impact on seismic behaviour.

The results were also compared according to years of professional experience. The most pronounced differences are observed among participants with the least experience, whose responses deviate considerably from those of more experienced respondents. This suggests that less experienced participants may lack sufficient practical insight to evaluate certain aspects accurately. In contrast, participants with more than 10 years of experience show greater consistency in their assessments. Some differences remain between the most experienced group and those with medium levels of experience (3–10 years), which may indicate a transitional stage of professional development in which opinions gradually align with increasing expertise.

A separate classification was also performed based on participants' self-assessed level of expertise in the field, measured on a scale from 1 to 5 (where 1 indicates no expertise and 5 indicates a high level of expertise). This subjective assessment does not necessarily correspond to years of professional experience but provides additional insight into how participants perceive their own expertise and how this perception influences their evaluation of the parameters. Differences are observed across all categories, with the most pronounced contrast between participants who do not consider themselves experts and those who identify as experts. These findings suggest that self-perceived knowledge and expertise can significantly influence how the importance of individual parameters is assessed.

When it comes to parameters related to the behaviour of buildings within an aggregate, the comparison of responses from Croatian experts with those from the rest of the world (Figure 6) reveals the most notable difference regarding the influence of adjacent buildings of varying heights. Croatian respondents rated this parameter as less influential, whereas international experts considered it the most significant. This discrepancy reflects the characteristics of the Croatian building stock, which is relatively uniform in both height and number of stories. Consequently, while Croatian experts recognize the relevance of this parameter, they assign it a lower influence, likely due to limited experience with building stocks where such variations are more pronounced.

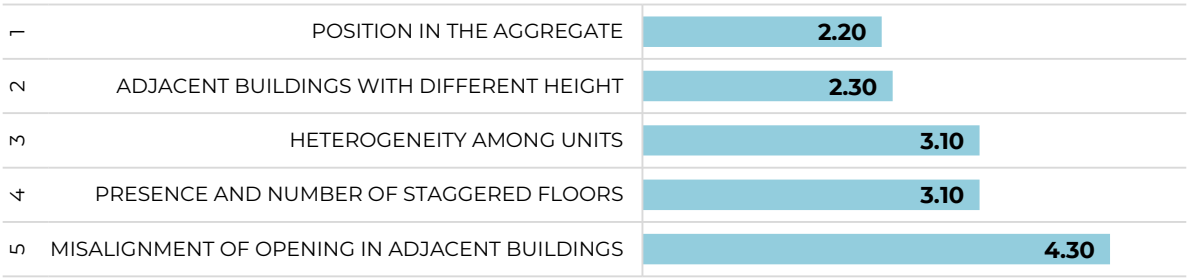

Figure 6 – Investigated aggregate vulnerability parameters and their rankings

In second group of questions, participants rated each group of parameters on a scale from 1 to 5, where 1 indicated low influence and 5 high influence. This question served as a consistency check for the first question. The results show that parameters related to building regularity were considered the most influential, aligning with the findings from the first question and reflecting participants' confidence in their evaluations. The agreement between these independent questions supports the reliability of the collected data and highlights the importance of consistency when assessing the influence of various parameters on the seismic behaviour of buildings.

The final part of the survey comprised nine pairwise-comparison questions, in which participants selected the more influential parameter and assessed its relative importance. As with the previous question, this section acted as a consistency check, given the practical limitations on the total number of questions. The results confirm the hierarchy of parameter influence established in the first question. All compared pairs follow the same ranking, except for the pair Percentage of openings and Maintenance condition, where 55% of participants rated Percentage of openings as more influential, contrary to the initial ranking. This discrepancy is minor, as the two parameters were ranked consecutively in the first question.

Based on the average ratings presented in Figure 5 and Figure 6, the ranking and influence of each parameter were analysed, with their consistency confirmed through responses to the remaining survey questions. To enable direct comparison with parameter influence rankings derived from empirical data using statistical methods, the average scores were normalised and converted into weighting factors (

Table **1**). A similar approach has been applied in related civil engineering studies requiring parameter weighting based on expert judgment (Ortega et al. 2021). Vulnerability index methods (Pinheiro et al. 2015; Ferreira, Vicente, and Varum 2014) typically assign parameter weighting factors ranging from 0.50 to 1.50 in increments of 0.25. Accordingly, weighting coefficients were defined by approximating the normalised regression coefficients to multiples of 0.25. The primary criterion was rounding normalised average scores to the nearest multiple of 0.10, with normalisation limits set between 0.055 (minimum) and 0.085 (maximum). In this study, the methodology was applied inversely: higher average ratings correspond to lower weighting factors, and lower average ratings correspond to higher weighting factors.

Table 1 – *Weight factors according to the survey results*

Number	Parameter	Average rating	Normalized rating	Weight factor
1	Plan regularity	4.9	0.0410	1.50
2	Organization of vertical elements	5.2	0.0436	1.50
3	Distribution of the lateral load-resisting system	5.7	0.0477	1.50
4	Type of material of vertical elements	5.8	0.0486	1.50
5	Height regularity	6.9	0.0578	1.25
6	Type of floor structure	7.1	0.0595	1.25
7	Location and type of foundation	7.1	0.0595	1.25
8	Number of storeys	7.3	0.0611	1.25
9	Maintenance condition	8.6	0.0720	1.00
10	Percentage of openings in the façade	8.7	0.0729	1.00
11	Wall slenderness	8.9	0.0745	1.00
12	Construction details	9.5	0.0796	0.75
13	Wall span	10.8	0.0905	0.50
14	Gable walls	11.4	0.0955	0.50
15	Roof type	11.5	0.0963	0.50
1	Position in the aggregate	2.2	0.1467	1.50
2	Adjacent buildings with different heights	2.3	0.1533	1.50
3	Heterogeneity among units	3.1	0.2067	1.10
4	Presence and number of staggered floors	3.1	0.2067	1.10
5	Misalignment of opening in adjacent buildings	4.3	0.2867	0.50

A notable dispersion is observed among the methods regarding the relative influence of individual parameters. For instance, parameter P2 (material type of vertical elements) is considered highly significant by most methods yet ranked as least important by (Petrini and Benedetti 1984). Similarly, for parameter P4 (configuration of the lateral load–resisting system), methods such as (Ožić 2025; Ortega et al. 2021) and the present survey assign high weights (1.25–1.50), while (Vicente, Varum, and Mendes da Silva.; Ortega et al. 2021) report lower influence. For P10 (maintenance condition), (Petrini and Benedetti 1984)and (Vicente, Varum,

and Mendes da Silva) classify it as highly influential, whereas (Ferreira, Vicente, and Varum 2014; Ožić 2025) assign much lower weights (0.50–0.75).

Some parameters, such as the number of stories, appear only in selected methodologies (Ferreira, Vicente, and Varum 2014; Ortega et al. 2021) and are omitted elsewhere. Wall span shows greater agreement, with most methods assigning medium importance, except Petrini and Benedetti 1984. Conversely, parameter Z1 (gable walls) receives the highest weight (1.25–1.50) in Ožić 2025 but is excluded from several other methodologies.

These findings demonstrate that different approaches attribute unequal significance to the same parameters, highlighting that the choice of method can substantially affect the final assessment. The omission of specific parameters (e.g., gable walls, staircases) indicates that methodologies are not universally applicable but tailored to particular construction typologies or regional conditions. Consequently, selecting a vulnerability assessment method requires careful consideration of the building characteristics and the purpose of the analysis to ensure reliable seismic vulnerability estimation.

Experts' opinions on the relative importance of aggregate vulnerability parameters differ from the weighting factors used defined by existing methods. Existing methodologies are primarily based on Italian or Portuguese building stocks and urban aggregates, where buildings typically share a common wall—a condition not generally present in Croatian buildings. Therefore, the observed differences were expected. For the Croatian context, the presence of adjacent units of different heights carries greater significance than in the Italian case, although in both contexts the position of a building within the row is considered the most influential parameter. Heterogeneity among units holds similar importance in both cases. Additionally, the survey results in the presence of adjacent units with different heights and number of staggered floors being equally important, whereas existing methodologies rank number of staggered floors as one of the least influential parameters. Conversely, the misalignment of openings between adjacent buildings is considered the least influential by the survey participants. These differences primarily reflect the structural distinctions between the building stocks: in Italy, adjacent units commonly share walls, whereas in Croatia, units typically lean against each other without structural interconnection

4. Conclusion

Numerous methodologies have been proposed for assessing the seismic vulnerability of historical URM buildings, all of which carry inherent advantages and limitations.This study aimed to identify key parameters influencing the seismic vulnerability of Croatian historic URM buildings and determine their relative importance through expert judgment. Although methods from other regions, particularly Italy, have been applied due to typological similarities, post-earthquake observations revealed discrepancies between predicted and observed damage. Croatian URM buildings exhibit unique features, and limited local earthquake data make empirical vulnerability functions underdeveloped, highlighting the need for region-specific assessment.

An online survey with 111 experts in earthquake engineering and masonry structures provided quantitative insight into parameter importance. Results showed high consistency among experienced experts and across academic and industry groups. Differences between Croatian and international respondents reflected regional variations in aggregate configuration and structural connectivity.

Still, these findings demonstrate that expert opinion is a valuable complement to empirical and analytical data in defining parameter weights for rapid assessment tools tailored to Croatian URM buildings. While the proposed weighting scheme provides a consistent expert-based framework, future work should also address its calibration against alternative weighting approaches and observational evidence. In this context, the derived weights could serve as an initial basis for calibrating existing vulnerability assessment methodologies, ensuring their adaptation to the specific characteristics of Croatian URM buildings and improving the reliability of rapid assessment tools through data-driven refinement of parameter

importance. Future work should further focus on systematic post-earthquake data collection and the development of national databases to support empirically grounded, locally adapted fragility functions and more robust vulnerability assessments.

Acknowledgments

This research is funded by the Institutional project POTEPUH, Vulnerability Assessment of Traditional Unreinforced Masonry Buildings in Aggregates in Croatia, project leader: Mislav Stepinac.

Abstract: Historic buildings represent a fundamental part of cultural heritage, as they reflect cultural, economic aspects and construction techniques characteristic of different historical periods. The preservation of these assets largely depends on knowledge of their construction characteristics, which can be achieved through the application of non-destructive testing, enabling the investigation of these structures without compromising their integrity and thereby supporting documentation, diagnosis, and maintenance actions. Furthermore, the integration of different diagnostic data becomes essential for a more comprehensive and reliable understanding of these structures. In this context, the use of artificial intelligence techniques has become increasingly relevant, as it optimizes processes and stages that require time and specialized interpretation, making analyses more efficient and systematic. Thus, this study aims to integrate a digital model based on a point cloud with radargram data interpreted through machine learning techniques. The study was carried out at the Church of São Sebastião, located in the municipality of Russas, Ceará, Brazil. Ground Penetrating Radar (GPR) surveys were conducted on internal and façade masonry, with the objective of identifying interfaces, construction layers, moisture presence, and other anomalies. The methodology was structured into five main stages: (i) selection of the building under study; (ii) data acquisition using GPR, laser scanning, and photogrammetry; (iii) development of the HBIM digital model based on the point cloud; (iv) application of machine learning techniques for the automatic detection of patterns in radargrams; and (v) integration of GPR data into the digital model. The results indicate the potential of the proposed approach for understanding the construction systems of historic buildings, highlighting the importance of integrating these data into a digital environment as a supporting tool for heritage conservation and management.

Keywords: Non-destructive testing; GPR; HBIM; Machine learning; Cultural heritage.

1. Introduction

Historic buildings represent a cultural heritage of great relevance to society, reflecting architectural, historical, and social characteristics over time. The proper preservation of these structures largely depends on technical knowledge of their construction features and the availability of historical documentation. However, this task represents a significant challenge, mainly due to the complexity of the construction techniques employed and the limited or nonexistent technical records (Binda e Saisi, 2001; Mesquita et al., 2016).

In this context, non-destructive testing (NDT) techniques are the most suitable for diagnosing historic heritage, as they consist of methods that do not cause physical or chemical alterations to the analyzed asset (Binda e Saisi, 2001). Among these techniques, three-dimensional laser scanning has been widely used to obtain accurate geometric data, enabling the generation of point clouds and digital models that faithfully represent the building geometry. This geometric representation is fundamental for heritage

documentation, as it serves as a basis for broader conservation-related processes (Parente et al., 2025). However, although this technique is effective for surface geometry, it does not provide information about the internal composition of structural elements. To overcome this limitation, several non-destructive techniques have proven effective in characterizing internal features, among which Ground Penetrating Radar (GPR) stands out as one of the most advanced technologies in civil engineering, with increasing application in the conservation of historic monuments (Annan, 2003; Jasieńko, Raszczuk e Frąckiewicz, 2024).

GPR is a geophysical method based on the propagation of electromagnetic waves in natural (geological) and artificial environments (masonry and concrete), detecting contrasts between materials with different dielectric properties. The equipment operates using transmitting antennas, which emit pulses, and receiving antennas, which capture signals reflected by embedded components. The results of these tests are two- or three-dimensional images of the captured reflections, known as radargrams (Carrik, 2017; Alvarado et al., 2025).

Despite its potential, the interpretation of GPR data is complex, especially in historic structures characterized by high material heterogeneity and a wide variety of construction patterns (Parente et al., 2025). The analysis requires operator expertise and careful definition of acquisition parameters, making the process time-consuming and labor-intensive (Pérez-Gracia et al., 2012; Ludeno et al., 2020). In this regard, Parente et al. (2025) highlight the need for process automation in the field of cultural heritage through the use of artificial intelligence, given the increasing volume and complexity of diagnostic data (Parente et al., 2025).

In recent years, advances in computational techniques have driven the application of machine learning models for radargram interpretation. These approaches enable the automatic recognition of disturbance patterns, construction interfaces, and structural anomalies, reducing subjectivity and optimizing the analysis workflow (küçükdemirci e sarris, 2022; Banfi e Liu, 2026; Li, Chiabrando e Sammartano, 2026). However, recent studies indicate that artificial intelligence applications in GPR data are predominantly focused on signal processing and the recognition of hyperbolic patterns in B-scans, typically associated with the detection of objects or localized discontinuities (Küçükdemirci e Sarris, 2022). Furthermore, most research focuses on AI applications for detecting thickness variations and pavement damage (Gao *et al.*, 2020; Li et al., 2021), archaeological investigations (Küçükdemirci e Sarris, 2022), detection of buried elements (Qiu et al., 2022), and concrete structures (Küçükdemirci e Sarris, 2022; Yuan, Yuan e He, 2024; Banfi e Liu, 2026). The exploration of more complex construction patterns, particularly in masonry and flooring systems of historic structures, remains limited.

At the same time, Historic Building Information Modeling (HBIM) has emerged as a relevant tool for digital heritage documentation, enabling the organization of geometric, historical, and diagnostic information within an integrated environment. Recent studies by Banfi (2026) demonstrate that HBIM has experienced a significant technological shift since 2019, evolving from a focus primarily on geometric surveying to encompassing intelligent heritage management (Banfi e Liu, 2026). In this context, several studies have explored HBIM as an interdisciplinary tool for integrating historical, geometric, and non-destructive testing data. In some cases, NDT techniques and artificial intelligence approaches have been associated with digital models to enrich building information (Solla et al., 2020; Coli et al., 2022; Cardinali *et al.*, 2023).

Despite the advances observed in recent decades, both in HBIM development and in the application of artificial intelligence techniques for GPR data processing, significant gaps remain in these approaches, particularly regarding the lack of standardized methods for structured information storage (Celli e Ottoni, 2023; Parente et al., 2025). Moreover, Parente (2025) highlights that most HBIM research focuses on the geometric definition of models (75.8%), while the characterization of internal structural elements remains one of the least explored areas (18.2%). This imbalance highlights the need for approaches that integrate diagnostic investigations into HBIM environments in a structured manner (Banfi e Liu, 2026), such as those provided by GPR testing.

In this context, the present research proposes an HBIM-based approach focused on the collection and organization of information regarding internal composition and potential pathologies in historic masonry structures. To this end, it integrates three-dimensional geometric surveying obtained through laser scanning with internal characterization performed using GPR testing, combined with machine learning techniques for the automatic identification of disturbance patterns in radargrams. The results are georeferenced within the digital model generated from the point cloud, enabling precise localization of the investigations and the association of diagnostic information with the corresponding structural elements. Thus, the HBIM model evolves beyond a purely geometric representation to incorporate internal information that supports analysis, conservation, and decision-making processes in the context of built heritage.

2. Materials and Methods

Initially, laser scanning surveys were carried out over the entire architecture of the church, with the aim of obtaining the building geometry. This survey enabled the generation of a three-dimensional model, serving as the basis for modeling and integrating the remaining investigative data.

Following the geometric survey, GPR tests were performed to identify construction patterns, characterize internal interfaces, and detect potential pathologies in the investigated areas. Subsequently, the data obtained from GPR underwent processing and the application of machine learning techniques, aiming to support the automated identification of internal features.

After completing the data acquisition and processing stages, the next step consisted of integrating the GPR data into the three-dimensional model of the building. The methodological process was carried out as shown in Figure 1.

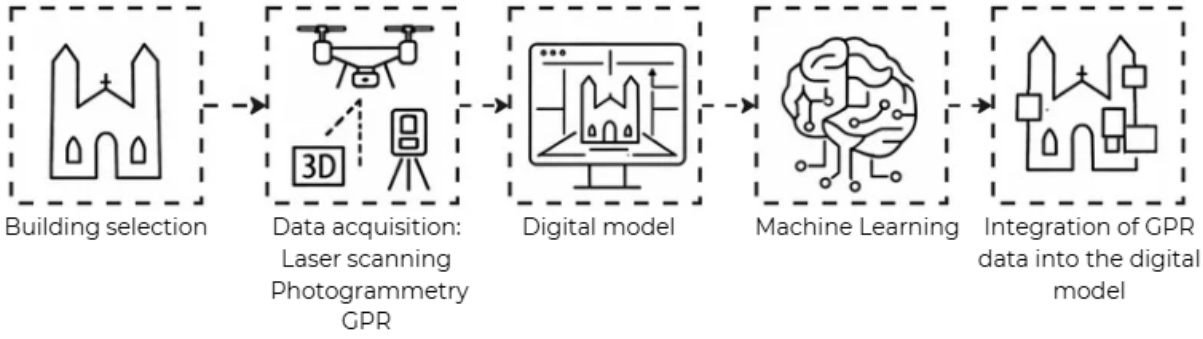

Figure 1: Methodological workflow adopted in the research

2.1 Building selection

The São Sebastião Church, located in the municipality of Russas, in the state of Ceará, Brazil, was selected as the case study for this research due to its significant historical, cultural, and religious value for the region, being considered an important part of the local heritage. In addition, the building preserves architectural elements characteristic of its construction period, particularly its internal space defined by structural arches, the presence of an altar, and ornamental features that retain original characteristics, allowing for a better understanding of the construction techniques employed.

Its origin dates back to the 19th century and is directly associated with significant historical events of that period, during which the region experienced severe drought and epidemic outbreaks, leading to the emergence of popular devotion to Saint Sebastian. In this context, the church was built in 1872 and has since played a central role in the religious and cultural expressions of the community, particularly during festivities dedicated to its patron saint (Araújo, 1986; Novenário de São Sebastião, 1996).

he church is constructed of brick masonry and has undergone localized maintenance and improvement interventions over time. Records indicate that the building has been subject to renovations over the years, including plaster restoration, replacement of deteriorated elements, and improvements to both interior and exterior finishes (Araújo, 1986; Novenário de São Sebastião, 1996). Figure 2 presents the church in its current condition, including its location, façade, and internal environment.

Figure 2: Church of São Sebastião – Russas/CE

2.2 Data acquisition

2.2.1 Laser Scanning and Photogrammetry Survey

The geometric survey of the building was carried out in two distinct stages, starting with laser scanning and subsequently using an unmanned aerial vehicle (drone), both of which served as the basis for the building modeling.

The laser scanner used was the portable Leica BLK2GO, a lightweight and wireless device with a height of 279 mm, a diameter of 80 mm, and an approximate weight of 775 g. It presents a relative accuracy ranging from 6 to 15 mm and an absolute accuracy of approximately 20 mm. The acquisition system consists of three main components: a portable LiDAR scanning sensor, a fixed reference unit, and a mobile device used for real-time visualization and monitoring of the data acquisition.

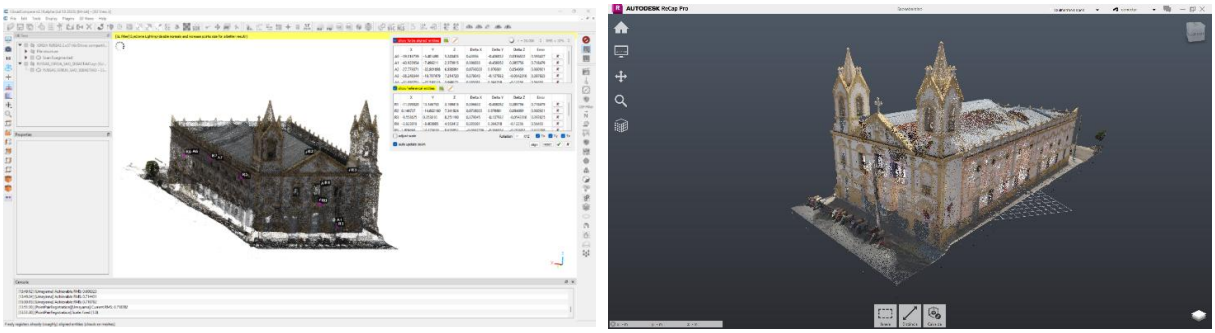

Figure 3: Integration of point cloud and photogrammetry data in CloudCompare software

During the survey, the fixed unit was positioned at a strategic location inside the building and remained stably mounted throughout the acquisition process. The portable BLK2GO sensor was manually operated through continuous walking along the building, while the mobile device connected to the system enabled real-time visualization of the generated point cloud, allowing for monitoring of data quality and adjustments to the acquisition path when necessary.

Following this stage, photogrammetry was performed using an unmanned aerial vehicle (UAV), specifically the DJI Mavic 3T, equipped with an integrated camera, to capture aerial images of areas with difficult access, such as the roof and façade of the church.

The processing of the point cloud obtained from the laser scanner was carried out using Cyclone Register 360 software. The photogrammetric processing using the UAV was conducted in RealityScan 2.1.0, which generated a point cloud from the captured images. After generating the internal and external point clouds of the building, both datasets were integrated using CloudCompare software (Figure 3). Finally, the complete model of the church was exported to Autodesk Revit software to initiate the modeling process and the creation of parameters for data integration into the HBIM model.

2.2.2 GPR Data Acquisition

The investigation of the internal characteristics of the church masonry was carried out using a Proceq GP8000 GPR system, a portable and wireless device with approximate dimensions of 22.1 × 18 × 14 cm and a weight of 1.5 kg, suitable for handling on vertical surfaces. The equipment operates with a central frequency antenna of 2000 MHz, appropriate for the investigation of shallow structures and for achieving high spatial resolution, allowing the identification of internal construction details (Elkarmoty et al., 2024; Jasieńko, Raszczuk e Frąckiewicz, 2024).

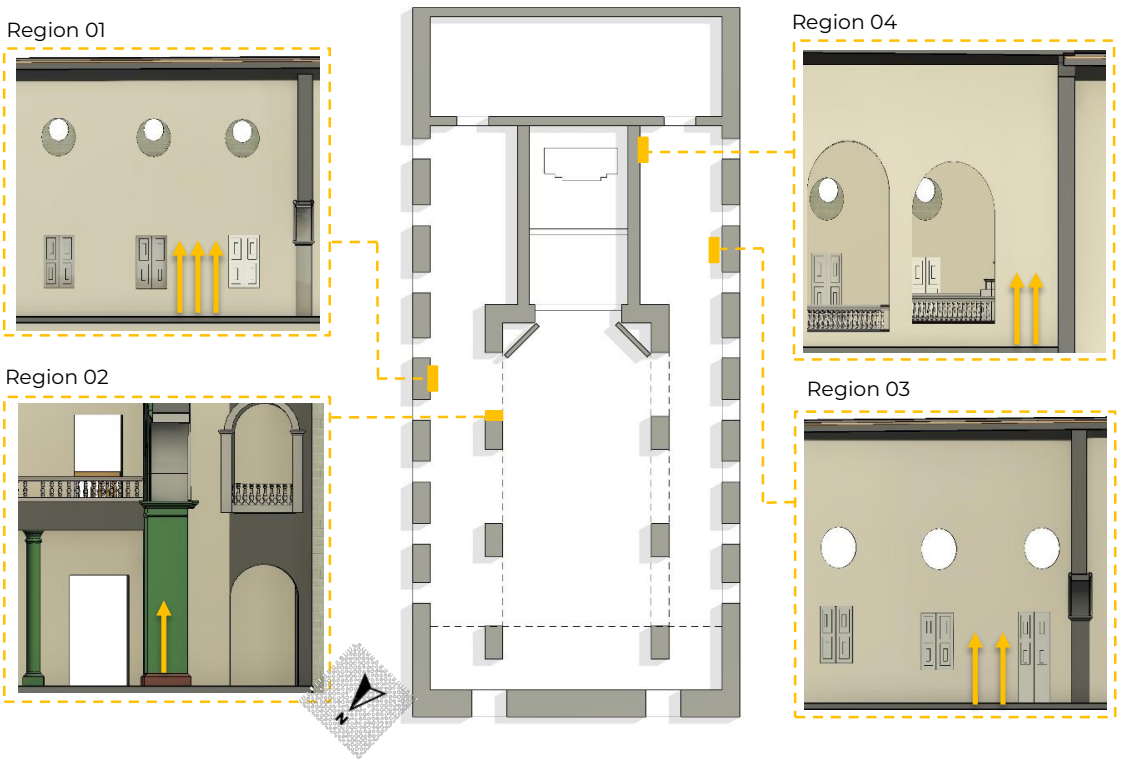

Figure 4: Floor plan showing the locations of GPR data acquisition on the church walls

Prior to data acquisition, the locations to be investigated were defined in order to cover different areas of the church. Four distinct regions of walls and pillars were selected with the aim of identifying construction patterns, interfaces between materials, and potential internal anomalies. In total, nine data acquisitions were performed, comprising three tests in Region 01, teste in Region 2 and two tests in each of Regions 03 and 04, as shown in Figure 4.

During data acquisition, the equipment was moved continuously and in a controlled manner along the surfaces, maintaining a uniform speed and consistent contact with the surface. The scanning profiles were carried out along vertical lines, starting from the base of the walls and extending up to approximately 1.60 m in height. This limit was defined based on the operator's reach and the area of interest, particularly with respect to the analysis of possible moisture-related phenomena at the base of the walls.

Subsequently, the raw signals were processed using Proceq GPR software through procedures such as noise filtering and depth adjustment based on the assumed dielectric constant, with the aim of reducing interference and noise while enhancing the received signal.

2.3 Digital Model

The modeling stage began with the import of the point cloud in RCP format into Revit, which served as the basis for the construction of the building's geometric model. Within the modeling environment, the simultaneous use of different views, plans, sections, and elevations, was adopted, allowing greater accuracy in the interpretation and modeling process based on the point cloud. Through this approach, it was possible to reconstruct the architectural elements while respecting their actual shape, position, and proportions. Part of the structural elements was represented using system families available in the software, while specific elements characteristic of the church and not included in the standard libraries were modeled using custom families.

The adopted level of development can be classified as LOD 300, in which elements are represented with correct dimensions, morphology, position, and orientation, enabling direct measurements within the model and the integration of non-graphical data (Cardinali *et al.*, 2023). According to Celli and Ottoni (2023), this level of detail is appropriate for HBIM models focused on data integration, where the objective is not to fully replicate the building geometry, but rather to maintain an adequate level of detail to distinguish individual architectural elements (Celli e Ottoni, 2023). Figure 5 illustrates the three-dimensional model of the building developed in Revit.

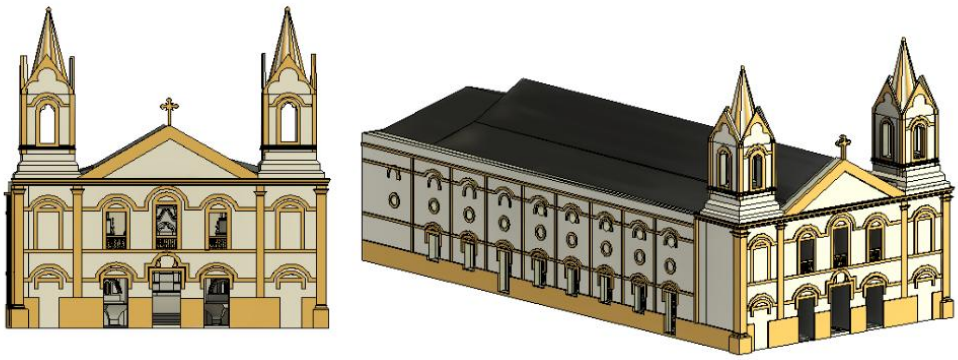

Figure 5: 3D modeling of the church in Revit software

2.4 Machine Learning

The methodology was based on the application of the YOLO (You Only Look Once) algorithm for the automatic detection of patterns in images. Initially, the computational environment was configured in Python, and an image dataset was constructed using images selected from open-source platforms such as Flickr, Unsplash, and Pexels. The images were annotated using the LabelImg tool, considering three main classes: interfaces between layers, regions associated with moisture, and potential voids (Figure 6a). The annotations were exported in .xml format and subsequently converted into a format compatible with the YOLO model within the Python environment.

The training process was carried out using a dataset of 174 annotated images, enabling the model to learn visual patterns associated with the defined classes. After training, a preliminary validation was performed

using the annotated images themselves, in which the model demonstrated consistent detections aligned with the manual annotations (Figure 6b).

Finally, the trained model was applied to radargram images from the São Sebastião Church that were not included in the training dataset.

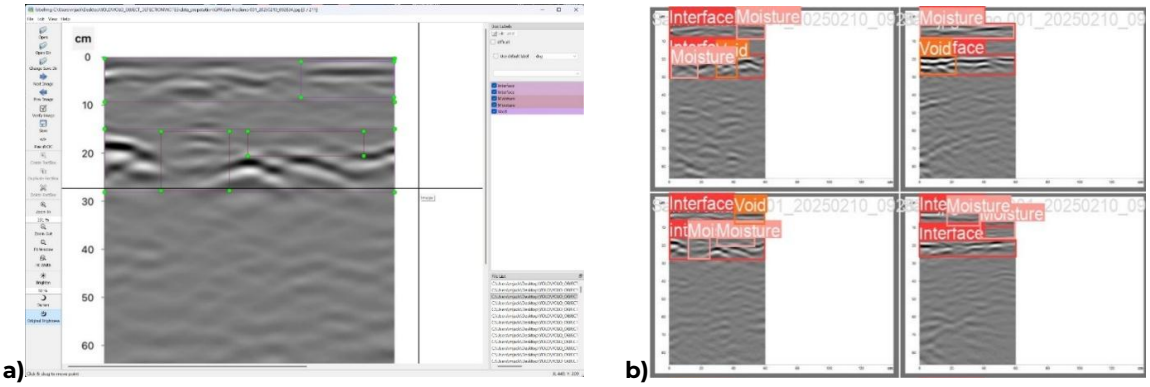

Figure 6: (a) Annotation of patterns using bounding boxes; (b) Model validation.

2.5 Integration of GPR Data into the Digital Model

The creation of informational content begins with the insertion of GPR test data into the HBIM model, respecting the actual size and location of the test execution within the structure.

The workflow starts with the modeling of a generic model component using the extrusion tool in Revit. This element was modeled according to the dimensions of the investigated section, where the height of the extrusion corresponds to the extent of the scanning line, the width corresponds to the signal penetration depth obtained from the test, and a representative thickness of 2 cm was adopted to avoid excessive interference with the model.

Once the geometric base was established, the insertion of GPR data was carried out using the *decal* tool. This command allows 2D images, such as radargrams, to be applied directly onto model surfaces. Through scale and rotation adjustments, the radargram is manipulated so that its boundaries exactly match the edges of the created object, ensuring the real scale of both the signal depth and extent (Figure 7). This process eliminates distortions in spatial interpretation and ensures that the detected anomalies are represented in their actual positions.

Finally, the element composed of both geometry and radargram is positioned within the overall geometry of the church, being inserted precisely at the location where the test was performed.

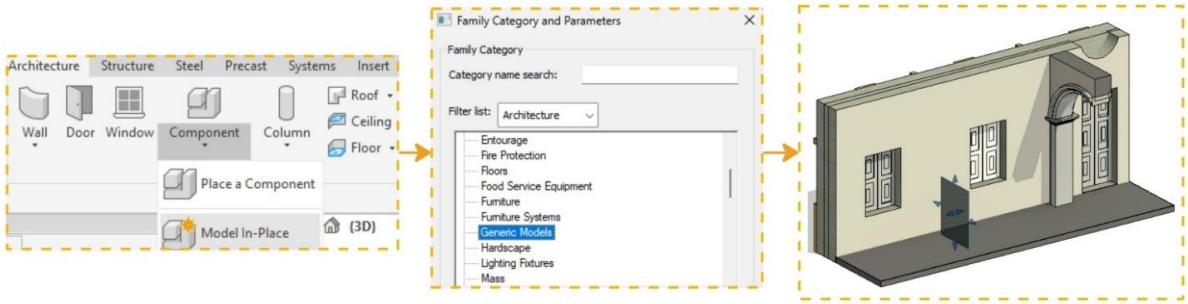

Figure 7: Modeling process of the generic model for radargram placement

3. Results

3.1 Machine Learning

Figure 8 presents the main radargrams obtained across the different investigated surfaces. In Figure 8a, in the near-surface region (0–10 cm), continuous high-amplitude reflections can be observed, associated with interfaces between masonry construction layers. Below this region, at depths between approximately 10 and 40 cm, a more heterogeneous pattern is identified, characterized by irregular reflections, possibly related to the presence of moisture.

When GPR is applied to materials with high moisture content, two main behaviors may be observed. In the first, the electromagnetic wave propagates through a highly conductive medium, undergoing strong attenuation and a consequent significant reduction in signal amplitude. Under this condition, the ability to detect internal interfaces is reduced, and some anomalies may become imperceptible in the radargram. In the second behavior, an increase in reflection amplitude is observed, which occurs when there is contrast between regions with different moisture contents, such as interfaces between dry and wet zones. The greater the difference in dielectric constant between these media, the stronger the reflection intensity (Pérez-Gracia et al., 2022).

The application of the machine learning model in Figure 8a enabled the identification of the near-surface interface with high reliability, correctly highlighting its continuity along the profile. In addition, regions associated with moisture near the surface were detected and highlighted by the bounding boxes generated by the model. However, the model showed limitations in interpreting deeper regions, as indicated by the white and orange arrows. The region marked by the orange arrow presents isolated disturbances without continuity, likely associated with the transition between wetter and drier zones. In contrast, the region indicated by the white arrow exhibits typical patterns of highly saturated zones, with significant signal attenuation, resulting in an area with no visible reflections.

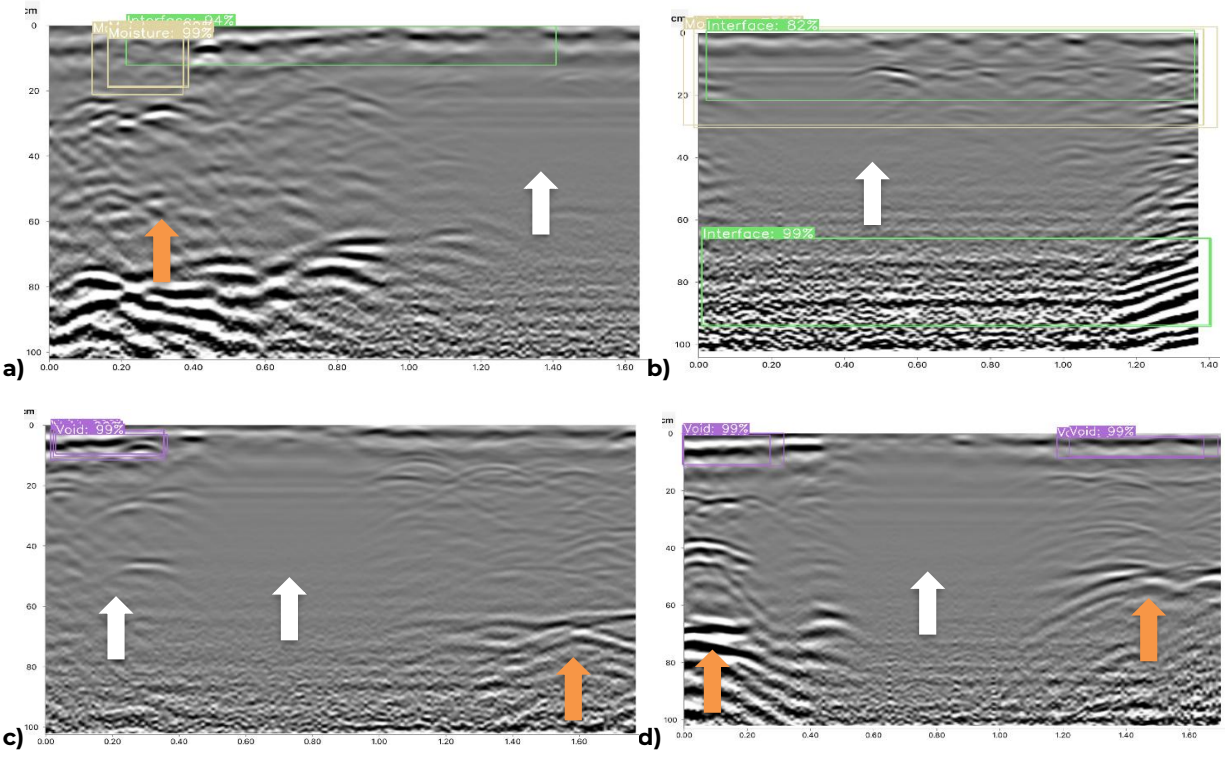

FigurE 8: Detection of radargram reflection patterns using YOLO. (a) Radargram from Region 01; (b) Radargram from Region 02; (c) Radargram from Region 03; (d) Radargram from Region 04.

In Figure 8b, the near-surface region shows continuous reflections of low to medium amplitude, associated with the outer masonry layer. In the intermediate zone, a reduction in signal amplitude is observed, possibly related to the presence of moisture. The machine learning model performed well in identifying the main interfaces, successfully detecting the near-surface interface and indicating moisture-related regions, as highlighted by the bounding boxes in the radargram. However, it did not explicitly identify the intermediate zone characterized by signal attenuation associated with high moisture content (white arrow).

At greater depths, the machine learning model indicated the presence of a new interface in this region. However, analysis of the radargram suggests that this response is associated with signal energy loss during propagation rather than a real physical interface, as incorrectly detected by the model.

The radargrams presented in Figures 8c and 8d show, in the near-surface portion (approximately 0–15 cm), medium- to high-amplitude reflections associated with the outer masonry layer. In Figure 8c, a region in the upper left area stands out, characterized by high-amplitude reflections and strong contrast, associated with the presence of voids or internal discontinuities. In Figure 8d, two regions at the edges of the profile exhibit similar characteristics, also consistent with the presence of shallow voids.

In the intermediate zone of both figures (8c and 8d), a pattern of low amplitude is observed, indicating strong signal attenuation (white arrows), possibly associated with high moisture content. In some portions of this layer, more pronounced reflections can be identified, suggesting the presence of multiple interfaces and internal variations within the structure, although these are not clearly defined due to signal loss in adjacent regions (orange arrows).

3.2 Integration of GPR Data into the Digital Model

Figure 9 presents the insertion of radargrams into the digital model, associated with their corresponding regions of the masonry. It can be observed that each test was represented by an individual element, positioned according to its actual location within the building.

The radargrams were incorporated into the model including the markings of the detected features, allowing direct visualization of the classified regions along the profiles. Detections associated with interfaces, zones of signal attenuation, and potential voids, identified through machine learning, are displayed on the surface of the created generic model, facilitating the visual identification of these characteristics within the context of the building.

In addition to the graphical representation, each radargram inserted into the model contains a set of associated information. These data can be accessed directly through the Revit properties panel by selecting the corresponding element. Among the available information are: profile identification, acquisition date, and the model and frequency of the equipment used.

To enhance the visualization of radargrams within the model, the “Hide in View” command can be applied to the masonry elements, allowing the test-representative object and its associated information to be clearly visualized without interference from other structural components.

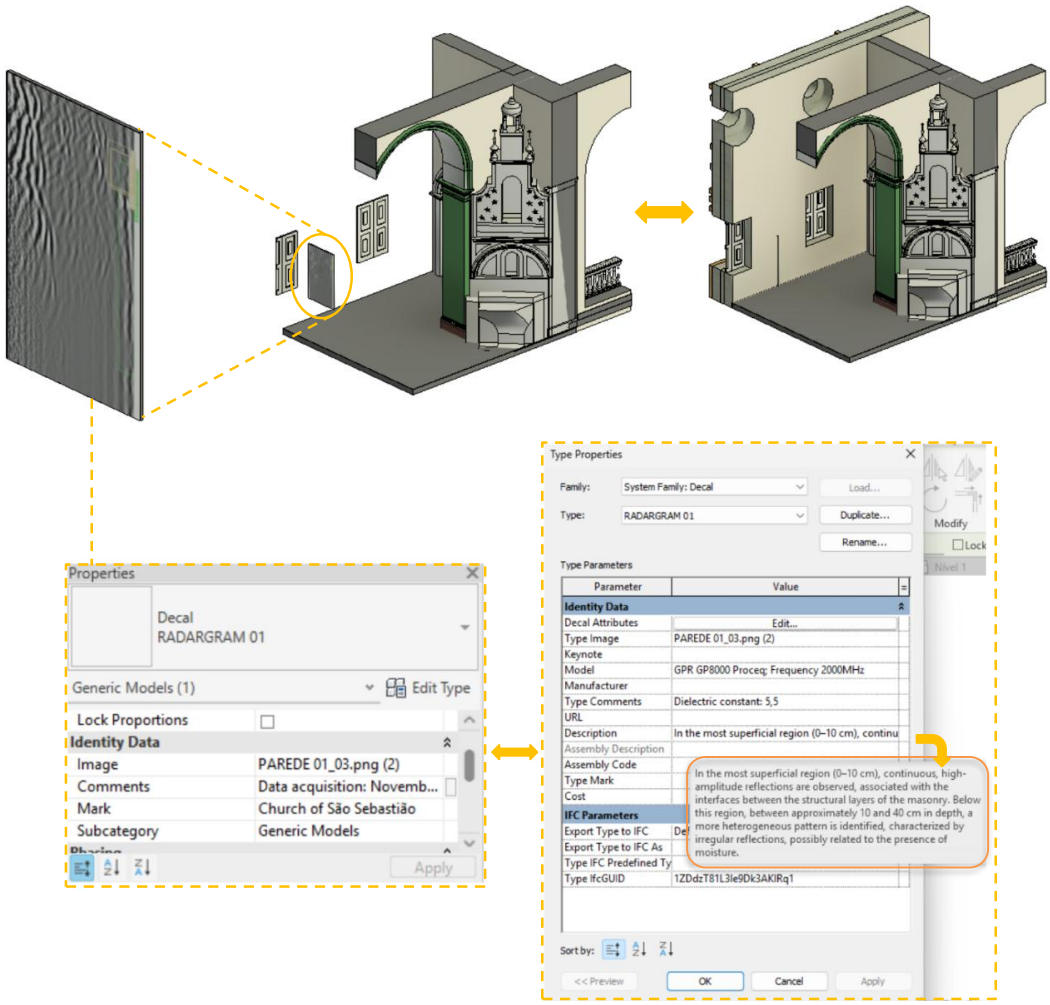

FigurE 9: Data Integration in the HBIM Environment

4. Conclusion

The present research aimed to apply machine learning techniques for the automatic detection of interfaces, moisture zones, and potential voids in GPR tests applied to historic masonry structures. Additionally, the obtained data were integrated into a digital environment, in which the building geometry was reconstructed from point cloud data, enabling the spatial representation of the test results.

The results obtained from GPR tests demonstrated the high capability of the method to identify internal interfaces and reflections, even in structures characterized by high complexity, such as historic masonry. Factors such as operator expertise, type of equipment used, and signal processing procedures are fundamental to achieving more reliable results.

The incorporation of machine learning techniques, through the YOLO model, proved to be effective in the automated detection of the analyzed features, enabling the identification of relevant patterns in radargrams with greater speed and consistency. However, it was observed that the model performance is directly influenced by the quality, diversity, and representativeness of the training dataset, as well as by the complexity of the investigated medium. In scenarios characterized by high material heterogeneity and overlapping reflections, limitations in the detection process were identified, with the occurrence of regions in the radargrams not recognized by the model.

These results highlight the need to improve the dataset and adopt more robust training strategies to enhance detection capability and accuracy in complex contexts. Despite these limitations, the model demonstrated promising performance, indicating that machine learning techniques can serve as a reliable support tool for the interpretation of GPR data in masonry structures.

The integration of results into the HBIM environment proved to be highly effective, allowing the association of geometric data with diagnostic information in a unified digital model. Furthermore, the data insertion process was found to be simple and easy to implement, not requiring complex procedures, which reinforces the practical feasibility of the proposed methodology. The georeferenced insertion of radargrams and their interpretations enabled the spatial visualization of the identified anomalies, promoting a more intuitive and integrated understanding of the building. This approach expands the role of HBIM as an informational platform capable of storing, organizing, and communicating complex technical data, contributing to more efficient heritage conservation processes.

As future perspectives, the need to expand and diversify the dataset used for training machine learning models is highlighted, aiming to improve their generalization capability and performance in more complex scenarios. Additionally, the potential for integrating data from different non-destructive testing techniques into the HBIM environment is emphasized, allowing the incorporation of multiple layers of diagnostic information into a unified model, which can contribute to more comprehensive, reliable, and management-oriented analyses of historic heritage.

Abstract: This study evaluates the impact of the simultaneous incorporation of waste glass grinding powder (WGP) and *bracejo* fibres (Stipa gigantea) in hydraulic lime mortars (NHL 3.5) for the rehabilitation of wattle and daub walls. The research was based on the hypothesis that combining the pozzolanic nature of WGP with the fibrous structure of *bracejo* (BCJ) could balance the requirements for strength, deformability, and hygrothermal behavior. Matrices with 10% and 30% binder replacement by WGP (by mass) were analyzed, with and without the addition of 2.5% BCJ (by volume). The mortars were characterized regarding workability, open porosity, bulk density, capillary absorption, water vapor permeability, and mechanical strength at 28 days. The results demonstrate that the matrix with 30% WGP showed better rheological compatibility with the fibres, resulting in a more interconnected porous network that enhanced vapor permeability and drying efficiency. Although the fibres reduced compressive strength, the 30% WGP mortars showed the lowest relative loss in flexural strength (only 7%), indicating a superior fibre-matrix interface. It is concluded that the combination of 30% WGP and 2.5% BCJ provides a sustainable and technically viable solution, ensuring substrate "breathability" and the mechanical compatibility required for the conservation of wattle and daub heritage.

Keywords: Lime mortars; Wattle and daub walls; Vegetal fibres; Waste glass grinding powder; Heritage rehabilitation.

1. Introduction

Bracejo (*Stipa gigantea* or *Celtica gigantea*) is a perennial grass with a reduced cross-section, common in dry terrains and medium-altitude areas in Portugal. This plant resource is traditionally exploited through artisanal craftsmanship in basketry and matting, and its use in wattle and daub is part of a vernacular logic as a fibrous filling material, without a primary structural function.

Studies report that the incorporation of plant fibres into lime mortars tends to reduce mechanical strength, although it improves shrinkage and cracking control, strain energy dissipation capacity, and porosity regulation, facilitating the "breathability" of the substrate. In contrast, literature on the incorporation of ground flat glass waste highlights, under certain conditions, strength gains primarily associated with its pozzolanic activity and, complementarily, to filler effects.

In this framework, it is hypothesized that the combination of *bracejo* (BCJ) and waste glass grinding powder (WGP) can generate a synergy capable of balancing conflicting requirements in rehabilitation mortars. The objective is not the maximization of strength, but rather the establishment of a compromise between load-bearing capacity, cracking control, and deformable compatibility with wattle and daub walls.

Thus, the present study analyzed hydraulic lime mortar mixes with 10% and 30% binder replacement (by mass) with WGP, and mixes with the addition of 2.5% BCJ (by volume). The mechanical performance of these

compositions was evaluated, as well as open porosity, bulk density, capillary water absorption, permeability, and drying index. The results indicate the compatibility of the mortars with regulatory requirements, contributing to the development of sustainable and technically suitable solutions for the conservation of wattle and daub heritage.

1.1 State of the Art

Lime mortars have been widely used in the rehabilitation of traditional construction systems, particularly in vernacular techniques such as wattle and daub walls, due to their mechanical compatibility, high vapor permeability, and deformation capacity (Ayat et al., 2022; Soares et al., 2021). In recent decades, there has been a growing interest in improving the performance of these mortars through the incorporation of industrial waste and bio-based materials, aiming for both sustainability and compatibility with historical substrates (Ruffolo et al., 2025; Rubio-Aguinaga et al., 2025).

The use of finely ground glass powder as a partial binder replacement has been the subject of several studies. Literature indicates that, when properly processed, glass exhibits pozzolanic activity, contributing to the formation of additional cementitious compounds and the increase of mechanical strength. Additionally, glass particles act as a filler material, promoting the refinement of the pore structure. However, the magnitude of these effects depends on particle size, replacement ratio, and curing conditions, with replacement levels between 10% and 30% frequently identified as ideal for balancing mechanical performance and durability (Aliabdo et al., 2016; Tironi et al., 2012; Velosa et al., 2009).

Nevertheless, the incorporation of waste specifically from the flat glass grinding process (WGP) remains poorly explored. In a recent study, Santos et al. (2024) observed that partial replacement of Portland cement with up to 10% WGP does not compromise compressive strength and may even increase it when the material replaces the aggregate, in addition to reducing capillary absorption and shrinkage.

Parallelly, the inclusion of lignocellulosic materials, such as BCJ, has been explored to confer toughness to lime matrices. These materials are characterized by low density and a flexible structure, although their incorporation generally results in an increase in porosity and a reduction in compressive strength due to the introduction of less rigid phases and weaker interfaces. In contrast, they offer critical advantages in shrinkage control and strain dissipation capacity, while also favoring vapor permeability and drying efficiency (Arizzi and Cultrone, 2012).

From a microstructural perspective, the distribution and connectivity of pores play a decisive role. In systems combining dense mineral additions (such as WGP) and absorbent plant inclusions (such as BCJ), the pore network may become less connected, influencing water and vapor transport differently from total porosity (Soares et al., 2025; Poyet, 2021).

Despite the individual potential of these materials, their combined use in lime mortars for rehabilitation is still incipient. This combination may originate synergistic or competing effects: while mineral additions refine the structure, plant materials expand it (Zicarelli et al., 2025). The present study contributes to filling this gap by analyzing hydraulic lime mortars with the simultaneous incorporation of WGP and BCJ. The objective is to sustain that the performance of these hybrid mortars results from a complex equilibrium that prioritizes compatibility with the original wattle and daub system, ensuring permeability, compatible strength, and reduction of cracking.

2. Experimental Campaign

The investigation was carried out in the laboratories of the Institute for Research and Technological Development in Construction, Energy, Environment and Sustainability (ITeCons), with the support of the Departments of Civil Engineering and Geosciences at the University of Aveiro. The study was structured into two main phases:

2.1 Preparation of Materials and Characterizations

The waste used (R3) consists of the powder obtained from the dehydration of the residual sludge generated during the industrial grinding of flat glass (including tempered, laminated, and common glass). The material was collected in a wet state directly from the sedimentation basins of the company Beiraglass (Oliveira de Frades, Portugal). Although the industrial process uses the flocculant FLOC AC 9S for water clarification, its volatile nature, combined with the rigorous laboratory drying process, ensures the integrity of the final material. This condition is corroborated by the low Loss on Ignition values (LOI < 3.6%) obtained in the chemical characterization, indicating the absence of significant organic residues in the precursor.

To obtain the powder, the sludge was oven-dried at 70°C ± 5°C. until constant mass. Due to the high fineness intrinsic to the grinding process, the material did not require laboratory grinding and was used directly after drying. The characterization of R3 included X-ray Fluorescence (XRF), Laser Diffraction Particle Size Analysis, and the determination of chemical reactivity through the Modified Chapelle Test.

The BCJ employed was provided by the Historical Villages of Portugal Tourism Development Association. The material was initially fragmented into lengths of less than 3 cm and subsequently subjected to an immersion treatment in a saturated calcium hydroxide solution [$Ca(OH)_2$] for 24 h in an airtight container. This procedure aims to remove impurities and extractables from the leaf surface, promoting modifications that favor the interface between the fibrous phase and the lime matrix (Siouta et al., 2024). After treatment, the BCJ was washed with running water, oven-dried at 70°C ± 5°C until constant mass and characterized by XRF and water absorption tests following a standard operating procedure (SOP) specifically developed for this study.

The binder used was a natural hydraulic lime (NHL 3.5), certified according to the EN 459-1 standard. As an aggregate, natural pit sand (Miranda do Corvo) was adopted in accordance with EN 13139, characterized through sieve-based particle size analysis.

To ensure the workability of the mixtures, a third-generation polycarboxylate-based (PCE) superplasticizer, Sika® ViscoCrete®-3003, was used. This admixture acts through surface adsorption and steric hindrance, allowing for a high reduction in mixing water and the maintenance of consistency without the introduction of chlorides.

2.2 Characterization of Mortars – Fresh and Hardened State

The molding of the prismatic specimens (40 ± 1) mm × (40 ± 1) mm × (160 ± 1) mm was performed in standardized metallic molds according to the EN 1015-11 standard. Workability was adjusted through the flow table test (EN 1015-3), ensuring consistency suitable for application in wattle and daub. Four distinct formulations were produced, organized into two series:

- **R3 Series (Mineral Matrices):** Mortars with partial replacement of hydraulic lime (NHL 3.5) by glass waste (R3) at levels of 10% and 30% (by mass), without fibre addition.
- **BCJ Series (Hybrid Mortars):** Produced by adding 2.5% (by volume) of BCJ to the matrices of the previous series. In these mixtures, an additional amount of water was included to compensate for the intrinsic absorption of the fibres, as previously determined by the SOP procedure, thus keeping the matrix workability constant.

Due to the slow initial hardening kinetics of natural hydraulic lime, demolding occurred after 48 h, a procedure provided for in the EN 1015-11 standard to ensure the physical integrity of the specimens. The total curing regime lasted 28 days, comprising an initial period of 7 days in hermetically sealed plastic bags (favoring the hydration of hydraulic phases), followed by 21 days in a controlled environment with a temperature of (20 ± 2) °C and relative humidity of (65 ± 5) %, conditions that promote the progressive carbonation of the lime.

The reported results correspond to the average values obtained from three specimens for the mechanical strength tests, four specimens for the water vapor permeability tests, and six specimens for the remaining tests.

The symbology used for specimen identification was as follows: SUS corresponds to the project abbreviation; R3 refers to the sludge glass residue; L indicates that the substitution was applied to the binder; and B indicates the use of *bracejo* fibers.

For example, SUS-R3LB-10% corresponds to a mortar containing sludge glass residue, with a 10% binder substitution and the incorporation of *bracejo* fibers.

3. Preliminary Results and Analysis

3.1 X-Ray Fluorescence (XRF)

The elemental chemical composition of both WGP-R3 and BCJ was determined by XRF, with the main mineral oxides presented in Figure 1. The tests were conducted following the protocols of the Materials and GeoResources Laboratories (I and II) at the University of Aveiro.

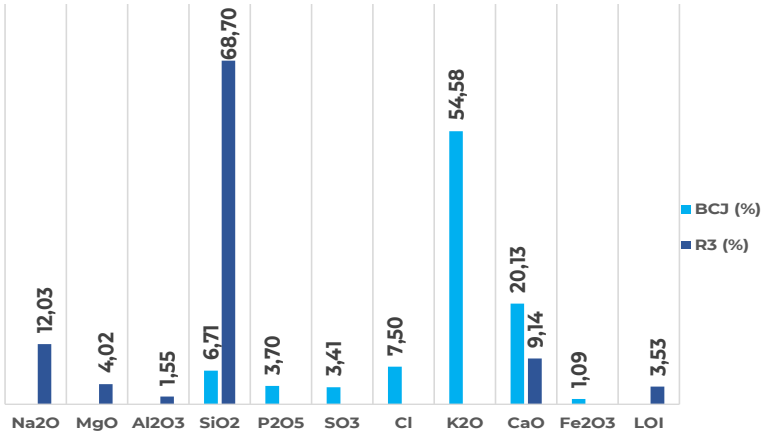

Figure 1 - Chemical Composition of Materials

Regarding R3, the results confirm a predominance of silica (SiO_2 = 68.70%), which may be a key element for the expected pozzolanic reactivity, if it is in the amorphous state. Furthermore, Na_2O (12.03%) and CaO (9.14%), contents were identified, which are characteristic of common soda-lime glasses. The low Loss on Ignition value (LOI = 3.53%) corroborates the effectiveness of the previous thermal treatment in eliminating volatiles, ensuring the integrity of the mineral precursor.

As for the BCJ, chemical analysis reveals that the residual mineral phase is primarily composed of potassium oxide (K_2O = 54.58%) and calcium oxide (CaO = 20.13%). It is essential to emphasize that these values represent the normalized distribution of oxides within the inorganic fraction, which typically constitutes a small percentage (usually <20%) of the total lignocellulosic fiber mass. Since Loss on Ignition (LOI) was not performed for this specific sample to quantify the organic/inorganic ratio, these results should be interpreted as a qualitative indicator of the mineral species present in the fibre's structure.

3.2 Pozzolanic Activity of WGP (R3)

The pozzolanic activity of the WGP-R3 residue was evaluated through the Modified Chapelle test, following the internal procedure LabCIVIL.MAT.PE004 (based on the French standard NF P 18-513).

This method quantifies the initial (rapid) reactivity of the material through its capacity to fix calcium hydroxide [$Ca(OH)_2$].

The obtained value was 814.60 mg of $Ca(OH)_2$ per gram of residue. According to the criteria established by Raverdy et al. (1980) and the guidelines of the NF P 18-513 standard, materials that fix more than 330 mg of $Ca(OH)_2$/g are classified as high reactivity pozzolans. The achieved result, being significantly higher than the normative limit, confirms the high potential of R3 to react with hydraulic lime, contributing to the reinforcement of the matrix through the formation of new cementitious compounds (C-S-H).

3.3 Particle Size Distribution of Aggregate and WGP (R3)

The particle size distribution of the sand (Figure 2) was determined according to the EN 933-1 standard, using the wet sieving method followed by drying and dry sieving. The sand exhibits a continuous and well-graded distribution, falling entirely within the limits specified by EN 13139 for aggregates intended for mortar production.

The particle size characterization of R3 (Figure 3) was obtained by laser diffraction using the Mastersizer 2000 (Malvern) equipment, based on Mie theory. The measurements, performed in triplicate, revealed the following statistical parameters: D_{10} = 2.063 µm, D_{50} = 13.181 µm and D_{90} = 43.283 µm, with a Span of 3.127 e Bulk Density = 716 Kg/m³.

A Span value greater than 2 indicates a broad and diversified particle size distribution. The curve shows an asymmetrical distribution with significant dispersion of particle sizes. The fact that the D_{50} is below 45 µm is a strong indicator of pozzolanic activity potential. This effect is reinforced by the D_{10} value (between 1.9 and 3.7 µm) which confirms a relevant presence of ultra-fine particles, increasing the specific surface area and, consequently, the chemical reactivity of the residue.

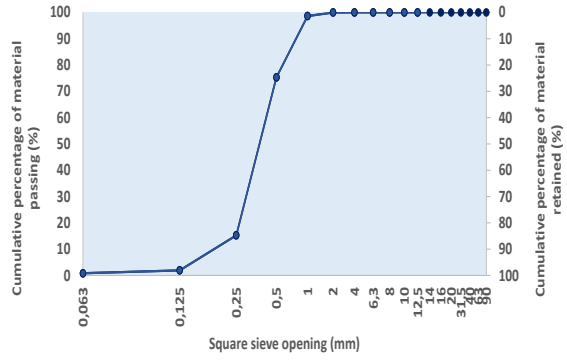

Figure 2 - Sand Particle Size Distribution Curve

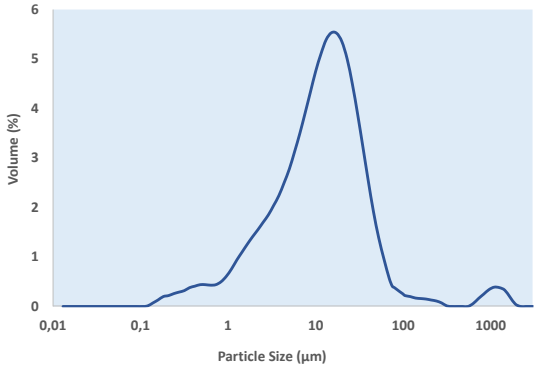

Figure 3 – R3 Laser Diffraction Particle Size Distribution Curve

3.4 Bulk Density

The determination of the bulk density of the materials was carried out in accordance with the EN 1097-3 standard, and the results are presented in Table 1. For contextual purposes, the literature indicates expected ranges between 1,500 and 1,600 kg/m³ for dry sand; between 700 and 800 kg/m³ for natural hydraulic lime (NHL 3.5); and between 740 and 1,250 kg/m³ for ground glass.

Table 1 - Bulk density of materials

MATERIALS	BULK DENSITY $\rho_{b\ (kg/m^3)}$
Fine sand	1509
Hydraulic lime NHL 3.5	700
R3	854

The values obtained highlight significant contrasts between the mixture's constituents. Fine sand exhibits the highest bulk density (1509 kg/m³), which is consistent with its granular nature and particle arrangement. In contrast, the hydraulic lime NHL 3.5 presents the lowest value (700 kg/m³), a characteristic associated with the high fineness of its particles and the larger volume of inter-particle voids in the uncompacted state.

The value observed for WGP-R3 (854 kg/m³) is at an intermediate level, being higher than that of the lime. This difference suggests that the partial replacement of the binder with R3 will promote a change in the overall particle size distribution of the matrix, positively influencing the packing density. Consequently, this variation is expected to impact the water demand for workability, the final porosity, and the mechanical performance of the resulting mortars.

3.5 Flow Spread Consistency

The determination of consistency by flow spread was performed in accordance with the EN 1015-3 standard. The results obtained are systematized in Table 2.

Table 2 - Water-to-binder ratio and Flow spread

Simple	Water-to-binder ratio (w/b) (%)			Flow spread (mm)
	$w_{(R3LP)}/b$	$w_{(BCJ)}/b$	w/b	
SUS-R3LP-10%	52			173
SUS-R3LPB-10%	52	1.25	53.25	157
SUS-R3LP-30%	55			177
SUS-R3LPB-30%	55	1.25	56.25	179

It is observed that all reference formulations (without fibres) presented flow spread values within the target range (175 ± 10 mm). However, the incorporation of BCJ resulted in distinct rheological behaviors depending on the binder matrix.

In the SUS-R3LPB-10% mix, the flow spread was lower than the normative range and the value of its respective reference. In contrast, the SUS-R3LPB-30% mix maintained a consistency practically identical to that of the fibre-free matrix. Since the BCJ underwent rigorous prior conditioning (saturation and drying) and laboratory conditions remained constant, these variations stem from the specific interaction between the fibres and the paste composition.

In the mix with 10% R3, the higher proportion of hydraulic lime (90% of the binder) results in a matrix with a higher specific surface area and inter-particle porosity, which increases the water demand of the matrix. Under these conditions, the introduction of BCJ fibres, even with compensation water, appears to reduce the overall mobility of the system due to the greater entrapment of free water within the lime's porous network.

On the other hand, in the mix with 30% R3, the higher presence of glass powder—a non-absorbent material with a less irregular surface—favors greater availability of free water in the system. This water acts as a lubricant at the fibre-matrix interface, mitigating the internal friction effect caused by the BCJ and maintaining the mortar's fluidity. Thus, it is concluded that the effect of plant fibres on workability is conditioned by the binder matrix's ability to maintain available water for the lubrication of solid inclusions.

3.6 Open Porosity and Apparent Density

The determination of apparent density and open porosity was performed in accordance with the EN 1936 standard. Apparent density is defined as the ratio of the mass of the dry specimen to its apparent volume, while open porosity corresponds to the volumetric percentage of interconnected pores relative to the total volume. The results are presented in Figure 4 and Figure 5, respectively.

The results show that the incorporation of BCJ led to a slight and consistent increase in open porosity across both series (average increment of 3%). Regarding apparent density, a reduction of approximately 2% was observed in the 10% R3 series after the introduction of the fibres, whereas in the 30% R3 series, the values remained practically unchanged.

A combined analysis of these datas with the consistency tests allows for a microstructural interpretation of the system. In the SUS-R3LP-10% series, the introduction of BCJ caused a loss of workability (reduction in flow spread), which hindered compaction and the rearrangement of particles during molding. This phenomenon resulted in less efficient packing, leading to increased porosity and a consequent reduction in density.

In contrast, in the SUS-R3LP-30% series, maintaining fresh-state consistency facilitated molding, allowing the density to remain stable even in the presence of fibres. In these compositions, the increase in porosity (from 20.61% to 21.25%) does not stem from poor compaction, but rather from the intrinsic nature of the plant material and the creation of potentially more porous Interfacial Transition Zones (ITZ) between the fibre and the mineral matrix.

Thus, the results suggest that the impact of BCJ on the microstructure is mediated by the rheology of the binder matrix: matrices with a higher R3 content prove to be more tolerant of fibre incorporation, preserving the density of the hardened material.

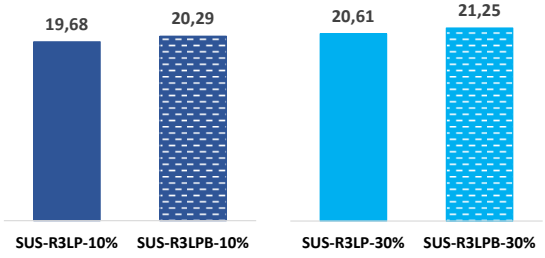

Figure 4 - Open Porosity (%)

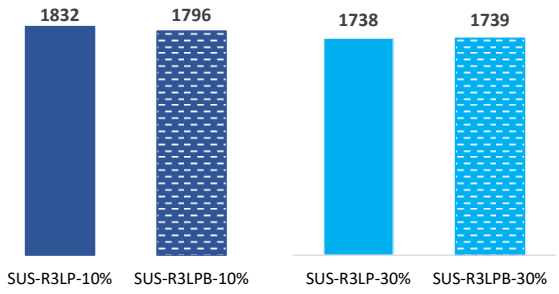

Figure 5 - Apparent Density (Kg/m³)

3.7 Water and Vapor Transport Behavior

The water absorption coefficient by capillarity (A_w) defines the rate of mass absorption per unit area as a function of the square root of time when the material face is in partial contact with water. The tests were performed in compliance with the ISO 15148 standard, and the results are systematized in Figure 6.

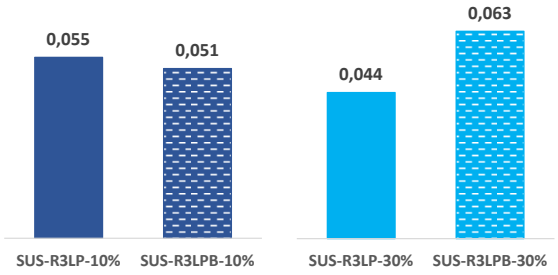

Figure 6 - Water Absorption by Capillarity [kg/(m^2.s$^{0.5}$)]

Data analysis reveals that the incorporation of BCJ influences capillary behavior in contrasting ways depending on the binder matrix. In the 10% R3 series, a slight reduction in the absorption coefficient was observed after the introduction of fibres. In contrast, in the 30% R3 series, the presence of BCJ resulted in a significant increase in this parameter (from 0.044 to 0.063 [kg/(m^2.s$^{0.5}$)]).

It is important to highlight that the reduction in workability observed in the SUS-R3LPB-10% mix is a direct consequence of the adopted methodology, which prioritized maintaining the original matrix's water-to-binder (w/b) ratio by adding only the strict compensation water for the BCJ. It is assumed that if the consistency had been fixed as an invariant parameter (through free adjustment of the mixing water), the microstructural and capillary behavior of this mixture might have resembled that observed in the 30% R3 mix. However, the choice to keep the mix proportions fixed allowed for the identification that the matrix with lower glass content is intrinsically more sensitive to the introduction of plant fibres regarding the maintenance of its internal mobility.

Thus, the results suggest that BCJ alters the connectivity of the porous network differently in each system. In the 10% R3 mix, the lower fluidity of the paste may have induced greater tortuosity or partial blockage of capillary channels by mechanical compression of the particles. Conversely, in the 30% R3 mix, maintaining consistency allowed for a fibre distribution that favored the creation of preferential transport paths. Under these conditions, the fibre-matrix interface and the internal channels of the BCJ appear to act as water conduits, facilitating capillary rise. This effect is particularly relevant for rehabilitation mortars, where moisture transport management is a determining factor for the conservation of wattle and daub substrates.

Water vapor permeability (δ_m) tests were conducted according to the EN 1015-19 and ISO 12572 standards, with results systematized in Figure 7. This property defines the rate of vapor transport through the material per unit of time, area, and pressure gradient, characterizing the "breathability" of the mortar.

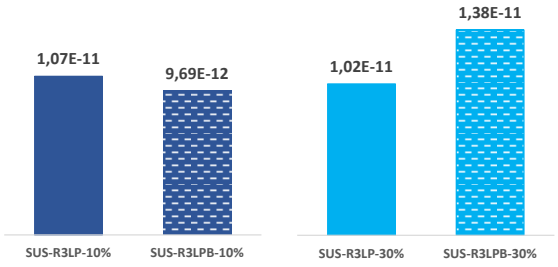

Figure 7 - Water vapor permeability (kg/(m·s·Pa))

The results show distinct behaviors consistent with the capillary absorption observations. In the 10% R3 series, BCJ incorporation resulted in a slight reduction in permeability (from 1.07x10^{-11} to 9.69x10^{-12} kg/(m·s·Pa)). In contrast, the 30% R3 series showed a significant increase in this parameter, reaching 1.38x10^{-11} kg/(m·s·Pa).

.

These data reinforce the previously presented microstructural interpretation: in the mix with lower glass content (10% R3), the porous structure became less connected or more tortuous due to lower matrix workability during molding. Inversely, in the 30% R3 mix, the presence of BCJ and the better fluidity of the paste favored the formation of a more interconnected porous network that is less resistant to diffusion. In this case, the interfaces between the fibres and the mineral matrix seem to function as preferential channels not only for liquid water but also for vapor flow, optimizing the hygrothermal performance of the mortar in wattle and daub systems.

Drying tests were performed following the RILEM II.5 recommendation and the EN 16322 standard to evaluate water evaporation kinetics. The Drying Index (I_s), presented in Figure 8, quantifies the material's

overall resistance to moisture loss, while the Knick Point (Table 3) identifies the transition between the constant drying rate period (surface evaporation) and the falling rate period (internal transport).

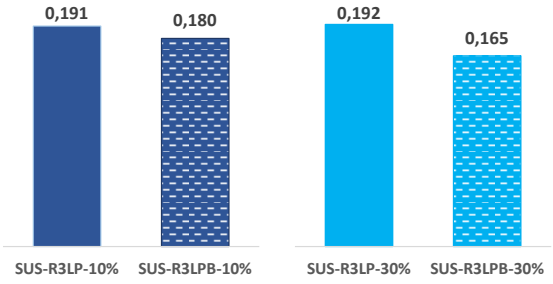

Figure 8 - Drying Index

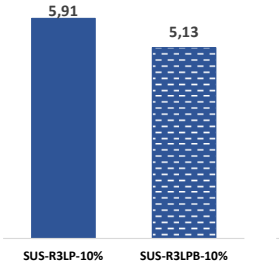
Table 3 - Knick Point

Sample	Knick Point (H)
SUS-R3LP-10%	13,54
SUS-R3LPB-10%	19,40
SUS-R3LP-30%	9,25
SUS-R3LPB-30%	18,30

Analysis of the results reveals that BCJ incorporation promoted a decrease in I_s in both series, with this reduction being more pronounced in the 30% R3 mix (dropping from 0.192 to 0.165). This behavior indicates greater drying efficiency, which is consistent with the previously observed increase in open porosity and vapor permeability.



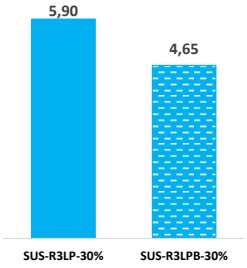
Regarding the Knick Point, a significant prolongation of the initial drying phase was verified in both fibre-containing compositions (nearly doubling the time in the 30% R3 mix). This phenomenon suggests that BCJ acts as an internal reservoir that feeds the evaporation surface for a longer duration, maintaining a high drying rate during the initial period.

Integrally, the results for capillarity (A_w), vapor permeability δ_m), and drying kinetics (Is) demonstrate that BCJ incorporation significantly influences the hygrothermal behavior of the mortars, acting differently depending on the WGP dosage. In the system with lower glass powder incorporation (10% R3), matrix rheology induced the formation of a less connected and more tortuous porous network, restricting water transport in both liquid and vapor phases. In contrast, in the system with higher glass powder content (30% R3), better workability allowed BCJ to promote a more open and interconnected structure. Under these conditions, the fibres and their interfaces function as preferential channels, favoring capillary absorption, vapor diffusion, and drying efficiency simultaneously.

This duality highlights that WGP acts not only as a pozzolanic precursor but as a rheological compatibilization agent, which is essential to ensure that the introduction of plant fibres results in a material with high moisture management capacity—a vital characteristic for the preservation of traditional wattle and daub buildings.

3.8 Compressive and Flexural Strength

The mechanical strengths were determined at 28 days of curing, in accordance with the EN 1015-11 standard, using 40×40×160 mm prismatic specimens and an Instron 5900R5884 universal testing machine. The results for compressive and flexural strength are systematized in Figure 9 and Figure 10, respectively.



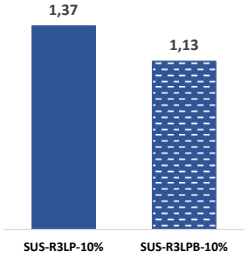


Figure 9 - Compressive Strength (MPa)

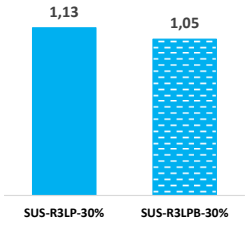

Figure 10 - Flexural Strength (MPa)

In general, the incorporation of BCJ resulted in a reduction in mechanical performance, an expected behavior due to the increase in open porosity previously discussed. Regarding compressive strength, a decrease of 13% was observed for the 10% R3 series and 21% for the 30% R3 series. However, the flexural behavior revealed important nuances: while the 10% R3 mix suffered a 17% drop, the 30% R3 mix presented the lowest relative reduction (only 7%).

This discrepancy between compressive and flexural stress reinforces the integrated analysis of the physical properties. In the 10% R3 mix, the loss of workability hindered compaction, generating macrostructural defects that impaired both stress regimes. Conversely, in the 30% R3 mix, the maintenance of fresh-state fluidity allowed for a more homogeneous distribution of the fibres and a better fibre-matrix interface (bond strength). Although the more open and connected structure (confirmed by capillarity and permeability tests) reduced the compressive load capacity, the fibres were able to act more effectively as "stress-transfer bridges" (crack-bridging) under flexion. This phenomenon mitigates the brittleness of the pozzolanic glass matrix, providing the mortar with a greater deformation capacity before failure—a fundamental characteristic for compatibility with deformable wattle and daub substrates.

4. Conclusion

The present study evaluated the impact of the simultaneous incorporation of waste glass grinding powder (WGP) and *bracejo* (BCJ) in hydraulic lime mortars for the rehabilitation of wattle and daub. The main conclusions are:

- **Matrix-Fibre Synergy:** The performance of the BCJ is strictly dependent on the WGP content. The replacement of 30% of lime with glass powder optimized the rheology, allowing for better fibre incorporation and a more efficient porous structure than in the mixes with only 10% WGP.
- **Hygrothermal Behavior:** The introduction of BCJ into matrices rich in glass powder (30% R3) promoted a more connected porous network, increasing vapor permeability and capillary absorption. Combined with the reduction of the Drying Index (I_s), this system demonstrated a superior moisture management capacity, essential for the preservation of historical substrates.
- **Mechanical Performance and Ductility:** Although fibre incorporation reduced compressive strength, the 30% R3 mix showed high retention of flexural strength (only 7% drop). This suggests a better fibre-matrix interface and a greater capacity for stress redistribution, favoring compatibility with deformable supports.
- **Sustainability and Applicability:** The combination of 30% WGP and 2.5% BCJ proved to be the most balanced solution. WGP acts not only as a pozzolanic precursor but as a rheological compatibilization agent, resulting in a sustainable mortar that prioritizes "breathability" and flexibility over mechanical stiffness.

5. Acknowledgements

This work was developed within the scope of the project "Sustainability of innovative **wattle and daub** mortars" (**COMPETE2030-FEDER-00845500**), co-funded by the European Regional Development Fund (ERDF) through the Support System for the Creation of Scientific and Technological Knowledge, under the Innovation and Digital Transition Program (COMPETE 2030). The authors would like to thank the Foundation for Science and Technology (FCT) for financial support through research grant **2022.13467/BD**, and the **CERIS** research unit (funding **UIDB/04625/2020**). Resumo: A requalificação de edificações representa um instrumento balizador desenvolvido pelos gestores urbanos no processo de tombamento do patrimônio histórico. A cidade de Sobral mantém preservado um sítio histórico composto de 2.500 edificações tombadas, a maioria contida numa área de aproximadamente 1,484 km². Dentre as diversas edificações situadas na área tombada estão marcos como o Paço Municipal, a Catedral da Sé e, com destaque analítico neste estudo, o Teatro São João. Construído entre 1875 e 1880 e tombado pelo Estado do Ceará (decreto nº 16237-1983) e posteriormente pelo Instituto do Patrimônio Artístico e Histórico Nacional (IPHAN), o teatro é referência por sua riqueza arquitetônica e erudição artística. Os objetivos deste trabalho foram apresentar aspectos referentes ao tombamento e à requalificação urbana em Sobral, as intervenções feitas no Teatro São João e o estado de conservação atual deste. A metodologia baseou-se em pesquisas bibliográficas e documentais, além de registros fotográficos e uso de fissurômetro. O processo de tombamento em Sobral considerou não apenas o valor arquitetônico, mas a dinâmica morfológica atual, refletida em projetos de mobilidade no entorno protegido. A edificação teatral foi submetida a quatro intervenções (1875-1885, 1940, 1973 e 2003), de modo que atualmente seu pavimento subterrâneo apresenta estado de conservação que compromete a segurança estrutural, contrastando com a beleza preservada de sua fachada e interiores.

Palavras-Chave: Patrimônio Histórico; Requalificação Urbana; Sobral; Teatro São João; Tombamento.

Abstract: The requalification of buildings represents a guiding instrument developed by urban managers in the process of listing historical heritage. The city of Sobral maintains a preserved historical site composed of 2,500 listed buildings, most of which are contained within a polygon of 5.33 km in an area of approximately 1.484 km², extending from the banks of the Acaraú River to Cel. Monte Alverne Street. This architectural and urban complex was listed as a national heritage site in 1999 by the National Institute of Historic and Artistic Heritage – IPHAN, leading the public authorities to carry out large planned investments in the requalification of its buildings, some of which date back to the 18th century, such as the São João Theater (neoclassical), a group of houses in the Art Nouveau style, townhouses decorated with Greco-Roman motifs, several religious buildings, such as the Sé Church (Sertanejo Baroque) and Nossa Senhora do Rosário Church (built by slaves), the Captain-Major's House (colonial) and the post office (Art Deco). The development of action plans for the restoration of these buildings was carried out through architectural surveys, damage mapping, and proposed interventions. Numerous difficulties were encountered, such as a lack of knowledge about the materials used at the time of construction and the construction techniques employed, with the maintenance of facades and total destruction of interiors being common. The objectives of this work were to present aspects related to the listing of historical heritage in the city of Sobral, the renovations carried out on its buildings,

and their current state of conservation. The methodology used was based on bibliographic research, laws, the study of heritage preservation, books, and documents, as well as photographic records. The listing process in Sobral took into account the artistic and architectural value of the buildings.

Keywords: Historical Heritage, Urban Redevelopment, Listing as a Heritage Site, Sobral, São João Theatre.

1. Introdução

A preservação do patrimônio cultural no Brasil transita, historicamente, entre o ideal de salvaguarda da memória e os desafios operacionais impostos pela dinâmica urbana contemporânea. o ato de tombar uma edificação ou um conjunto arquitetônico não se encerra na homologação de decretos; trata-se, na verdade, do início de um processo contínuo — e frequentemente conflituoso — de gestão, manutenção e requalificação. à medida que as políticas patrimoniais superam a visão estritamente monumentalista em favor de uma compreensão integrada da cidade como organismo vivo (Fonseca 2017), o sítio histórico da cidade de Sobral, no estado do Ceará, desponta como um laboratório a céu aberto para a análise das políticas de preservação no país. nele, evidenciam-se as tensões cotidianas entre a modernização das infraestruturas viárias e a perpetuação da identidade cultural.

A cidade mantém preservado um polígono histórico rigorosamente delimitado que abriga cerca de 2.500 edificações tombadas, concentradas em uma área de aproximadamente 1,484 km². essa expressiva densidade patrimonial não é fruto do acaso, mas o reflexo direto da opulência econômica vivida pela região no século XIX. impulsionada pelo ciclo do algodão e da carne de charque, uma elite sertaneja emergente financiou a construção de praças, templos e equipamentos culturais (Ponte 2014). diferentemente de núcleos coloniais formados de maneira puramente orgânica, o traçado e as construções sobralenses foram fortemente moldados por uma sociedade que buscava espelhar os ideais civilizatórios europeus no semiárido nordestino. o resultado é um conjunto arquitetônico coeso, que transita com fluidez entre o neoclassicismo e o ecletismo, marcando o espaço público com uma estética burguesa singular. Nesse cenário consolidado, edificações de caráter religioso e administrativo ancoram a leitura visual e a dinâmica funcional do território. O Teatro São João, construído entre 1875 e 1880, consolida-se como um dos maiores símbolos da influência europeia no interior nordestino. Mais do que um mero edifício de espetáculos, o teatro representava o ápice do refinamento de uma época ansiosa por modernidade e, atualmente, atua como um dos principais pontos focais das políticas de fomento e restauro na região.

Contudo, a proteção legal e a refuncionalização de bens dessa magnitude suscitam debates complexos no campo da arquitetura e do urbanismo. Autores de referência na teoria do restauro, como Kühl (2018), alertam que a requalificação urbana, quando excessivamente focada na valorização cenográfica das fachadas e na estética dos espaços de fruição, corre o risco de negligenciar degradações invisíveis, criando uma falsa sensação de preservação. É precisamente essa dicotomia — o descompasso entre a requalificação de superfície e a integridade construtiva — que instiga a presente investigação.

Diante desse contexto, o presente artigo tem como objetivo analisar o impacto do tombamento realizado pelo Instituto do Patrimônio Histórico e Artístico Nacional (IPHAN) na requalificação dos espaços urbanos de Sobral (Figura 1), articulando as recentes ações de urbanismo na malha histórica com um estudo de caso focado no Teatro São João (Figura 2). Ao evidenciar o contraste entre a beleza conservada das áreas de

convivência e a vulnerabilidade latente nas fundações da edificação teatral, este trabalho propõe uma reflexão crítica sobre os limites dos projetos contemporâneos de revitalização e a urgência da adoção de planos de manutenção preventiva contínua no patrimônio edificado brasileiro.

1.1 O Tombamento como Instrumento de Requalificação Urbana

O debate sobre a proteção de sítios históricos ganhou novos e complexos contornos nas últimas décadas, refletindo um amadurecimento nas doutrinas de preservação no Brasil. Se no início do século XX a tônica das políticas patrimoniais recaía quase exclusivamente sobre a monumentalidade isolada — priorizando as grandes obras de "pedra e cal" do período colonial —, hoje a compreensão abrange a dinâmica funcional e morfológica dos espaços sociais como um todo (Chuva 2012). Essa mudança de paradigma reconhece que a cidade não é um mero suporte físico para construções antigas, mas um organismo vivo cujas relações sociais, trânsito e economia local são intrínsecos à memória do lugar. Assim, a proteção patrimonial contemporânea exige metodologias que articulem a preservação do passado com as demandas habitacionais e viárias do presente. Essa transição teórica é fundamental para mitigar os riscos inerentes aos processos de tombamento descontextualizados. Como adverte Choay (2001), a fetichização do monumento pode esvaziá-lo de sua função social autêntica, transformando-o em um corpo estranho na malha da cidade. Quando um edifício histórico é tratado apenas como um artefato intocável de contemplação, ele tende a sofrer um processo de museificação que afasta a população local, gerando áreas urbanas cenográficas, porém esvaziadas de vitalidade cotidiana.

Em Sobral, o processo de tombamento municipal, estadual e federal adotou, de maneira convergente, uma perspectiva de conjunto arquitetônico e urbanístico. Castriota (2019) argumenta que a requalificação urbana em centros históricos deve atuar primordialmente como um mediador entre o ímpeto do desenvolvimento contemporâneo e a salvaguarda inegociável da memória coletiva. Em vez de congelar o centro da cidade, a gestão sobralense buscou delimitar um polígono de proteção rígida que permitisse a leitura clara de sua evolução histórica, ao mesmo tempo em que incentivava intervenções capazes de modernizar a infraestrutura de suporte aos cidadãos e ao comércio local.

A justificativa para essa tutela em larga escala encontra respaldo na singularidade da formação urbana do município. O traçado e a volumetria das edificações sobralenses materializam o apogeu econômico vivenciado no século XIX, impulsionado pelas rotas comerciais do algodão e pela indústria do charque (Ponte 2014). Esse capital excedente foi traduzido na construção de casarões de porão alto, igrejas majestosas e equipamentos culturais de grande porte, conformando uma paisagem onde o ecletismo e o neoclassicismo predominam. Preservar a dinâmica morfológica desse traçado significa, portanto, manter legível a história de uma elite sertaneja que buscou mimetizar os hábitos europeus no interior do semiárido nordestino. A materialização prático-espacial dessa premissa de integração é visível nos projetos recentes de intervenção viária, com destaque para as ações que integram o projeto conhecido como "Sobral Novo Centro". Essa

iniciativa buscou resolver o crônico conflito entre a matriz urbana do século XIX e o volume de tráfego motorizado do século XXI. A requalificação das vias adjacentes aos monumentos históricos incluiu a substituição criteriosa da pavimentação asfáltica tradicional por blocos intertravados (Figura 3). Além de reduzir a velocidade dos veículos (traffic calming), esse tipo de piso favorece a drenagem das águas pluviais, mitigando alagamentos que frequentemente ameaçam as alvenarias de fundação dos casarões seculares ao longo da malha tombada e contribui para a melhoria do conforto térmico.

Figura 3: blocos intertravados

Fonte: Arquivo do autor

Outro acerto urbanístico dessa requalificação foi o ambicioso projeto de internalização da fiação elétrica e de telecomunicações no polígono central. Historicamente, o emaranhado de cabos aéreos atua como uma poluição visual severa, fragmentando a leitura estética das fachadas e desvalorizando os detalhes ornamentais das platibandas e beirais. Com o enterramento de uma grande parte das redes, recuperou-se o cone visual de marcos estruturantes da cidade. O pedestre contemporâneo passou a vivenciar a escala real da Praça de Cuba e a apreciar a verticalidade das torres da Catedral da Sé, promovendo uma reapropriação afetiva e estética do espaço público por parte da população (Fonseca 2017).

Contudo, a gestão de um conjunto com tamanha densidade impõe severos e constantes desafios de conservação preventiva. É fundamental que a academia e os órgãos de fiscalização mantenham um olhar crítico sobre as obras de revitalização. O verniz do planejamento urbano de superfície — traduzido no embelezamento de praças, na nova iluminação cênica e nas vias repavimentadas — é indubitavelmente crucial para a apropriação do espaço pela população. No entanto, essa maquiagem urbana muitas vezes oculta fragilidades estruturais agudas nas infraestruturas seculares.

A introdução de novas infraestruturas em centros históricos, ainda que benéfica do ponto de vista urbanístico, exige intervenções no subsolo que frequentemente alteram o microclima do terreno. Valas para fiação subterrânea ou novas redes de drenagem podem modificar a acomodação do lençol freático, refletindo diretamente nas fundações de pedra ou tijolo maciço das edificações antigas. Ribeiro e Oliveira (2021) destacam que a incompatibilidade de materiais em restauros e intervenções viárias — como o uso excessivo de concreto armado e cimento Portland ao redor de alvenarias tradicionais que precisam "respirar" — é uma das maiores causas de patologias silenciosas, resultando em umidade ascendente e fissuras estruturais crônicas.

Portanto, conclui-se que o impacto do tombamento e das subsequentes requalificações em Sobral é amplamente positivo no que tange à preservação da morfologia e ao uso social do espaço. Entretanto, para que essa salvaguarda seja sustentável a longo prazo, o planejamento urbano deve transcender a camada visual da paisagem. Requer-se a implementação de análises prediais mais criteriosas e contínuas, garantindo que o sucesso estético e funcional de edificações de ponta, como a Casa da Cultura (Figura 4) e

o Musel Dom José Tupinambá da Frota (Figura 5), sejam acompanhados por um rigoroso controle de saúde estrutural, evitando que os monumentos colapsem por trás de suas fachadas recém-restauradas.

1.2 O Caso do Teatro São João: Erudição, Intervenções e Patologias

Referência máxima de requinte no tecido urbano sobralense, o Teatro São João evidencia o grau de erudição artística e o poderio econômico alcançados no final do século XIX. A construção do edifício, erguido entre 1875 e 1880, não foi uma obra isolada ou um capricho estético aleatório, mas a materialização de um projeto de classe. Conforme aponta Ponte (2014), a emergente elite local, enriquecida pelos ciclos do algodão e da carne de charque, necessitava de equipamentos urbanos que legitimassem seu status e aproximassem a urbe sertaneja dos padrões civilizatórios europeus. Assim, o teatro nasce como um marco de distinção social, encravado no centro de uma cidade que passava por intensas transformações urbanísticas e econômicas.
Do ponto de vista morfológico e arquitetônico, a fachada principal do Teatro São João funciona como um imponente cartão de visitas neoclássico com flertes no ecletismo. A frente do edifício é ritmada por uma sucessão de arcos de volta inteira no pavimento térreo. Esses vãos não apenas facilitavam a ventilação cruzada, essencial para o conforto térmico no semiárido, mas também conferiam leveza a uma estrutura de alvenaria autoportante robusta. Coroando essa composição, a fachada culmina em um frontão curvo majestoso que abriga um óculo central vazio, um detalhe tipicamente europeu que anunciava aos transeuntes o luxo e a grandiosidade das dependências internas.

Ao ultrapassar o saguão de entrada, o visitante é imediatamente inserido na clássica configuração de palco à italiana e plateia em formato de ferradura. Essa tipologia espacial, amplamente difundida na Europa dos séculos XVIII e XIX, foi perfeitamente adaptada à realidade cearense. A disposição em "U" das varandas curvas, sustentadas por delgadas colunas de ferro fundido, foi projetada não apenas para otimizar a acústica do recinto, mas para atender à dinâmica social do "ver e ser visto" (Ponte 2014). A burguesia local ocupava os camarotes superiores, exibindo suas vestimentas e joias, enquanto o espetáculo ocorria simultaneamente no palco e na própria platéia.

É na materialidade de seus interiores que o edifício consolida sua aura de Belle Époque sertaneja. A mobília original, composta por elegantes assentos com encosto e assento em palhinha indiana, demonstra uma notável inteligência projetual. Diferente dos pesados estofados de veludo usados na Europa, a palhinha permitia a transpiração dos espectadores frente às altas temperaturas de Sobral. Em contrapartida, o palco permaneceu emoldurado por densas e tradicionais cortinas vermelhas, mantendo o peso cenográfico e a

ambiência dramática exigida pelas óperas e operetas da época. Esse hibridismo material atesta a sofisticação de um projeto que soube fundir o cânone internacional com as exigências climáticas locais.

No entanto, a compreensão contemporânea de uma edificação tão singular exige ir além da contemplação de sua beleza pretérita. Choay (2001) adverte que a fetichização do monumento — ou seja, o apego excessivo apenas à sua imagem gloriosa do passado — pode transformá-lo em uma alegoria vazia, descolada da realidade estrutural presente. O Teatro São João, sob a chancela do tombamento, transcendeu sua função original de mero local de entretenimento aristocrático para se converter em um bem cultural de apropriação coletiva. Contudo, manter essa monumentalidade viva e operante no século XXI impõe desafios técnicos que a simples fruição visual muitas vezes ignora.

A erudição estética que admiramos hoje não chegou até nós de forma inalterada; ela é o resultado direto de sucessivas campanhas de restauro e modernização. Castriota (2019) argumenta que o patrimônio histórico não é uma entidade cristalizada no tempo, mas um instrumento dinâmico que sofre contínuas reelaborações. No caso específico do teatro de Sobral, a edificação foi submetida a grandes intervenções, notadamente nas décadas de 1940, 1970 e no início dos anos 2000. Tais ações buscaram adequar o edifício às novas normas de segurança, acessibilidade e climatização, garantindo que o teatro não fosse reduzido a um museu inerte, mas permanecesse como um equipamento cultural ativo e vibrante.

Além desses dados históricos, houve outras modificações que foram feitas com a finalidade de deixar o Teatro São João como era originalmente. Dessa forma, ressalta-se:

> O desenho original da curva da alvenaria que delimita o bordo do procênio, foi encontrado sob o aterro existente e reconstruido em seu desenho original mais elegante e equilibrado.
> A boca de cena visivelmente alterada em sua largura e fechamento superior com elementos construtivos retilíneos de concreto armado, foi recomposta com o fechamento em arco abatido de desenho original, conforme registro fotográfico.
> Foram removidos elementos de concreto – escadas e plataformas – na área do palco, elementos esses aposto em data recente e inadequados às necessidades técnicas e ao sistema de movimentação da mecânica cênica.
> As aberturas de vãos de acesso ao palco e nichos encontrados sob emparedamento, foram reabertos ou deixados à mostra como registro.
> As escadas de acesso até então existentes interligando a plateia aos dois balcões e visivelmente estranhas aos níveis e às aberturas dos vãos das portadas laterais, foram removidas e substituidas por escadas novas metálicas de desenvolvimento helicoidal, reasgatando a solução de acesso anteriormente existente. (Rodrigues, 2005)

As Figuras 6 e 7 mostram antes e depois da substituição dos dois níveis de camarotes pela solução concebida no desenho original, ou seja, apenas um nível.

Apesar da inegável importância dessas intervenções para a sobrevida funcional do teatro, a história das políticas de preservação revela um descompasso estrutural severo. Historicamente, os órgãos de tutela patrimonial voltaram suas energias muito mais para a homologação legal (a chancela do bem) e para a recuperação das fachadas do que para a manutenção estrutural profunda (Chuva 2012). Fonseca (2017) corrobora essa visão ao apontar que a preservação federal no Brasil muitas vezes tratou o edifício como uma "casca esteticamente perfeita", negligenciando o monitoramento contínuo das infraestruturas invisíveis, como os telhados ocultos, os porões e as fundações.

É exatamente nessa lacuna de gestão preventiva que emergem as patologias críticas do Teatro São João. Avaliações recentes demonstraram que, em total oposição ao deslumbramento proporcionado pelo salão de espetáculos, o pavimento subterrâneo da edificação clama por socorro. Esse espaço inferior, originalmente concebido para a movimentação de maquinários cênicos e ventilação do assoalho, apresenta hoje um quadro crônico de degradação. Fissuras de origem diferencial mapeiam as alvenarias de embasamento, evidenciando o sofrimento da estrutura original perante acomodações do solo e flutuações do lençol freático.

Esse cenário de risco é potencializado por equívocos técnicos cometidos nas próprias campanhas de intervenção do passado. Ribeiro e Oliveira (2021) destacam que as obras de consolidação estrutural realizadas nas décadas de 1970 e 1980 no Brasil padecem, frequentemente, da incompatibilidade mecânica e química de materiais. No afã de "salvar" as ruínas, utilizou-se massivamente o concreto armado e o cimento Portland (de alta rigidez e baixíssima porosidade) diretamente sobre alvenarias históricas de tijolo maciço e argamassas de cal. O resultado desse choque tecnológico é a retenção implacável da umidade no interior das grossas paredes antigas, que perdem sua capacidade de transpirar.

No Teatro São João, essas cicatrizes de intervenções passadas cobram um alto preço na base da edificação. A umidade ascendente, sem poder evaporar pelas paredes agora impermeabilizadas por argamassas incompatíveis, migra verticalmente, carreando sais e promovendo a desagregação lenta e silenciosa dos aglomerantes históricos. Esse processo não é apenas uma "falha estética" restrita a um porão oculto, mas um vetor de risco contínuo que ameaça diretamente a estabilidade global do palco e das pesadas arquibancadas em ferradura que se apoiam sobre essa superestrutura. Portanto, o estudo das patologias do Teatro São João desnuda um alerta crucial para o futuro da salvaguarda arquitetônica. A beleza arrebatadora de suas cortinas vermelhas e a nostalgia de sua plateia em palhinha criam uma ilusão de integridade definitiva. Contudo, a verdadeira preservação de um ícone da Belle Époque sertaneja não pode se sustentar apenas na manutenção de sua vitrine visual. É urgente que os paradigmas contemporâneos de gestão do patrimônio incorporem a conservação curativa e a engenharia diagnóstica como eixos inseparáveis do restauro, garantindo que o requinte do passado repouse sobre fundações seguras no presente.

De fato, a sala de espetáculos e a fachada principal apresentam um excelente estado estético, fruto direto dos esforços das últimas intervenções governamentais. A pintura impecável do frontão, a restauração minuciosa das poltronas e varandas de ferradura, aliadas à requalificação do entorno com a bela pavimentação externa de blocos intertravados, transmitem uma imediata sensação de dever cumprido por parte das polí-

ticas públicas. Castriota (2019) reconhece que essas ações de embelezamento e integração urbana são instrumentos válidos para mediar a relação entre a sociedade e a memória, promovendo a apropriação do bem. Todavia, essa mesma maquiagem cenográfica acaba por gerar uma perigosa anestesia em relação à manutenção profunda, criando uma narrativa de preservação que se encerra na camada mais superficial do edifício histórico. O esforço municipal, embora louvável do ponto de vista do planejamento viário e da mobilidade no centro expandido, frequentemente desconsidera as repercussões hidrogeológicas de suas trincheiras e novas pavimentações no microclima do subsolo histórico. Trata-se do clássico paradoxo da gestão urbana patrimonial: investimentos volumosos na urbanização do entorno enquanto o núcleo estrutural do próprio monumento padece de uma negligência orçamentária para a conservação curativa preventiva de suas infraestruturas ocultas.

Nesse diapasão, a realidade diagnosticada no Teatro São João serve como um contundente estudo de caso para desmistificar a eficácia isolada dos instrumentos legais de proteção. O tombamento pelo IPHAN ou pelas instâncias estaduais não imuniza a edificação contra a degradação silenciosa provocada pelas acomodações do solo e pela umidade estrutural persistente. Como argumentam Chuva (2012) e Fonseca (2017), a chancela de patrimônio é um marco declaratório vital que reconhece o valor cultural, mas que carece de eficácia prática se não for sucedida de políticas perenes de financiamento para manutenção diária.

Conclui-se, portanto, que a sobrevivência do Teatro São João e da integridade física do próprio sítio histórico de Sobral depende de uma reestruturação imediata nos paradigmas de intervenção urbana. É imperativo transitar de um modelo de revitalização focado no impacto da imagem turística para uma gestão técnica que valorize a engenharia diagnóstica e a manutenção contínua das áreas invisíveis aos olhos do público. O esplendor dos lustres da sala de espetáculos e a vivacidade neoclássica das fachadas só terão significado duradouro se a base subterrânea que as sustenta for tratada com o mesmo rigor científico, garantindo que o edifício resista ao tempo de forma verdadeiramente integral.

2. Metodologia

De acordo com Chaves (2015), os métodos para avaliação e análise de edifícios revelam-se importantes ferramentas utilizadas para tomada de decisão, onde seu estudo e compreensão constitui o primeiro passo para o desenvolvimento de metodologias adequadas às exigências atuais. A partir de uma abordagem qualitativa, fundamentada em levantamentos bibliográficos, análise documental e inspeção física in loco com o uso sistemático de registros fotográficos e fissurômetro, busca-se discutir como as intervenções de requalificação estética e urbana dialogam com a necessidade de conservação estrutural profunda. Foram analisados inventários de bens e registros históricos realizados nas diferentes épocas das intervenções construtivas do Teatro São João, localizado na cidade de Sobral-Ce.

A avaliação contemporânea da integridade de bens patrimoniais exige o distanciamento da mera contemplação estética, adentrando o rigor do diagnóstico técnico. Nesse escopo, os registros realizados por meio de inspeção visual sistemática, utilizando câmera fotográfica de alta resolução, e a medição das patologias ativas com o auxílio de fissurômetro de precisão revelaram dados alarmantes e profundamente contrastantes no Teatro São João. A metodologia de prospecção adotada buscou ultrapassar a superfície visível que frequentemente engana o observador leigo ou o turista circunstancial. Como alerta Choay (2001), a alegoria construída em torno do monumento tende a ocultar sua materialidade vulnerável, fetichizando a sua imagem pública em detrimento de sua substância física. A investigação demonstrou que, enquanto as áreas de grande circulação ostentam um apuro visual irretocável, o miolo construtivo da edificação padece de um processo de arruinamento contínuo.

3. Resultados e Discussões

Os dados apresentados evidenciam um paradoxo profundo no modelo brasileiro de gestão patrimonial, perfeitamente ilustrado na dinâmica do Sítio Histórico de Sobral. Ao proteger legalmente cerca de 2.500 edificações e promover ações de infraestrutura como o projeto "Sobral Novo Centro", a gestão urbana demonstra notável maturidade na valorização macroespacial do patrimônio. Como argumenta Fonseca (2017), a trajetória das políticas de preservação no Brasil superou a visão de isolamento do bem, passando a compreender o território como uma paisagem cultural viva. Em Sobral, essa evolução é inegável: a liberação visual das fachadas da Casa da Cultura e do Musel Dom José Tupinambá da Frota, agora livres do emaranhado de fios elétricos e valorizadas por pavimentações adequadas, comprova um esforço ímpar de reintegração da memória à paisagem e ao usufruto cotidiano.

Esse sucesso macroespacial reflete o amadurecimento das próprias diretrizes institucionais de proteção no país. Chuva (2012) relembra que as políticas de tombamento do IPHAN, em sua gênese, carregavam um viés fortemente monumentalista, focado na chancela de bens coloniais isolados. Hoje, o entendimento abrange a complexidade da malha urbana. Castriota (2019) corrobora essa perspectiva ao afirmar que a requalificação urbana contemporânea deve atuar como um mediador ativo entre o desenvolvimento da cidade e a salvaguarda da memória. Ao adaptar o entorno para pedestres e modernizar as vias sem descaracterizar a morfologia do século XIX — período de opulência econômica fundamentada no algodão e no charque Ponte (2014) —, Sobral evita a cristalização de seu centro, mantendo-o como um espaço de governança e fé pulsantes.

A trajetória de uma edificação histórica transcende o momento de sua inauguração, configurando-se como um palimpsesto arquitetônico onde diferentes épocas inscrevem suas necessidades, tecnologias e visões de mundo. Como postula Choay (2001), o monumento histórico raramente chega aos dias atuais em sua pureza original; ele é moldado pelas sucessivas apropriações e pelos esforços de salvaguarda ou modernização que sofre ao longo do tempo. Compreender a saúde estrutural de um bem tombado exige, portanto, uma análise diacrônica de suas modificações. No caso de edifícios de uso coletivo e contínuo, as intervenções não são apenas estéticas, mas operacionais, visando adequar a estrutura se secular às exigências contemporâneas de segurança, conforto e habitabilidade.

Nesse sentido, ao longo de seus mais de 140 (cento e quarenta) anos de existência, o Teatro São João passou por diversas modificações arquitetônicas e estruturais para se adequar a novas normativas de uso e resolver falhas crônicas de manutenção. Conforme levantamento documental realizado nos arquivos públicos e nos registros dos órgãos de proteção patrimonial, a edificação foi submetida a quatro grandes ciclos de intervenção. Para facilitar a compreensão temporal e metodológica dessas campanhas de obras, a Tabela 1 sintetiza o cronograma, os objetivos e o caráter principal dessas ações modificativas.

Tabela 1 – Resumo das intervenções estruturais e arquitetônicas realizadas no Teatro São João ao longo de sua história:

Ano(s) da Intervenção	Objetivo Principal / Procedimentos Adotados
1875 a 1885	Período de edificação e conclusão de acabamentos finos da fachada e interiores
1940	Reformas pontuais para modernização e adaptações funcionais de maquinário.
1973	Intervenção de consolidação estrutural liderada por órgãos estaduais de proteção.
2003	Projeto contemporâneo de requalificação, focando em acessibilidade e climatização.

A adaptação para o conforto contemporâneo de 2003 exigiu um alto preço técnico. A instalação de pesados sistemas de ar-condicionado central introduziu novas cargas dinâmicas (vibrações contínuas) na estrutura centenária. No Teatro São João, a união de um ambiente interno artificialmente frio com o calor externo do Ceará potencializou a formação de microclimas úmidos, especialmente nas áreas menos ventiladas, como o pavimento subterrâneo.

Ao se inspecionar os níveis inferiores do teatro, constatou-se que o foco crítico e emergencial da edificação reside em seu pavimento subterrâneo. Originalmente concebido no século XIX para servir como câmara de ventilação natural e espaço de acomodação para os maquinários cênicos primitivos (Ponte 2014), esse porão encontra-se atualmente em um estado de insalubridade e degradação estrutural severa. A ausência de luz natural e a drástica redução da circulação de ar — agravada pelo selamento das aberturas durante as reformas para climatização moderna — transformaram esse espaço em um ambiente propício à proliferação de agentes biodeterioradores e à acumulação de patologias mecânicas que ameaçam todo o conjunto superior.

E uma negligência estrutural é, paradoxalmente, agravada por equívocos técnicos cometidos nas próprias tentativas de salvaguarda ao longo do tempo. O diagnóstico do subsolo do teatro revela que as intervenções das décadas de 1970 e de 2003 introduziram sérias incompatibilidades construtivas. Ribeiro e Oliveira (2021) enfatizam que o uso indiscriminado de cimento Portland e elementos de concreto armado em estruturas históricas tradicionais altera a permeabilidade das alvenarias, aprisionando a umidade do lençol freático e gerando até manifestações patológicas estruturais (Figuras 8 e 9). Foram realizadas vistorias no início de março e ao final de maio de 2026 observando-se a evolução destas manifestações patológicas. Sabe-se que a parte inferior da viga é a região tracionada, e o aço sendo principal responsável por suportar os esforços de flexão. Neste caso, com a utilização do fissurômetro observou-se que a camada de concreto afetada deslocou-se para fora em relação ao alinhamento original 0,6mm. A intervenção padrão propõe o escoramento da estrutura, escareação com a remoção de todo o concreto solto e deteriorado, limpeza da armadura com a substituição das barras comprometidas, aplicação do primer anticorrosivo e argamassa estrutural, respeitando o cobrimento mínimo exigido pelas normas técnicas. Uma fissura de 0,5mm, classificada como trinca moderada e também observada em uma parede próxima, sugere que a estrutura comprometida da viga continua sob forte tensão e espalhando o esforço para outras áreas.

Figura 8: Corrosão de armaduras

Fonte: Arquivo do autor

Figura 9: Corrosão de armaduras

Fonte: Arquivo do autor

Dessa forma, as patologias hoje observadas nas fundações do Teatro São João não são apenas fruto da ação do tempo, mas também o resultado de restauros passados que ignoraram a fisiologia original dos materiais construtivos do século XIX.

A umidade proveniente do lençol freático, que antes evaporava naturalmente pela base das paredes, agora é forçada a subir por capilaridade até encontrar áreas de reboco tradicional para escapar. Esse fenômeno de umidade ascendente causa o descolamento crônico das pinturas, a eflorescência de sais e a degradação acelerada dos tijolos maciços localizados no porão da edificação (Figuras 10 e 11).

Figura 10: Infiltrações e umidade

Fonte: Arquivo do autor

Figura 11: Infiltrações e umidade

Fonte: Arquivo do autor

Por conseguinte, conclui-se que as requalificações urbanas contemporâneas não podem prescindir de uma engenharia diagnóstica contínua. O modelo de intervenção baseado em grandes reformas esporádicas e no embelezamento de fachadas deve ceder espaço para a cultura da manutenção preventiva. É imperativa a exigência de laudos estruturais permanentes e a aplicação de tecnologias não destrutivas (como termografia e georadar) visando antecipar colapsos antes que eles ameacem a integridade do bem e a segurança do público.

4. Conclusões

As principais descobertas deste trabalho indicam que o Sítio Histórico de Sobral é um exemplo de vanguarda no reconhecimento da dinâmica urbana. Projetos contemporâneos de pavimentação e zeladoria revitalizaram o entorno de equipamentos vitais, como o Museu Dom josé Tupinambá da Frota e os espaços religiosos, fomentando a vitalidade cultural da cidade.

Portanto, a sobrevivência do Teatro São João e da integridade física do próprio sítio histórico de Sobral depende de uma reestruturação imediata nos paradigmas de intervenção urbana. É importante transitar de um modelo de revitalização focado no impacto da imagem turística para uma gestão técnica que valorize a engenharia diagnóstica e a manutenção contínua das áreas invisíveis aos olhos do público. O esplendor dos lustres da sala de espetáculos e a vivacidade neoclássica das fachadas só terão significado duradouro se a base subterrânea que as sustenta for tratada com o mesmo rigor científico, garantindo que o edifício resista ao tempo de forma verdadeiramente integral.

A contribuição inédita desta análise, contudo, reside no diagnóstico crítico da assimetria das requalificações. No caso do Teatro São João, apesar das quatro grandes campanhas de intervenção (1875-1885, 1940, 1973 e 2003), a eficácia foi predominantemente estética e funcional. A requalificação garantiu a fruição visual e o conforto do público, mas negligenciou aspectos vitais de engenharia em sua superestrutura.

Como implicação prática, conclui-se que é imperativa a elaboração de um Plano de Manutenção Preventiva para os monumentos do Sítio Histórico. Somente através da superação da cultura das "reformas estéticas de superfície" em favor de uma engenharia de "conservação estrutural contínua" será possível assegurar que o patrimônio tombado sobreviva com segurança e autenticidade.

Componentes pré-fabricados de argamassa armada: quadro analítico dos danos em um CAIC em Goiânia

Gabriel Lopes MONTANINE[1], Vanda Alice Garcia ZANONI[2]

[1] Universidade de Brasília, Brasília, Brasil, gabriel.montanine@aluno.unb.br
[2] Universidade de Brasília, Brasília, Brasil, vandazanoni@unb.br

Resumo: A argamassa armada é uma tecnologia construtiva definida como uma variante do concreto armado, diferenciando-se pelas propriedades, composição e processo de produção. Caracterizada por uma malha de aço difusa, alto teor de cimento e agregado miúdo, a argamassa armada possibilita a execução de elementos de grande dimensão e pequena espessura. Apesar da sua invenção no século XIX, foi experimentada e aprimorada na segunda metade do século XX. No Brasil, o arquiteto João Filgueiras Lima, o Lelé, adotou a pré-fabricação de componentes em argamassa armada como solução construtiva para seus edifícios escolares e equipamentos urbanos. Os Centros de Atenção Integral à Criança e ao Adolescente – CAICs, complexos escolares pré-fabricados em argamassa armada projetados por Lelé e construídos na década de 90, atualmente tornaram-se objetos de estudos e debates sobre seu estado de conservação, principalmente pelas intervenções inadequadas à sua preservação como patrimônio cultural. Os processos de degradação da argamassa armada são semelhantes aos do concreto armado, no que se refere aos agentes, mecanismos de degradação e manifestações patológicas, conforme as condições de exposição ambiental dos edifícios. Nesse sentido, o objetivo deste artigo é estabelecer um quadro analítico de suporte às ações de inspeção e diagnóstico de edificações em argamassa armada. Para tanto, foram realizadas inspeções visuais e levantamento fotográfico em um CAIC, identificando, classificando e analisando as principais manifestações patológicas nos componentes da cobertura, apontando os possíveis agentes e mecanismos de degradação. Os resultados permitiram constatar que os danos presentes nos componentes do sistema de cobertura ocorrem principalmente em função das condições de exposição ambiental e reduzido cobrimento das armaduras da argamassa armada. O estudo pretende contribuir para as ações de manutenção e conservação, cujas intervenções dependem do entendimento dos processos de envelhecimento desse material, considerando suas especificidades.

Palavras-chave: mapeamento de danos; sistema de cobertura; manifestações patológicas; estado de conservação; manutenção.

1. Introdução

A argamassa armada foi desenvolvida por Jean Louis Lambot na segunda metade do século XIX, sendo inicialmente aplicada em pequenas embarcações que, devido à alta impermeabilidade do material, tornavam-se capazes de resistir à ação da umidade. O engenheiro civil italiano Pier Luigi Nervi (1891-1980) foi um dos expoentes pela difusão da argamassa armada, reconhecido pelo uso do material em suas formas estruturais fluídas e sistemas de coberturas leves pré-moldadas. Nervi acreditava no potencial econômico do material, conferindo rigidez e leveza às estruturas por meio de nervuras.

De acordo com Hanai (1981) e Librório (1989), a argamassa armada é caracterizada por elementos de pequena espessura, limitando-se a 40 mm, composta por um arranjo de malhas de aço distribuídas por toda a seção do elemento. De acordo com a NBR 11173 (ABNT, 1990), o cobrimento de argamassa varia de acordo com as condições de exposição, considerando a espessura de 4 mm para ambientes protegidos e

6 mm em ambientes não protegidos. Lajaj *et al.* (2015) apontam que o tipo de malha e sua configuração influenciam no comportamento e resistência da argamassa armada.

A argamassa armada representa a gênese do concreto armado e, segundo Hanai (1981), ambos pertencem à mesma família com pequenas distinções de processos de produção e composição, caracterizando-se como uma extensão da tecnologia do concreto armado.

João Filgueiras Lima, o Lelé, foi um dos arquitetos precursores da tecnologia da argamassa armada no Brasil, por meio da aplicação do material na pré-fabricação de componentes leves. Os Centros Integrados de Atendimento à Criança e ao Adolescente – CIAC (1990-1992) compõem o conjunto de escolas projetadas por Lelé utilizando a tecnologia. Implantados por todo o território brasileiro, os CIACs passaram, por razões políticas, a ser denominados Centros de Atenção Integral à Criança e o Adolescente – CAICs.

Lelé concebeu o projeto-piloto das escolas com componentes padronizados e pré-fabricados, prevendo uma substituição periódica dos componentes como uma estratégia de conservação. O arquiteto acreditava que sua execução simplificada e seu custo operacional inferior ao de peças de concreto armado representariam a solução construtiva adequada à incipiente industrialização do país (Nobre, 2010). No entanto, a rede de fábricas idealizada por Lelé não se consolidou devido à desarranjos no programa governamental, o que comprometeu a efetividade da construção das escolas e o controle da produção dos componentes. Além disso, a desativação das fábricas de argamassa armada e a falta de cuidados periódicos nas escolas dificultaram os processos de conservação (Vilela e Ficher 2025).

Após 30 anos de existência, alguns autores têm discutido o estado de conservação dessas unidades escolares. Nos levantamentos realizados por Pereira *et al.* (2022), foram identificados que das 269 unidades remanescentes do programa, 85% estão ativas e 15% inativas, demonstrando que a maioria das escolas ainda permanecem em uso, cumprindo sua função social, enquanto a outra parcela encontra-se em estado de vulnerabilidade e abandono.

Alguns fatores como a falta de manutenções periódicas em seus sistemas, a descaracterização por substituições e intervenções inadequadas, além da incipiente atuação das instituições de preservação, têm prejudicado a permanência desse conjunto arquitetônico (Vilela 2018). Com a falta de manutenção e ações que priorizam a conservação preventiva, os componentes e elementos construtivos ficam sujeitos à degradação, afetando a durabilidade, principalmente daqueles que compõem a envoltória, como o sistema de cobertura. Nos cenários de conservação dos CAICs, o sistema de cobertura é o mais afetado, devido à constante exposição às intempéries, à falta de manutenção e substituições por novas coberturas metálicas (Pereira e Oliveira 2023 e Vilela 2018).

Librório (1989) destaca em seus estudos que não é possível determinar o comportamento global e definir parâmetros de durabilidade do material, pois é necessário considerar os diversos ambientes e microrregiões de implantação dos edifícios. Nas inspeções realizadas pelo autor em componentes de argamassa armada, foram identificados que os elementos expostos à ação das chuvas, molhagem e secagem frequentes ou em contato com substâncias agressivas, devem receber em sua superfície uma camada de tratamento de proteção. A argamassa armada é um material poroso e a remoção da camada superficial pode potencializar essa condição de exposição aos agentes de degradação, levando à despassivação da armadura e eventual deterioração da malha de aço pela ação da corrosão.

Segundo Zanoni (2015), as ações externas de origem climática constituem um dos principais agentes de degradação que reduzem o desempenho ao longo da vida útil das edificações. Esse processo de degradação da cobertura ocasiona um conjunto de prejuízos funcionais e estéticos, que podem ser mitigados mediante a adoção de um plano de manutenção continuada e inspeções periódicas (Zanoni 2015 e Santos 2025).

O Documento de Madrid – Nova Deli (2017) aponta que as condições de deterioração dos materiais do século XX devem ser analisadas cuidadosamente, identificando e compreendendo os danos visíveis para delinear procedimentos adequados de intervenção. Por essa, entre outras razões, é essencial compreender

o comportamento dos materiais diante da influência dos agentes de degradação e condições de exposição.

Nesse contexto, este artigo tem o objetivo de elaborar um quadro analítico das manifestações patológicas dos componentes de argamassa armada do sistema de cobertura a partir dos levantamentos físicos *in loco* e das análises das causas, mecanismos e agentes de degradação. Para isso, foi realizada uma inspeção predial em uma unidade remanescente do CAIC (atualmente ocupada pela Unidade Universitária de Goiânia – Laranjeiras, da Universidade Estadual de Goiás - UEG).

Busca-se compreender e identificar, por meio da inspeção predial no conjunto arquitetônico, quais as manifestações patológicas mais recorrentes no sistema de cobertura em argamassa armada, considerando as condições de exposição ambiental. O estudo justifica-se pela necessidade de aprofundar as pesquisas sobre as manifestações patológicas presentes nos componentes de argamassa armada, bem como pelo cenário de vulnerabilidade observado na conservação de algumas unidades dos CAICs. Dessa forma, o trabalho oferece uma base referencial e ilustrativa dos danos para os responsáveis pela gestão da manutenção, auxiliando no planejamento futuro das ações de conservação.

2. Método

O estudo tem caráter exploratório e a análise das manifestações patológicas nos componentes pré-fabricados em argamassa armada configura-se de natureza qualitativa, apoiada em inspeção predial, conforme diretrizes indicadas na NBR 16747 (ABNT 2020). Para o desenvolvimento do quadro analítico, foram adotados os seguintes procedimentos: I - Levantamento de campo e aquisição de imagens aéreas do sistema de cobertura do CAIC; II – Identificação e classificação dos danos; III – Classificação do nível de gravidade.

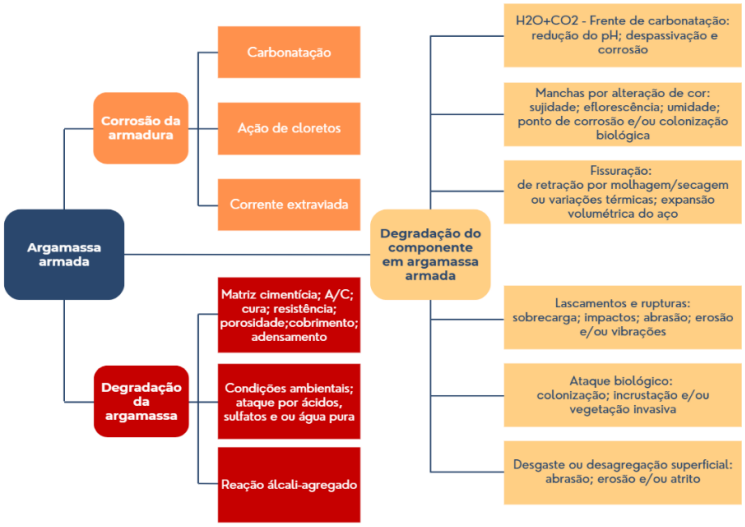
Após sistematização dos dados coletados, elaborou-se um quadro analítico (Quadro 1) que sintetiza a avaliação do estado de conservação da cobertura do CAIC Laranjeiras. Cada manifestação patológica identificada durante a inspeção *in loco* é ilustrada por meio de imagem, classificada, associada à descrição das possíveis causas, agentes e mecanismo de degradação e classificada quanto ao nível de gravidade. Ressalta-se que a investigação e análise foi realizada sem o suporte de testes laboratoriais e instrumentos de medição da extensão dos danos, fundamentando-se na inspeção visual e sensorial e em referências bibliográficas.

2.1 Levantamento de campo e aquisição de imagens aéreas do sistema de cobertura do CAIC

O levantamento de campo foi realizado na unidade do CAIC - a atual Unidade Universitária de Goiânia – Laranjeiras da UEG (Figura 1). Localizado na cidade de Goiânia, no Estado de Goiás, região centro-oeste do Brasil, o complexo educacional encontra-se em ambiente urbano, e por esta condição, de acordo com a NBR 6118 (ABNT 2023), enquadra-se na Classe de Agressividade Ambiental (CAA) do tipo moderada com risco pequeno de deterioração da estrutura. A unidade ainda preserva sua cobertura original em argamassa armada, permitindo inspecionar o estado de conservação do sistema.

Foram inspecionados os cinco componentes que compõem o sistema de cobertura do CAIC: telha- capa; telha-canal; telha de borda (presente nas extremidades do edifício); placa de cobertura; e sheds. O levantamento de campo foi realizado de forma sistemática e sensorial e as imagens foram adquiridas por um drone (DJI Air 2s) com câmera acoplada. Em algumas regiões, foram realizadas inspeções mais detalhadas, utilizando um dispositivo móvel para registro fotográfico das manifestações patológicas.

Figura 1 – Unidade Universitária de Goiânia – Laranjeiras, da Universidade Estadual de Goiás (UEG)



Fonte: Os autores, 2025.

2.2 Identificação e classificação dos danos

Após o levantamento de campo, foi realizada a identificação e classificação das manifestações patológicas. Os critérios para classificação e interpretação dos danos foram baseados em Librório (1989), Helene (1989) e Bertolini *et al.* (2013). A análise de cada manifestação patológica considerou as prováveis causas e mecanismos de degradação, a partir dos fatores de degradação da argamassa armada e processos de corrosão da armadura, conforme Figura 2.

Figura 2 – Causas e mecanismos

Fonte: Os autores (2026), baseado em Helene (1989), Librório (1989) e Bertolini *et al.* (2013)

2.3 Classificação do nível de gravidade

O nível de gravidade abrange a análise do risco oferecido aos usuários, ao meio ambiente e ao bem edificado. Para indicar o nível de gravidade dos danos registrados nos componentes, foi definido uma escala de classificação, por meio de uma régua graduada de cores em 5 níveis com os diferentes critérios - desprezível, mínima, moderada, crítica e altamente crítica -, conforme representado na Figura 3. A

definição dos níveis foi baseada nos critérios de classificação apresentados por Carvalho (2018) e Zanoni *et al.* (2023). As réguas graduadas com cores foram inseridas e demarcadas no quadro analítico.

Figura 3 – Critérios de classificação do nível de gravidade

Nível de gravidade	Cor padrão	Critério de classificação
Desprezível		Risco de impacto ao patrimônio edificado geralmente reversível, sem prejuízo À saúde e segurança dos usuários ou ao meio ambiente. Alterações na argamassa armada que não se enquadram nas condições das outras categorias, com ocorrência eventual e não sistêmica.
Mínima		Risco de causar prejuízos menores à aparência estética do patrimônio edificado, sem prejuízo ao usuário ou ao meio ambiente. Danos de baixa gravidade, com causas bem definidas, que não interferem na estanqueidade do sistema e se limitam ao componente, eventualmente afetando outras camadas.
Moderada		Risco de provocar a perda parcial de desempenho e funcionalidade por afetar a estanqueidade do sistema, podendo resultar em sua degradação precoce. Danos de pequeno grau de gravidade quanto a saúde e segurança do usuário, mas que ao gerar pontos de vulnerabilidade no sistema, podem evoluir para consequências mais graves no futuro, para um ou mais componentes do sistema.
Crítica		Risco para o patrimônio edificado e para o meio ambiente, com perda de desempenho e funcionalidade que compromete a vida útil do sistema e a segurança e a saúde do usuário. Danos resultantes de outros processos de degradação, de modo sistêmico ou não, e que podem afetar um ou mais componentes do sistema.
Altamente crítica		Danos graves do ponto de vista da saúde e segurança do usuário, afetando também o patrimônio edificado e o meio ambiente, resultantes de outros processos de degradação, de modo sistêmico ou não, e que afetam mais de um componente.

3. Resultados e Discussões

Durante a inspeção do sistema de cobertura do CAIC Laranjeiras, foram identificadas diversas manifestações patológicas, tais como: manchas de sujidade, manchas de umidade, variação cromática, exposição e corrosão da armadura, desgaste superficial, fissuras geométricas, lascamentos nas extremidades das telhas, desbotamento, fraturas dos apoios da telha, desplacamento da argamassa armada e infiltração.

A Figura 4 mostra o estado de conservação dos componentes da cobertura. Na Figura 4(a), observa-se que a superfície dos componentes de telha possui manchas de sujidade e umidade. A Figura 4(b) ilustra a superfície após processo de limpeza e proteção efetuado recentemente. O mapeamento dos danos foi realizado nos dois casos: sem limpeza e com limpeza.

Figura 4 – Registro com drone das áreas da cobertura com potencial de análise

(a) (b)

Fonte: Os autores, 2025.

Os sheds, no momento da inspeção, apresentavam-se em bom estado de conservação, embora com sinais de envelhecimento próprios do tempo de vida útil em serviço e das condições de exposição. Foram identificados desbotamento da pintura azul e algumas manchas de sujidade, principalmente na parte externa superior dos componentes.

As telhas-capa são apoiadas sobre as telhas-canal por meio de abas laterais. Esse sistema de montagem permite deslocamentos das telhas no sentido do eixo longitudinal (Figura 5). Durante a vistoria foram identificadas fraturas nos apoios e lascamentos nas extremidades do componente. A maior concentração de argamassa nas extremidades da peça, em decorrência do processo de produção, torna a região mais suscetível a lascamentos e desgaste. Causas mecânicas de impacto e vibrações ou sobrecarga de equipamentos instalados na cobertura podem condicionar aos lascamentos, o que afeta o aspecto físico do painel e a integridade dos apoios laterais. Dependendo da dimensão e profundidade do lascamento, ocorre também a exposição da armadura.

Figura 5 – Deslocamentos no eixo longitudinal das telhas-capa

Foi identificado nas telhas-canal, telha-capa e telha de borda que o desgaste superficial, manchas de sujidade, mancha de umidade e fissuração geométrica são as manifestações patológicas mais recorrentes. Devido à reduzida espessura de cobrimento da argamassa armada, o desgaste superficial contribui para o aumento da porosidade do material e a diminuição da camada de proteção da malha de aço. Consequentemente, o desgaste superficial potencializa uma ação mais agressiva da frente de carbonatação pela exposição constante da superfície às intempéries e à poluição urbana. Fatores intrínsecos relacionados à produção da argamassa armada - como a qualidade da matriz cimentícia e a variabilidade do cobrimento nominal -, podem acelerar a corrosão das armaduras. Além disso, o cobrimento insuficiente em contato com a umidade por meio dos ciclos de molhagem e secagem aceleram os mecanismos de retração superficial da pasta, propiciando a entrada de agentes de degradação pelas fissuras.

Manchas de sujidade são provenientes de partículas atmosféricas, poeira, poluição e dejetos animais que se depositam na superfície dos componentes expostos às intempéries, afetando o aspecto físico e a variação cromática da superfície. Manchas de sujidade podem ocasionar retenção de umidade, pois favorecem o empoçamento de água.

As manchas de umidade em coberturas planas ocorrem pela retenção das águas pluviais, em situações de escoamento inadequado, insuficiência dos sistemas de drenagem, obstruções ou presença de vegetação ou sujeira acumulada. A umidade constante pode resultar na colonização biológica e desenvolvimento de fungos, bolor e microorganismos. De acordo com Librório (1989), as superfícies infectadas e constantemente úmidas promovem a redução do pH da argamassa e a desagregação superficial, tornando a superfície porosa e favorecendo a despassivação da armadura.

Foram identificadas fissuras geométricas de padrão reticulado na região das armaduras. A fissuração pode estar relacionada às variações higrotérmicas dos componentes ou associada às tensões internas provocadas pela expansão do volume da armadura com corrosão. De acordo com Souza e Ripper (1998),

as fissuras localizadas na região das armaduras são mais nocivas, pois permitem a infiltração direta de agentes de degradação, facilitando a corrosão das armaduras.

As vigas-calhas possuem dupla função: estrutural e de canal para escoamento das águas pluviais até os tubos de queda embutidos nos pilares. Nas áreas voltadas para as fachadas, foram identificados acúmulos de umidade decorrentes de falhas na inclinação de escoamento, comprometendo o desempenho do sistema de drenagem. Além disso, desplacamentos da camada de argamassa armada foram identificados nessas áreas, resultando na exposição das armaduras. Esta condição favorece o processo de corrosão, uma vez que a perda da proteção superficial permite o contato direto do aço com os agentes de degradação.

Observa-se na Figura 5 a presença de sujeira e folhas no fundo da viga-calha, dificultando o escoamento das águas e o acúmulo de umidade no bocal de entrada do tubo de queda nos pilares. A umidade constante nesse local provoca processos corrosivos no tubo de descida, o que facilita a infiltração no teto das salas.

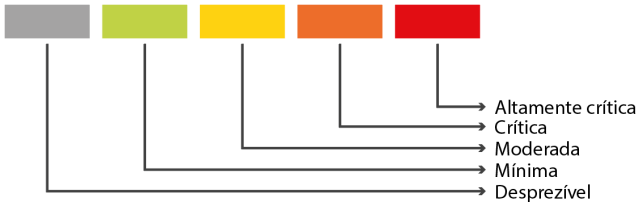
As placas de cobertura localizadas abaixo dos componentes de telhas desempenham a função de laje de forro. Entre as placas e os painéis de telha existe um espaço ventilado e vazio, onde foram identificadas manchas de sujidade e acúmulo de entulhos provenientes de serviços anteriores de manutenção.

As superfícies internas estavam em bom estado de conservação, porém em algumas regiões foram detectadas infiltrações causando manchas de umidade e sujidades. Foi identificado empolamento e formação de bolhas na pintura da superfície interna das vigas-calhas decorrente da infiltração de água na interface entre a laje e viga-calha.

3.1 Quadro analítico

Por meio da identificação e análise das principais manifestações patológicas constatadas, o Quadro 1 apresenta uma síntese dos dados, composta por imagens exemplificativas registradas no momento da inspeção, classificação e descrição de cada manifestação patológica. O quadro relaciona essas ocorrências às condições de exposição, agentes e mecanismos de degradação envolvidos.

Quadro 1 – Quadro analítico das manifestações patológicas.



Classificação da manifestação patológica	Imagem	Descrição
Manchas de sujidade 		Presença de sujidades na superfície da telha decorrentes da deposição de partículas atmosféricas, poeira, poluição e dejetos animais. As telhas com superfícies mais porosas propiciam maior impregnação de sujeira. Esta condição pode afetar o aspecto físico da superfície e causar variação cromática.
Deposição de sujeira na superfície da placa de cobertura 		O espaço para a camada de ar existente entre a telha e a placa de cobertura torna-se um lugar favorável para o acúmulo de sujidade e detritos provenientes de serviços de manutenção. A água da chuva pode direcionar esses detritos para as calhas e chegar aos tubos de queda, entupindo a entrada dos coletores. O acúmulo de entulho pode causar danos à superfície da placa, por ações mecânicas, além de favorecer pontos de infiltração.

Empolamento da tinta 		Infiltrações na laje provenientes das águas pluviais da cobertura escoam para as vigas e danificam a pintura. Possíveis falhas no tratamento e proteção adequada das superfícies podem ter provocado o empolamento da tinta.
Obstrução do bocal do tubo de queda por acúmulo de sujidade e folhas 		Deposição de folhas no bocal do tubo de queda devido à existência de árvores de grande porte próximas ao edifício. A falta de manutenção e acúmulo desses detritos vegetais provocam o entupimento dos coletores de água pluvial. Além disso, entulhos e restos de construção costumam ser depositados inadequadamente sobre as lajes e, em períodos chuvosos, são carreados para as calhas e tubos de queda, ocasionando obstruções e novos entupimentos.
Manchas de umidade 		Manchas de umidade provenientes de empoçamento, acúmulo de sujeira e escoamento inadequado, quando persistentes, tendem a escurecer e podem indicar a presença de colonização biológica por fungos, bolores e outros microorganismos. A ocorrência dessas manchas também pode sinalizar ciclos repetitivos de molhagem e secagem, responsáveis por provocar variações volumétricas no material e acelerar os mecanismos de retração superficial da pasta.
Desgaste superficial 		Perda gradual da pasta devido à exposição contínua da argamassa armada às intempéries, somada ao desgaste natural provocado pela ação do tempo ou por falhas no processo de produção. Esse desgaste resulta em porosidade excessiva e na degradação da camada de pasta responsável pela estanqueidade do componente, tornando-o vulnerável à ação e à penetração de agentes agressivos que podem atingir as armaduras.

(Continua)

Corrosão da malha de aço 		Corrosão eletroquímica ocorre pela despassivação do aço, resultante da interação destrutiva das armaduras com agentes de degradação, como a umidade e o gás carbônico que penetram pela porosidade superficial, processo favorecido pelo desgaste superficial ou por falhas no cobrimento de argamassa.
Fissuração geométrica 		Fissuras localizadas na região da malha podem estar associadas às tensões internas provocadas pela expansão volumétrica da armadura com corrosão. O reduzido cobrimento de argamassa favorece o mapeamento das fissuras geométricas que acompanham a posição das barras na malha de aço.
Lascamento nas extremidades do componente 		Perda de seção da telha por lascamento da argamassa armada. A região afetada localiza-se na extremidade onde ocorre a concentração de pasta de argamassa durante o processo de produção. Nesse ponto, não há presença de armadura. A causa pode estar relacionada a fatores de origem mecânica, como impacto na região.
Fratura nos apoios laterais 		Deslocamentos horizontais da telha, impactos e sobrecargas podem provocar lascamentos nos apoios laterais, fragilizando a estruturação do componente. As movimentações estruturais e térmicas dos painéis também podem favorecer a fratura dos apoios laterais.

(Continua)

Deslocamento da telha capa 		Nas regiões onde foram realizadas a limpeza das telhas-capa foram identificados deslocamentos horizontais dos pontos de apoios. As movimentações podem ocorrer por ações humanas devido às falhas de operação durante a manutenção, instalação de equipamentos e/ou reparos.
Desplacamento do cobrimento de argamassa armada 		Desplacamento do cobrimento de argamassa armada devido ao acúmulo de umidade por falhas no sistema de drenagem, possíveis deficiências na matriz cimentícia ou problemas no processo de produção. A dificuldade de adensamento do material nas regiões onde os coletores são posicionados costuma resultar em pontos com menor aderência e maior porosidade, favorecendo a degradação precoce.
Legenda: 		

Fonte: Os autores, 2026.

Com a inspeção verificou-se que os componentes de argamassa armada da cobertura são acometidos por manifestações patológicas relacionadas a diversas naturezas e causas. Dentre as manifestações patológicas identificadas, as manchas de umidade e manchas de sujidade ocorrem devido a falhas nos escoamentos das águas pluviais e ausência de manutenções periódicas, sendo considerado mínimo o seu nível de gravidade.

A retenção de umidade na telha pode levar a ocorrência de outras manifestações patológicas como a colonização biológica, afetando as características físicas da superfície, favorecendo o desgaste superficial e consecutivamente o aumento da porosidade superficial da argamassa. Esta condição, quando não tratada, pode levar a exposição das armaduras, permitindo o contato de agentes de degradação, resultando na corrosão das armaduras. Com isso, a relevância de manutenções periódicas, recuperação da camada de cobrimento, limpeza e aplicação de camadas impermeabilizantes podem reduzir os riscos de exposição das armaduras e prolongar a vida útil do componente.

Os lascamentos e fraturas laterais dos apoios das telhas não representam uma manifestação patológica predominante, porém quando acometem os componentes podem afetar sua integridade estrutural. As fissuras geométricas em torno da malha de aço representam um risco para sua durabilidade e desempenho, podendo evoluir para consequências mais graves se os agentes de degradação atingirem as armaduras.

Os desplacamentos de argamassa identificados nas vigas-calhas representam as manifestações patológicas com nível de gravidade crítico, pois ocorre o risco de perda de desempenho com a exposição das armaduras, comprometendo a vida útil do sistema. Esta condição ocorre devido às falhas no escoamento de água que resultam no acúmulo de umidade nas extremidades da viga. A falta de manutenção, ausência de inspeção e falta de limpeza dos tubos de queda das águas pluviais podem potencializar a corrosão das armaduras e diminuir o desempenho estrutural do elemento, além de prejudicar esteticamente o conjunto arquitetônico, pois localizam-se em regiões visíveis nas fachadas.

A ausência de manutenções periódicas e de sistemas de escoamento eficientes tornam a retenção de umidade e sujidade como o principal agente de degradação. Durante a vistoria não foram detectadas manifestações patológicas com nível de gravidade altamente crítica.

4. Conclusões

Por meio da inspeção predial realizada no CAIC foi possível analisar e compreender as manifestações patológicas presentes nos componentes de argamassa armada, bem como suas causas, agentes e mecanismos. Passados mais de 30 anos de existência depois de sua construção, os resultados demonstram que a cobertura do CAIC, considerando as condições de exposição e agressividade ambiental de Goiânia, apresenta um estado de conservação razoável. Os procedimentos metodológicos adotados podem ser utilizados e adaptados nos CAICs implantados em outros contextos regionais para analisar e avaliar o estado de conservação, de modo a propor práticas corretivas e delinear os procedimentos de manutenção e intervenção para cada região.

A dificuldade de reposição dos componentes com o mesmo padrão original, devido a desativação das fábricas de argamassa armada propostas por Lelé, tornam as manutenções preventivas e corretivas essenciais para garantir a durabilidade e a integridade do edifício. Ainda assim, este estudo exploratório e qualitativo evidência que, os mecanismos, causas e agentes de degradação da argamassa armada são semelhantes com os presentes no concreto armado, embora possuam características e composição material distintas.

O quadro analítico sintetiza as manifestações patológicas detectadas na vistoria e apresenta o nível de gravidade como indicativos do risco e grau de degradação, com o propósito de orientar as atividades de inspeção, de reparo e manutenção nos componentes pré-fabricados em argamassa armada, servindo como base referencial para os profissionais responsáveis e gestores das edificações. A formatação adotada que associa a cor para a correspondência do nível de gravidade da manifestação patológica auxilia na priorização dos procedimentos de intervenção. Portanto, trata-se de um instrumento que contribui para a preservação do conjunto arquitetônico escolar pré-fabricado de Lelé, de modo a assegurar a continuidade de sua função social e suporte físico para a educação de diversas crianças e adolescentes no Brasil.

Abstract: The architectural documentation of built heritage is a fundamental step in preserving cultural memory, providing a basis for future interventions, and enabling the proper management of these assets. In the Brazilian context, many historic buildings present documentary gaps resulting from the absence of systematized technical records over time. This research addresses the architectural documentation of the San Sebastian Church, located in the municipality of Russas, Ceará, Brazil, built in 1872, whose historical trajectory includes significant interventions throughout the 20th century, such as the first recorded renovation in 1922 and the complete repainting carried out in 1995. The study aims to survey and systematize the architectural and historical data of the building and to incorporate this information into a digital model of the historic asset. The methodology comprised three main stages: a bibliographic and documentary survey of existing sources; laser scanning to obtain the geometry of the building through the generation of a point cloud; and the integration of historical information into the digital model. As a result, relevant historical documents were identified, and a digital model was developed based on the point cloud, incorporating information on the transformations that have occurred over time and the current condition of the church. The research highlights the importance of integrating documentary data and field survey data with digital technologies as strategies for conservation and information organization, supporting future restoration and preservation efforts.

Keywords: Architectural heritage; Architectural documentation; Point cloud; Digital survey

1. Introduction

Historic buildings constitute an important component of cultural heritage, as they preserve architectural, social, and historical values across generations. These assets represent material records of the evolution of construction techniques, social dynamics, and local identities, playing a fundamental role in understanding the urban and cultural development of communities (Tan et al., 2026). Furthermore, such buildings contribute to the construction of collective memory, functioning as physical landmarks that connect past and present. In this sense, their preservation goes beyond material conservation, encompassing the maintenance of their historical and cultural meanings. The valorization of these assets directly contributes to strengthening local identity and promoting culture (Atik et al., 2023). Therefore, built heritage assumes a strategic role both in academia and in society.

However, the long-term preservation of these structures is directly conditioned by the existence of technical and historical records that allow understanding their original configuration, transformations, and current state (Hussein et al., 2024). The absence or insufficiency of documentation significantly compromises the preservation of built heritage memory, hindering the analysis of past interventions and the proposal of future actions (Salah et al., 2025). Moreover, it limits the production of scientific knowledge related to built heritage, as it restricts access to essential information about its evolution. This scenario highlights the need for systematic processes of data recording and organization. Thus, architectural documentation emerges as an essential element for heritage safeguarding, as it enables the recording, interpretation, and transmission of information over time.

Architectural documentation is, therefore, one of the fundamental pillars for the preservation of built heritage (Merzhiievska et al., 2026). Through it, it is possible to systematically record the physical, constructive, and historical characteristics of buildings, allowing the understanding of their evolution over time. This process enables the identification of transformations, degradation, and interventions that affect the integrity of heritage assets (Li et al., 2023). Additionally, it provides essential technical support for historical studies, conservation projects, and valorization actions. In contexts where consolidated technical records are lacking, documentation becomes even more relevant, acting as a tool for reconstructing the construction history of buildings. In this way, it contributes both to the preservation of material memory and to the advancement of scientific knowledge (Moyano et al., 2025).

With the advancement of digital technologies, new approaches have been incorporated into architectural documentation processes, significantly enhancing their accuracy, reliability, and capacity for data integration. Among these approaches, the use of three-dimensional digital models stands out, as they allow a more faithful representation of the geometric characteristics of buildings (Penjor et al., 2024). In addition, these technologies enable the organization of large volumes of information within structured digital environments. As a result, there has been a transformation in how heritage is documented, analyzed, and managed. This technological progress has driven the development of new methodologies for recording and interpreting built heritage, incorporating dimensions that were previously less explored, such as the integration of geometric and informational data (Cardinali et al., 2023).

In this context, Historic Building Information Modeling (HBIM) has emerged as a relevant tool for the documentation and management of historic buildings. Unlike conventional Building Information Modeling (BIM), HBIM seeks to integrate geometric, constructive, and historical data into digital models, enabling a more comprehensive representation of heritage. This approach allows not only the three-dimensional modeling of the building, but also the incorporation of information about the historical and cultural value associated with its elements. Recent studies have expanded this discussion by introducing different levels of information applied to HBIM. The Level of Information (LOI) emphasizes the incorporation of technical and historical data (Brumana et al., 2019), while the Level of History (LOH) focuses on the inclusion of historical narratives (Stefano Brusaporci et al., 2021). Complementarily, the Level of Knowledge (LOK) proposes dynamic and continuously updated models (Korro Bañuelos et al., 2021).

At the same time, reality capture technologies have played a central role in the evolution of architectural documentation. Terrestrial laser scanning (TLS) stands out as one of the main techniques used in this context (Kubacka et al., n.d.). This technology enables the acquisition of highly accurate geometric data through the generation of three-dimensional point clouds (Fellas & Demosthenous, 2025). The process is based on the emission of laser beams capable of capturing millions of points in space, accurately recording building geometry. As a result, complex and hard-to-access elements can be represented with a high level of detail. In addition, TLS offers advantages such as rapid data acquisition and error reduction (Merzhiievska et al., 2026). Therefore, it is considered a highly suitable tool for heritage documentation.

Despite these technological advances, there is still a significant gap in the integration of geometric data and systematically organized historical information (Fernandes Dionizio et al., 2025). In many cases, digital models focus primarily on geometric representation, neglecting the historical dimension that characterizes heritage. This limitation compromises the development of more complete and informative models and reduces their analytical potential over time. In this sense, there is a clear need for approaches that combine digital surveying with documentary analysis. The integration of these dimensions enables the creation of richer and more representative models, enhancing the understanding of architectural heritage (Moral Saiz et al., 2021).

In recent years, digital heritage documentation has significantly advanced, driven by the integration of reality capture techniques and information modeling. Since 2020, studies have emphasized the combination of HBIM, photogrammetry, and laser scanning, enabling the generation of detailed and semantically structured three-dimensional models (Cardinali et al., 2023). At the same time, collaborative

platforms for point cloud annotation and digital twin applications for heritage management have been developed (Medjdoub et al., 2026). These approaches allow not only documentation but also continuous monitoring of buildings. As a result, the potential applications of digital models have expanded (Atik et al., 2023), reinforcing the importance of integrating multiple technologies in architectural documentation (Lewińska et al., 2022).

More recently, advances in artificial intelligence, machine learning, and extended reality technologies have further expanded the possibilities for analyzing and managing built heritage (Martinenko et al., 2025). These tools enable the automation of data interpretation processes, the identification of degradation patterns, and support decision-making in interventions. Additionally, they allow the creation of immersive environments for visualization and analysis (Carvalho Ottoni & Cordeiro Ottoni, 2025). This trend reflects a transformation in how heritage is studied and preserved. The integration of these technologies with HBIM points to new perspectives in architectural documentation, consolidating a scenario of increasing digitalization of cultural heritage.

Despite these advancements, studies that consistently integrate historical information into digital models are still scarce. Such data are essential for understanding the trajectory of buildings, their meaning, and the context in which they were constructed and transformed over time (Lukito, 2025). Furthermore, they enable the identification of interventions, renovations, and spatial changes. The absence of this historical dimension limits heritage interpretation and reduces the informational value of digital models. Therefore, it is necessary to develop approaches that integrate historical and geometric data in a structured manner. This integration enriches heritage representation and enhances its cultural, historical, and scientific value (Ribeiro et al., 2026).

In this context, this study aims to perform the architectural documentation of the San Sebastian Church, located in the municipality of Russas–CE, Brazil, through the integration of digital surveying and documentary analysis. The research seeks to systematize geometric, architectural, and historical information about the building, contributing to the organization of knowledge related to this heritage asset. Furthermore, it aims to provide support for historical studies and to enhance the understanding of the building's transformation process over time. To this end, reality capture technologies are employed, particularly terrestrial laser scanning, enabling the generation of a three-dimensional point cloud and the development of a digital model. Thus, this study contributes to advancing practices in built heritage documentation.

2. Historical Building – San Sebastian Church

The present study focuses on the San Sebastian Church, a religious building located in the municipality of Russas, in the Jaguaribe Valley, state of Ceará, Brazil. The selection of this case study is justified by its historical, cultural, and architectural relevance within the regional context, as well as its significant level of preservation when compared to other religious buildings in the semi-arid region of Ceará that have undergone more extensive transformations over time. In this sense, the church represents an important example of local built heritage, allowing an integrated analysis of historical, constructive, and architectural aspects.

The origin of the building is directly related to the socio-environmental context of the 19th century in the interior of Ceará, marked by severe droughts and epidemics such as cholera and bubonic plague, which strongly affected the population (Araújo, 1986). In this scenario, popular religiosity played a central role as a form of collective coping, resulting in the construction of devotional spaces. The San Sebastian Church thus emerged from a vow made by the local community and was dedicated to the saint traditionally associated with protection against diseases, highlighting the strong relationship between faith, territory, and social memory.

The construction of the temple was led by the parish priest Lino Deodato Rodrigues de Carvalho and was completed around 1872 (Araújo, 1986). Since then, the building has maintained its original layout and presents relative spatial integrity, despite interventions carried out over time. In addition to its material value, the church preserves its religious and symbolic function, serving as a venue for cultural expressions and festivities that remain active. This continuity of use, combined with its historical relevance and the potential for analyzing constructive transformations, reinforces its suitability as a study object, particularly in research focused on architectural documentation and heritage information modeling. Figure 1 presents an external view of the San Sebastian Church.

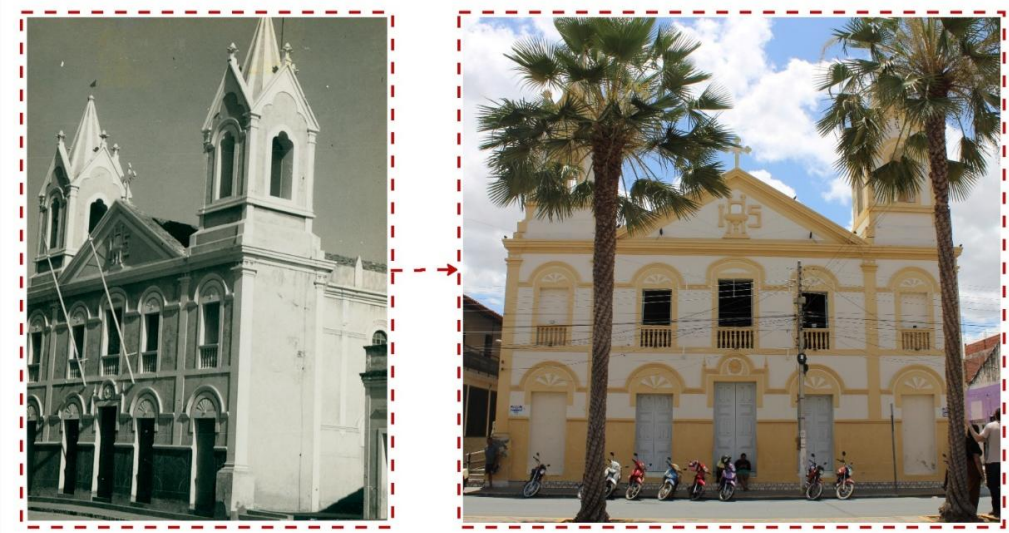

Figure 1 – Comparative external views of the San Sebastian Church in 1951 and 2026.

3. Methodology

3.1 Documentary and historical survey

The historical and documentary survey of the San Sebastian Church was conducted using an exploratory approach, aiming to identify buildings of relevance in the municipality of Russas with potential for research development. Initially, consultations were carried out in the local museum archive, where the church was selected as the study object due to its historical value and its relatively high level of preservation, especially when compared to other religious buildings in the region.

After defining the case study, contact was established with the parish priest, through whom authorization was obtained to access the church's documentary archive. The analyzed material includes a variety of primary sources, such as written records, historical photographs, administrative documents, and materials related to religious festivities. Among these, notebooks and booklets used during the celebrations of San Sebastian stand out, as they contain information on the organization of festivities, community fundraising, and interventions carried out in the building.

The document analysis was conducted systematically, allowing the indirect identification of different stages of maintenance, renovation, and adaptation of the church over time. These data were organized into a timeline and subsequently correlated with the geometric information obtained from the digital survey. This procedure enabled the development of a consistent basis for understanding the building's evolution, highlighting the importance of integrating local historical sources with digital technologies in architectural heritage documentation. Figure 2 presents examples of the historical documentation collected during the research.

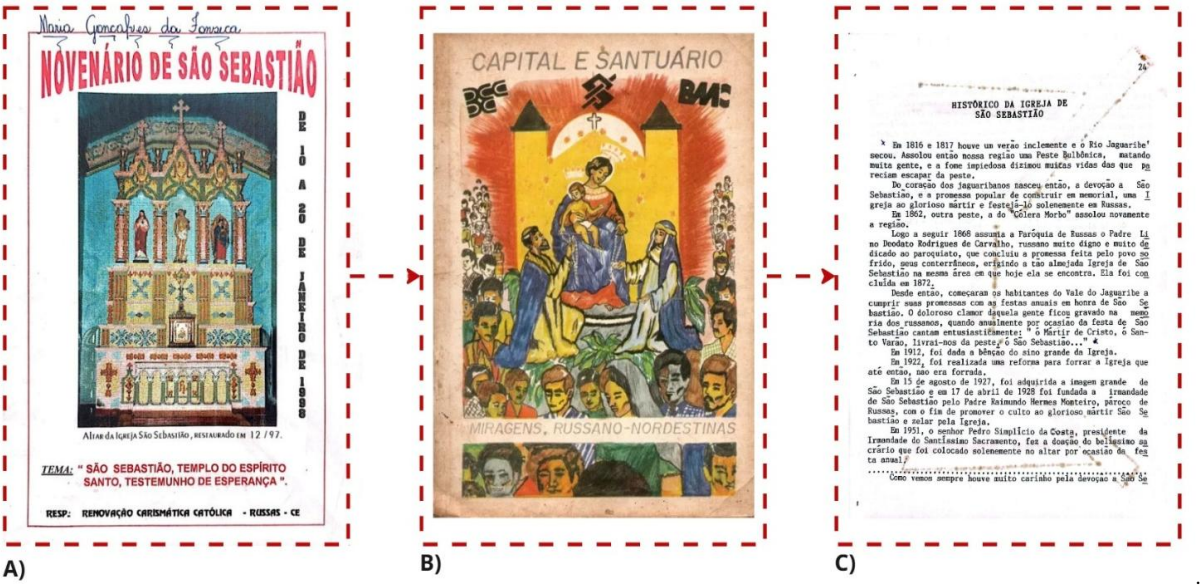

Figure 2 – Historical documents collected: (a) novena booklet cover; (b) cover of a historical publication on the San Sebastian Church; (c) excerpt from the novena booklet containing historical descriptions and records of interventions.

3.2 Laser scanning survey

The geometric survey of the San Sebastian Church was carried out using terrestrial laser scanning with the portable Leica BLK2GO scanner (Leica Geosystems), based on SLAM (Simultaneous Localization and Mapping) technology, which enables continuous acquisition of three-dimensional data without the need for fixed stations. Data collection was performed through a continuous path inside the building, covering all interior spaces, with real-time monitoring to ensure data quality and coverage. After acquisition, the point cloud was processed using proprietary Leica Geosystems software, resulting in a detailed three-dimensional model that served as the basis for digital modeling and the integration of historical information.

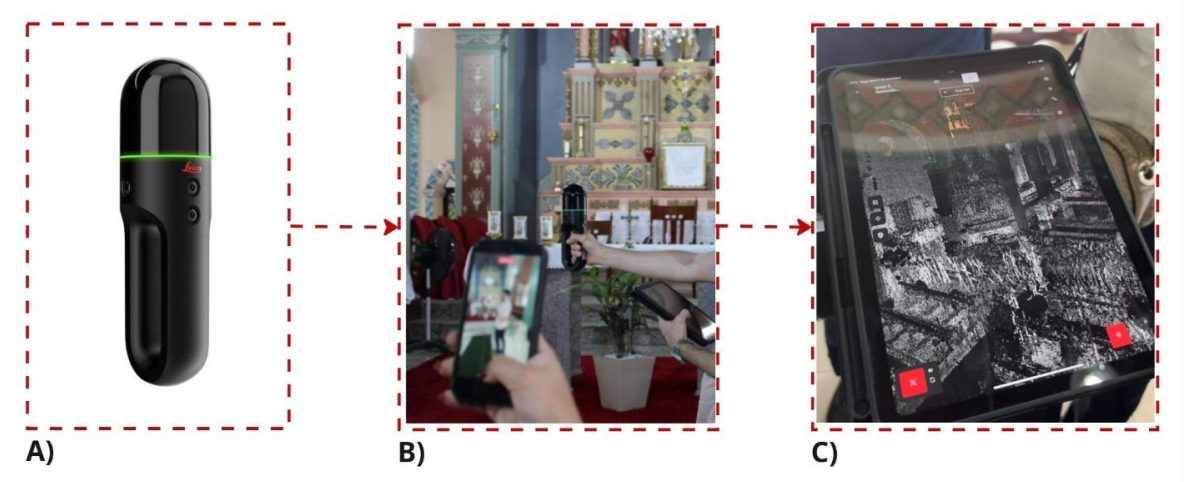

Figure 3 – Architectural survey using the BLK2GO laser scanner: (a) BLK2GO device; (b) in situ data acquisition process; (c) real-time monitoring of point cloud generation on a tablet during scanning.

3.3 Point cloud processing and digital modelling

After acquisition, the point cloud was processed and imported into Autodesk Revit, where it served as the basis for the digital modeling of the building. The data were previously organized and verified for geometric

consistency, enabling the construction of a parametric three-dimensional model representing the main architectural features of the San Sebastian Church, including walls, openings, and roof elements. The modeling process followed the BIM logic, allowing the structuring and association of information, with the incorporation of historical data related to interventions over time. Thus, the resulting model acts as an integrated information repository, aligned with HBIM principles and oriented toward the historical analysis of the building. Figure 4 presents the simplified flowchart of the methodological steps adopted in this research.

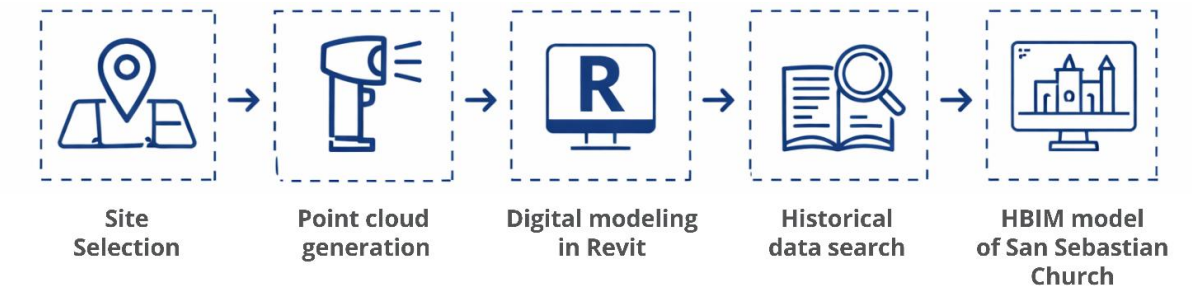

Figure 4 – Flowchart of the methodological workflow for the documentation of the San Sebastian Church.

4. Results and Discussion

4.1 Digital model based on point cloud

The digital modeling process resulted in a parametric three-dimensional representation of the Church of São Sebastião, accurately capturing its main architectural elements, such as walls, openings, and roof structures. Based on the point cloud, the model presents high geometric fidelity, ensuring consistency and alignment with the existing building. The rendered façade reinforces the reliability of the model in representing the built reality. In addition to its geometric accuracy, the model is structured parametrically, allowing the integration of historical and semantic data within the HBIM framework. Thus, it constitutes a comprehensive digital asset for documentation, visualization, and future analyses. Figure 6 illustrates the process of point cloud generation, integration, and application, as well as the resulting model.

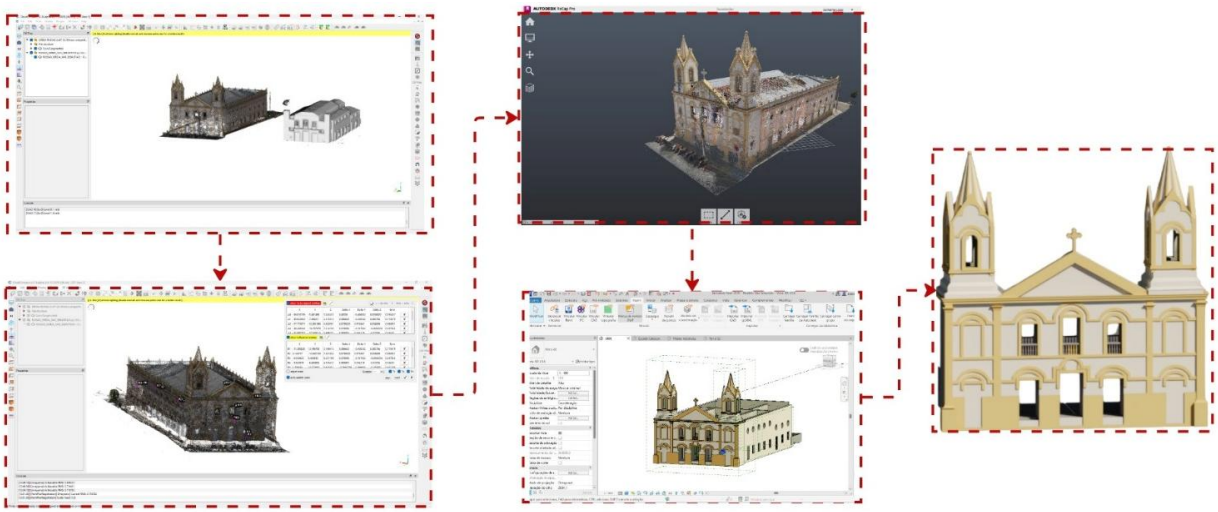

Figure 6 – Representation of point cloud processing and subsequent architectural modeling.

4.2 Historical documentation

The documentary survey conducted within the archive of the San Sebastian Church parish enabled the identification of a relevant set of historical sources related to the building. Among the analyzed materials, religious booklets used in local festivities stand out, as they contain descriptive records about the church's history, as well as information regarding interventions carried out over time. Additionally, excerpts from the book Imagem e Santuário were identified, contributing to the understanding of the building's origin, its constructive aspects, and the context of its implementation. These sources, combined with complementary searches, allowed the consolidation of a consistent historical overview of the study object.

The analyzed documents reveal different interventions carried out on the building, including renovations, restorations, and acquisitions of liturgical elements. In addition to written records, historical photographs were identified, visually documenting these transformations, such as changes to the altar, restoration works, and roof replacement. It is also noteworthy that some changes were not formally recorded in written documents but were inferred through comparative image analysis. This is the case of the replacement of the original flooring—previously hydraulic tile—with ceramic covering, as evidenced by photographic records from different periods.

The systematization of this information enabled the construction of a timeline of interventions carried out on the San Sebastian Church, presented in Table 1, which summarizes the main modifications identified over time. Additionally, Figure 5 illustrate the evolution of the building, facilitating the understanding of the transformations that occurred. Together, these elements contribute to the organization of the building's historical knowledge and serve as a basis for its integration into the HBIM model, allowing the association of historical data with the digital representation of the heritage asset.

Table 1 – Summary of the interventions carried out at the San Sebastian Church over time. Source: Authors' elaboration based on documentary survey (2025).

Year / Period	Type of Intervention	Description of Modification	Technical Characterization
1868–1872	Construction	Construction of the church under the coordination of the parish priest Father Lino Deodato Rodrigues de Carvalho, in fulfilment of a vow made by the local population after epidemics	Original implementation of the building at the current site; traditional construction system
1912	Acquisition	Blessing and installation of the main bell	Addition of a liturgical and functional element to the tower
1922–1924	Renovation	Installation of the church's internal ceiling	Intervention in the upper enclosure element (ceiling), previously non-existent
1927	Acquisition	Acquisition of the image of Saint Sebastian	Addition of an artistic and symbolic element to the interior
1951	Acquisition	Donation and installation of the tabernacle on the altar	Incorporation of a fixed liturgical element into the main altar
1991	Cleaning and Restoration	General cleaning, plaster repairs, termite removal, and renewal of the Stations of the Cross	Conservation intervention and recovery of finishes and decorative elements

1992	Construction and Renovation	Construction of restrooms, sacristy, and lateral arches; new interior painting	Expansion of the building and updating of interior finishes
1993	Acquisition	Installation of a sound system and new altar elements	Functional modernization and liturgical adaptation
1994	Restoration and Acquisition	Restoration of side altars and acquisition of fans and benches	Intervention in artistic elements and improvement of environmental comfort
1995	External Renovation and Restoration	Façade painting and partial ceiling recovery with wood replacement	Maintenance of the external envelope and localized structural repair
1996	Electrical Renovation	Replacement and expansion of the electrical system and lighting improvements	Update of the building's electrical system
1997	Artistic Restoration	Restoration of the Saint Sebastian altar with artistic painting	Intervention in a historical-artistic element
2020	Renovation	Replacement of the roof with a metal structure	Significant modification of the roofing system (material and performance)

Figure 5 – Historical records of interventions at the San Sebastian Church: (a) altar restoration in 1997; (b) roof renovation process in 2020; (c) installation of the new metal roofing system.

4.3 Digital model and integration of historical information

The stage of integrating historical information consisted of incorporating into the digital model the previously cataloged data (Table 1), including records of interventions, dates, and documentary evidence. The information was integrated according to its availability: interventions with photographic records had the images linked to the corresponding elements of the model (Figure 7), while those with limited data were represented through temporal annotations.

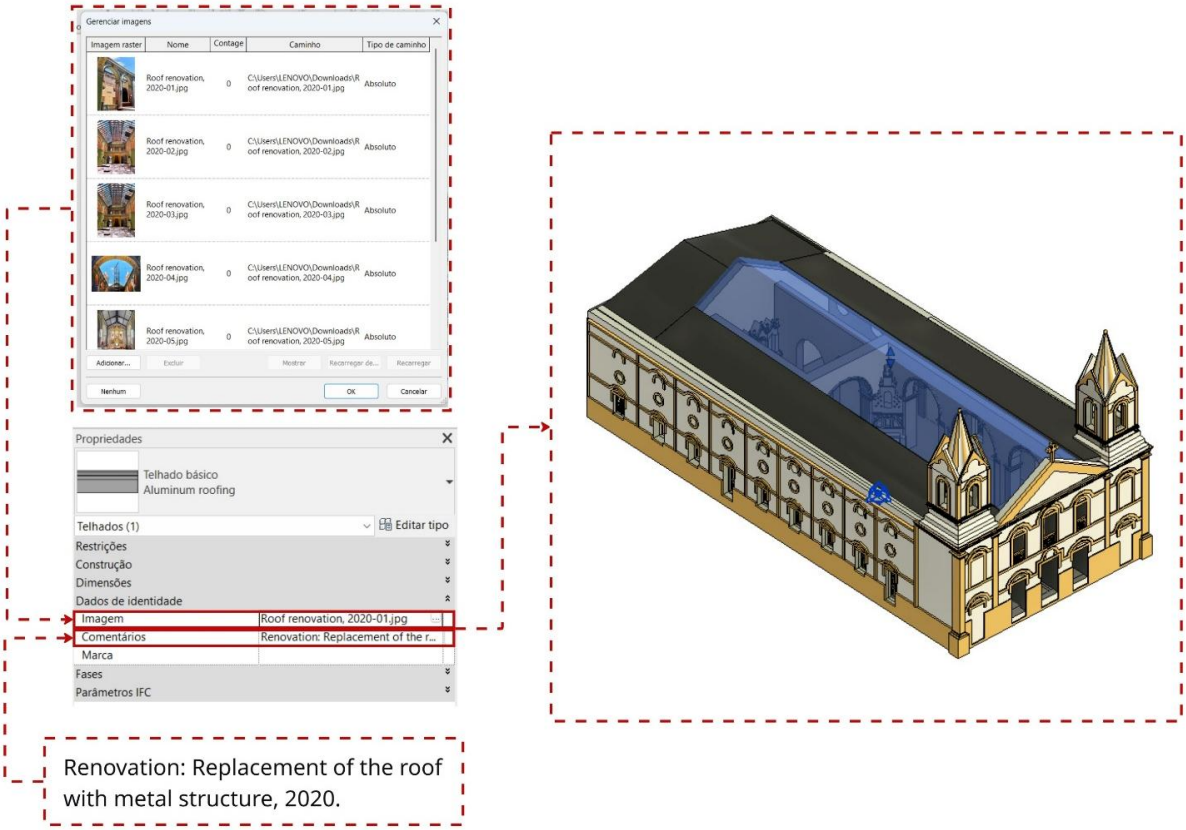

Figure 7 – Illustration of the integration of documentary information into the model, incorporating images and semantic data derived from literature and personal records.

Additionally, the chromatic changes of the building were modeled through the creation of different model states, allowing the faithful representation of distinct moments over time. In this context, two main scenarios were developed: the current model, in which the building is represented in yellow, and the model corresponding to the year 2006, represented in green, as evidenced by the historical records (Figure 8).

This approach enabled the development of an enriched HBIM model, in which geometric and historical information are integrated within a single digital environment. The resulting model not only represents the physical configuration of the building but also systematizes its evolution over time, serving as a tool to support historical analysis, heritage documentation, and decision-making in future interventions.

Figure 8 – Representation of the façade color changes over time (A–2005; B–2026).

5. Conclusions

This study demonstrated the potential of integrating terrestrial laser scanning and HBIM methodologies for the documentation and analysis of built heritage, using the San Sebastian Church as a case study. The results highlight the importance of generating an accurate geometric survey through point cloud acquisition and its subsequent conversion into a parametric digital model, particularly in contexts where no prior technical documentation, such as architectural drawings or plans, is available. In this sense, the developed model not only represents the current physical configuration of the building but also establishes a reliable digital record of the asset.

The main contribution of this research lies in the integration of historical information into the digital model, based on documentary sources, photographic records, and institutional materials. The association between geometric data and historical evidence enabled the identification and interpretation of interventions carried out over time, including constructive and chromatic changes. This approach reinforces the role of HBIM as a comprehensive tool for heritage documentation, allowing the systematization of dispersed information within a structured and accessible environment.

Furthermore, this work highlights the importance of maintaining continuous and organized records of interventions in historic buildings. The absence of formal documentation, observed in the case study, reflects a common reality in many contexts, while also demonstrating how informal records, such as photographs and notes, can be essential in supporting future conservation actions. In this regard, the adoption of systematic documentation practices by religious institutions and heritage management bodies can significantly contribute to heritage preservation. As a future perspective, the expansion of the model through the incorporation of additional temporal layers, the improvement of information standardization,

and the application of the methodology to other historic buildings are highlighted, strengthening digital heritage documentation practices.

Acknowledgments

The authors would like to thank the parish priest, Father Pedro, for his availability and authorization to conduct this research at the San Sebastian Church. The authors also extend their gratitude to the entire team of the Nossa Senhora do Rosário Parish for their hospitality, cordiality, and support throughout the development of this study. Special thanks are given for providing access to historical records, documents, and personal archives, which were essential for the development and consolidation of the results presented.

Integração entre tradição e inovação: desafios para aplicação da madeira laminada colada em patrimônios edificados

Mônica NICOLAU[1], Ricardo DIAS SILVA[2]

[1] Centro Universitário Cidade Verde, Maringá, Brazil, monicanicolau.engenharia@gmail.com
[2] Universidade Estadual de Maringá, Paraná, Brazil, rdsilva@uem.br

Abstract: This study aims to evaluate the potential of glued laminated timber (Glulam) as a solution for the structural rehabilitation of a historic building located in the city of Viseu, Portugal, through a qualitative and analytical approach based on a case study. The methodology applied in this research is grounded in the need to develop an integrated understanding of the existing structural behavior, the identified pathological manifestations, and the compatibility between the original construction systems and contemporary solutions, such as engineered timber. For the development of the study, an architectural and structural characterization of the building was carried out, including a dimensional survey, identification of the original construction systems, and technical inspections. The structural diagnosis was supported by systematized visual inspections aimed at assessing the state of conservation and the load-bearing capacity of the structural elements. Based on the data obtained, this article presents a proposal for structural rehabilitation using Glulam, founded on the principles of mechanical compatibility, durability, reversibility, and minimal intervention, in accordance with heritage preservation guidelines. The study thus discusses the importance of harmonizing tradition and innovation, highlighting its decisive role in durability, structural safety, and the preservation of the cultural values of the built heritage.

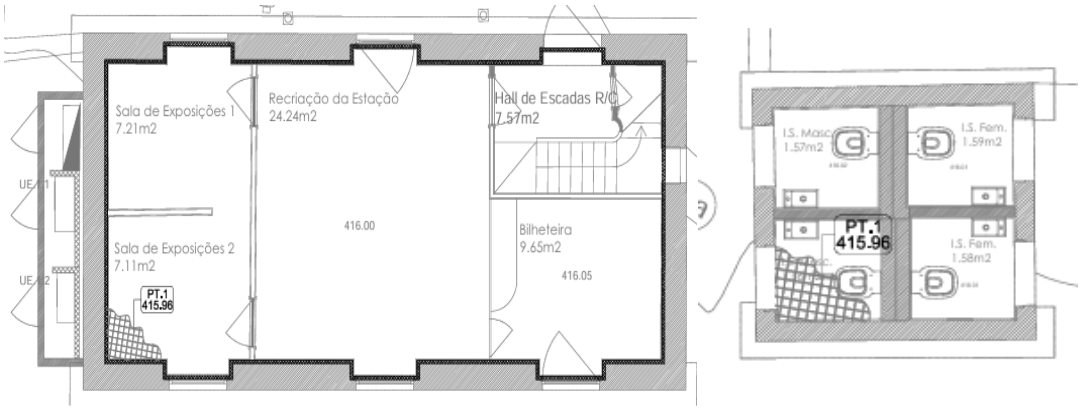
Keywords: Glued Laminated Timber, structural behaviour, heritage, wood structures, engineered wood

1. Introdução

A preservação do patrimônio edificado representa um campo de atuação complexo e multidisciplinar, no qual se articulam valores históricos, culturais, sociais e técnicos. As edificações históricas constituem testemunhos materiais de técnicas construtivas, modos de vida e contextos tecnológicos específicos de seu tempo, sendo, portanto, fundamentais para a construção da memória coletiva e da identidade urbana. Intervir nesses bens exige uma abordagem criteriosa, capaz de assegurar a integridade material e simbólica das construções, ao mesmo tempo em que se atendem às exigências contemporâneas de segurança estrutural, funcionalidade e durabilidade. Nas últimas décadas, a reabilitação do patrimônio cultural construído tem se consolidado como uma alternativa sustentável à substituição do edificado existente, alinhando-se a diretrizes internacionais de conservação e às políticas de redução de impactos ambientais no setor da construção civil. Nesse contexto, a reabilitação estrutural assume papel central, uma vez que muitas edificações históricas apresentam manifestações patológicas decorrentes do envelhecimento natural dos materiais, de intervenções inadequadas ao longo do tempo ou de alterações nas solicitações de uso. A escolha das soluções estruturais torna-se, portanto, um ponto crítico, exigindo compatibilidade entre os materiais originais e os sistemas introduzidos (Tavares, 2010). Paralelamente, observa-se um avanço significativo no desenvolvimento de materiais e sistemas construtivos inovadores, especialmente no campo da madeira engenheirada (Delfino; Silva, 2025). Entre esses, a madeira laminada colada (MLC) destaca-se por suas elevadas propriedades mecânicas, estabilidade dimensional, possibilidade de vencer grandes vãos e flexibilidade arquitetónica. Além disso, a MLC apresenta vantagens ambientais relevantes, associadas ao uso de matéria-prima renovável e ao seu potencial como sumidouro de carbono, fatores que reforçam seu

alinhamento com os princípios da construção sustentável. A aplicação da MLC na reabilitação estrutural tem ganho destaque, sobretudo em edifícios históricos com sistemas em madeira ou alvenaria tradicional associada à madeira. A introdução da MLC em patrimônios edificados envolve desafios técnicos, normativos e conceituais, incluindo compatibilidade de materiais, comportamento estrutural, reversibilidade e respeito aos princípios da conservação. Diretrizes como a mínima intervenção, a distinguibilidade entre o novo e o antigo e a reversibilidade das ações, impõem limites e condicionantes à adoção de soluções estruturais inovadoras. Nesse sentido, a utilização da MLC deve ser precedida por um diagnóstico rigoroso do estado de conservação da edificação, pela compreensão aprofundada dos sistemas construtivos originais e por uma avaliação crítica da adequação da solução proposta ao contexto patrimonial específico. O artigo analisa a integração entre tradição e inovação na reabilitação patrimonial, avaliando o potencial da MLC, seu desempenho e compatibilidade com os princípios de conservação, por meio de um estudo de caso em Viseu. A metodologia aplicada baseia-se na necessidade de compreender, de forma integrada, o comportamento estrutural existente, as manifestações patológicas identificadas e a compatibilidade entre os sistemas construtivos originais e soluções contemporâneas, como a madeira engenheirada. Para o desenvolvimento do trabalho, procedeu-se à caracterização arquitetónica e estrutural do edifício, incluindo levantamento métrico, identificação dos sistemas construtivos originais e inspeções técnicas. O diagnóstico estrutural baseou-se em inspeções visuais sistematizadas para avaliar o estado de conservação e a capacidade resistente. Com base nos dados, propõe-se a reabilitação com MLC, orientada pelos princípios de compatibilidade mecânica, durabilidade, reversibilidade e mínima intervenção, alinhada à preservação patrimonial. Destaca-se a importância de conciliar tradição e inovação para garantir durabilidade, segurança estrutural e preservação cultural.

2. Identificação do Edifício



Trata-se de um edifício originalmente classificado como apeadeiro, localizado na freguesia de Torredeita (Figura 1), no concelho de Viseu, Portugal, caracterizado como uma infraestrutura ferroviária de pequena escala, concebida para atender paragens locais ao longo da linha férrea. A sua concepção arquitetónica assenta na simplicidade construtiva e operacional, destinando-se predominantemente ao embarque e desembarque de passageiros, sem incorporar os serviços e a complexidade funcional inerentes a uma estação ferroviária convencional. A intervenção analisada neste estudo refere-se a uma obra de reabilitação, cujo objetivo consistiu na adaptação do Apeadeiro de Torredeita para uso museológico e sanitários como infraestruturas de apoio (Lopes, M), assegurando a compatibilização entre a preservação das características originais do edifício e a introdução de novas funções, em consonância com os princípios da conservação e reabilitação do património edificado.

Figura 1: Apeadeiro da Estação Ferroviária

2.1 Caracterização arquitetónica e estrutural do edifício

Do ponto de vista arquitetónico e construtivo, originalmente o edifício é composto por um volume único, de planta retangular, desenvolvido em dois pavimentos, com área total de 107,15 m² (Figura 2), implantado paralelamente à via-férrea. Originalmente, as paredes exteriores portantes foram executadas em alvenaria de pedra, ligadas por argamassas à base de cal, solução que confere ao edifício robustez estrutural e elevada inércia térmica. Estas paredes apresentam, de modo geral, bom estado de conservação, não sendo observadas deformações estruturais percetíveis. Os paramentos exteriores são revestidos com reboco tradicional, de acabamento simples, compatível com a função original do edifício e com as práticas construtivas correntes à época da sua construção.

a) Piso Térreo b) Instalações Sanitárias

Figura 2: Plantas Arquitetónicas (Lopes, M)

A cobertura era do tipo inclinada, executada com asnas tradicionais, possuindo estrutura em madeira maciça, constituída por vigas principais e elementos secundários. O telhado é realizado com telha cerâmica tradicional, solução construtiva amplamente utilizada no período histórico em que o edifício foi construído. Os pavimentos térreos assentam diretamente sobre o solo, sem a presença de soluções de impermeabilização ou de isolamento térmico, refletindo as práticas construtivas vigentes à época da sua execução. Esta configuração construtiva favorece a ocorrência de fenómenos de umidade ascensional, com potenciais repercussões negativas na durabilidade dos materiais e no desempenho higrotérmico dos espaços interiores. No que se refere às paredes interiores, estas são executadas em tabique, técnica amplamente difundida no período, caracterizada por uma estrutura leve de madeira preenchida com argamassa tradicional (Nicolau, 2023). Tal sistema construtivo revela-se coerente com a lógica construtiva do edifício, embora apresente vulnerabilidade acrescida à ação da umidade e à ausência de manutenção continuada. As aberturas conservam elementos em madeira, nomeadamente portadas e balcões, executados de acordo com as técnicas da época, com recurso a carpintaria artesanal. Estes elementos apresentam não apenas valor funcional, associado à proteção solar, à ventilação natural e ao controle da iluminação, mas também valor simbólico e patrimonial, contribuindo para a autenticidade do conjunto. Adicionalmente, a sua permanência permite a leitura das soluções originais de sombreamento e ventilação passiva, fundamentais para o conforto ambiental antes da introdução de sistemas mecânicos. A preservação destes componentes assume, assim, relevância no contexto de intervenções de reabilitação, devendo ser privilegiadas estratégias de conservação e reforço compatíveis com os materiais e técnicas originais. O diagnóstico do estado de conservação evidenciou a presença de patologias construtivas recorrentes em edifícios ferroviários históricos, fortemente associadas à ação da umidade e à ausência de manutenção continuada. Verificaram-se manifestações de umidade ascensional nas paredes, com degradação progressiva dos rebocos, eflorescências salinas e destacamento superficial dos revestimentos. Adicionalmente, foram identificadas infiltrações provenientes da cobertura, responsáveis por manchas de umidade persistentes e pela deterioração localizada de elementos estruturais e não estruturais. A exposição

prolongada à água favoreceu ainda o aparecimento de fenómenos de biodeterioração, como o desenvolvimento de fungos e bolores, com impacto negativo na salubridade dos espaços interiores. Nos elementos de madeira observaram-se apodrecimento, fissuração e ataque de insetos xilófagos, comprometendo a resistência e durabilidade. A ausência de drenagem e impermeabilização agravou as patologias e sua disseminação. Esse quadro exige uma reabilitação integrada, baseada em diagnóstico rigoroso, que corrija os danos e elimine suas causas, garantindo a conservação do património edificado. As intervenções estruturais e construtivas foram concebidas de modo a minimizar a remoção de material original, recorrendo a técnicas de consolidação compatíveis com a alvenaria e a madeira existentes. A adaptação museológica implicou a introdução de infraestruturas contemporâneas, como sistemas elétricos, iluminação expositiva, condições mínimas de conforto ambiental e dispositivos de segurança, integrados de forma discreta e não intrusiva. O projeto procurou preservar a legibilidade histórica do edifício, valorizando seus elementos construtivos originais e reforçando seu caráter identitário.

3. Inspeções Técnicas

O edifício existente caracterizava-se por apresentar um estado de degradação significativo, evidenciando um baixo nível de conservação geral, compatível com um prolongado período de ausência de manutenção sistemática. Foram identificados diversos danos de natureza construtiva e estrutural, comprometendo parcialmente o desempenho global do edifício e a sua capacidade de resposta às solicitações de uso. Verificou-se a ocorrência de percolação de águas para o interior, tanto ao nível da cobertura como dos pisos, resultando em manifestações patológicas visíveis em diferentes elementos construtivos, como manchas de umidade, destacamento de revestimentos e degradação de materiais sensíveis à água. Ao nível dos pavimentos, observaram-se deformações localizadas, associadas à ação prolongada da umidade e ao envelhecimento natural dos materiais, bem como a presença de elementos de revestimento em avançado estado de degradação. Em algumas áreas, estas deformações indiciam perda de rigidez e comprometimento da estabilidade local, exigindo avaliação técnica mais aprofundada. Adicionalmente, foram identificados sinais de deterioração em elementos estruturais e não estruturais adjacentes, agravados por infiltrações recorrentes e pela exposição a agentes bióticos e abióticos. Este conjunto de patologias (Figura 3), evidencia a necessidade de uma intervenção de reabilitação integrada, fundamentada em diagnóstico técnico rigoroso. O diagnóstico do estado de conservação evidenciou as manifestações de umidade ascensional nas paredes, acompanhadas de degradação dos rebocos, eflorescências salinas e destacamento superficial dos revestimentos, sobretudo nas zonas inferiores dos paramentos. Adicionalmente, foram identificadas infiltrações provenientes da cobertura, responsáveis pelo aparecimento de manchas de umidade e pela degradação localizada de elementos de madeira, nomeadamente na estrutura de suporte da cobertura e em componentes secundários.

Figura 3: Conjunto de patologias - Estado de conservação do edifício

Nestes elementos, constataram-se indícios de biodeterioração, com ocorrência de ataques de insetos xilófagos e deterioração associada à exposição prolongada à umidade, comprometendo parcialmente o desempenho estrutural de alguns componentes. Apesar das patologias identificadas, não se verificaram, à observação visual, indícios evidentes de colapso iminente, nem deformações excessivas ou abatimentos generalizados da cobertura, o que sugere que, no momento da inspeção, o edifício apresentava um desempenho estrutural global ainda satisfatório, embora carecendo de intervenções de conservação e reabilitação adequadas para assegurar a sua estabilidade e durabilidade a médio e longo prazo, face ao aumento da sobrecarga exigida pela nova funcionalidade do edifício.

4. Identificação dos Sistemas Construtivos

Os métodos construtivos adotados nas construções históricas refletem um conjunto de soluções técnicas desenvolvidas a partir do conhecimento empírico, da disponibilidade de materiais locais e da necessidade de adequação às condições climáticas e funcionais de cada época. Estes sistemas caracterizam-se, de modo geral, pela utilização de materiais naturais, por processos construtivos artesanais e por uma lógica estrutural claramente legível. Entre os sistemas construtivos mais representativos encontrados no edifício, destaca-se o tabique, amplamente utilizado em paredes interiores e, em alguns casos, em divisórias leves (Fernandes, 2015; Padrão et al., 2021a; Padrão et al., 2021b). Este método baseia-se numa estrutura de madeira maciça, composta por montantes, travessas e ripas, preenchida e revestida com argamassas à base de terra e/ou cal, frequentemente reforçadas com fibras vegetais (Figura 4). O tabique apresenta vantagens associadas à leveza, à flexibilidade construtiva e à boa adaptação às compartimentações interiores, além de contribuir para o comportamento higrotérmico do edifício. Do ponto de vista estrutural, este sistema revela um desempenho satisfatório quando adequadamente conservado, permitindo uma distribuição eficiente das cargas próprias e uma resposta favorável a pequenas deformações. No entanto, a sua durabilidade está condicionada à proteção contra a umidade, uma vez que a madeira e as argamassas tradicionais são particularmente sensíveis à ação da água. A ausência de ventilação adequada e a presença de infiltrações podem conduzir à degradação dos elementos de madeira, ao apodrecimento biológico e à perda de coesão dos revestimentos. Observam-se, com frequência, fissurações, destacamentos do reboco e deformações localizadas, frequentemente associadas a variações higrométricas e a intervenções incompatíveis realizadas ao longo do tempo. Acresce que a substituição das argamassas tradicionais por materiais cimentícios rígidos pode agravar patologias existentes, comprometendo a capacidade de respiração das paredes. Neste contexto, a compreensão aprofundada do funcionamento do tabique é essencial para a definição de estratégias de reabilitação compatíveis, que respeitem a lógica construtiva original, garantam a reversibilidade das soluções adotadas e promovam a melhoria do desempenho térmico, acústico e estrutural do edifício, sem comprometer o seu valor histórico e patrimonial.

Figura 4: Estrutura de madeira existente no interior do Apeadeiro

As estruturas de madeira maciça desempenham um papel central no sistema construtivo original do edifício, sendo empregadas em pavimentos, coberturas e elementos de escoramento, assumindo simultaneamente funções estruturais e construtivas. As ligações eram, maioritariamente, realizadas por meio de encaixes, cavilhas de madeira ou elementos metálicos simples, garantindo um comportamento estrutural compatível com as solicitações da época e com os conhecimentos técnicos então disponíveis. Este tipo de solução evidencia um elevado grau de racionalidade construtiva, assente na utilização eficiente dos recursos materiais e na mão de obra especializada. A madeira utilizada, geralmente proveniente de espécies locais, apresentava secagem natural e seções dimensionadas de acordo com critérios empíricos, mas eficazes, de resistência e durabilidade (Appleton, 2023). O sistema estrutural revela ainda uma conceção flexível, permitindo acomodar pequenas deformações sem perda imediata de estabilidade, característica relevante em edifícios antigos. Contudo, a ação prolongada de agentes bióticos e abióticos, como umidade, fungos e insetos xilófagos, pode comprometer significativamente a integridade destes elementos ao longo do tempo. A inexistência de tratamentos de proteção adequados agrava este processo. A cobertura era complementada por beirados portugueses (Figura 10-b2). Para além da sua função técnica, assumem também um papel relevante na leitura arquitetónica característica das construções tradicionais, conferindo identidade formal ao edifício. As portadas de madeira, associadas aos vãos envidraçados, constituíam outro elemento recorrente nas edificações, característico das construções históricas do período, integrando-se de forma coerente no sistema construtivo e na expressão arquitetónica do edifício. Para além do seu valor estético e patrimonial, desempenhavam funções fundamentais no controle da iluminação natural, na regulação da ventilação e na proteção térmica dos espaços interiores, contribuindo para estratégias passivas de conforto ambiental. Estes elementos permitiam a adaptação do edifício às variações climáticas diárias e sazonais, reduzindo a incidência direta da radiação solar e favorecendo a ventilação cruzada. A sua execução seguia técnicas artesanais, com recurso a madeiras de espécies locais, selecionadas pela sua durabilidade e resistência mecânica. As portadas eram geralmente articuladas por ferragens simples, também de produção artesanal, que asseguravam o seu correto funcionamento. De forma complementar, destacam-se as escadas de madeira como elementos estruturais e funcionais relevantes na organização espacial do edifício, assegurando a circulação vertical entre pisos. Executadas com madeira maciça e sistemas de encaixe tradicionais, estas escadas refletiam soluções construtivas ajustadas às limitações técnicas e espaciais da época. Tal como as portadas, as escadas de madeira encontram-se particularmente expostas aos efeitos do uso continuado, da umidade e do envelhecimento natural dos materiais, apresentando desgaste nos degraus, folgas nas ligações e perda de rigidez estrutural. Assim, a sua conservação e eventual reabilitação exigem uma abordagem criteriosa, que preserve a autenticidade construtiva e garanta condições adequadas de segurança, funcionalidade e integração patrimonial. As argamassas tradicionais à base de cal são fundamentais em construções históricas, devido à sua permeabilidade, compatibilidade com a alvenaria e capacidade de acomodar deformações, contribuindo para a durabilidade e evitando patologias decorrentes de materiais incompatíveis.

5. Proposta de reabilitação estrutural com MLC

Em particular, todos os elementos introduzidos, nomeadamente novas estruturas e/ou novos materiais, foram devidamente avaliados de forma a não danificarem, ou alterarem o funcionamento, ou estabilidade física e química dos elementos existentes, quer estruturais, quer de revestimento.

5.1 Pavimento

A solução de intervenção passa pela execução de um piso de madeira, com a substituição dos elementos existentes, para também fazer face ao aumento da sobrecarga prevista para o edifício, recorrendo a vigas de madeira laminada colada de pinho nórdico (Pinus Sylvestris) da classe resistente GL24h com a execução de tarugos em vigas de madeira maciça de pinho nacional (Pinus Pinaster) da classe resistente C18 (Figura 5). Todos receberam um tratamento prévio contra agentes bióticos.

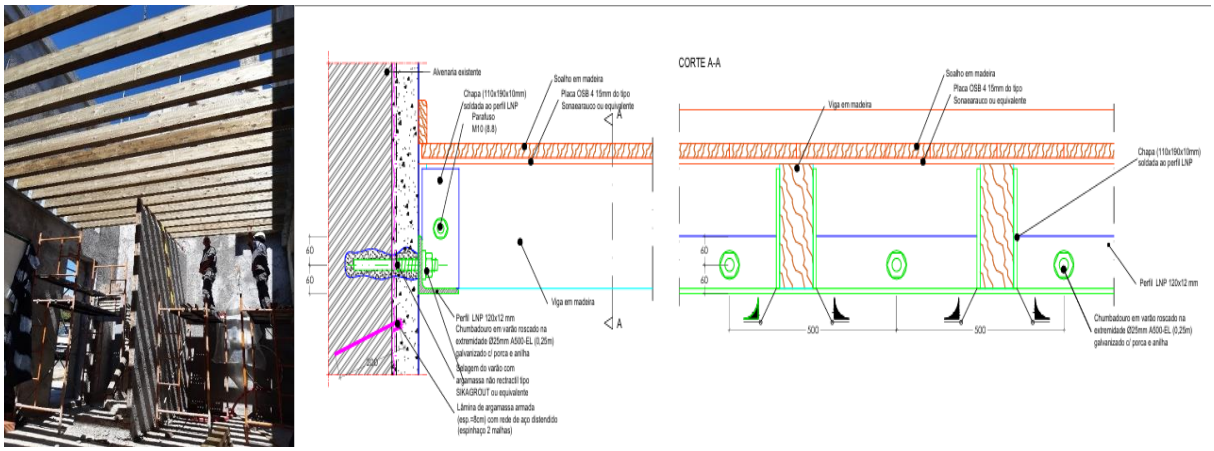


Figura 5: Pavimento de madeira – Interface entre Pav. 01 e Pav. 02 e Detalhe – Piso 1 - Apoio das vigas novas (Lopes, M)

A introdução da chapa metálica soldada e ancorada à alvenaria existente do edifício revelou-se necessária para corrigir as irregularidades geométricas das aberturas originais, uma vez que a parede, executada em alvenaria de pedra natural, apresentava variações significativas de alinhamento, prumo e espessura. Estas irregularidades inviabilizavam a fixação direta e rigorosa dos elementos estruturais em madeira, comprometendo o correto posicionamento das vigas e a regularidade do sistema construtivo. Assim, a chapa metálica (Figura 6), foi chumbada na alvenaria por meio de varões roscados, fixados com porcas e anilhas, garantindo uma ligação mecânica eficiente e controlada. A ancoragem foi complementada com selagem em argamassa não retrátil, assegurando a correta transferência de esforços, a eliminação de folgas e a durabilidade da ligação ao longo do tempo. Esta solução permitiu a criação de um plano regular e contínuo de apoio, funcionando como elemento de transição entre a alvenaria existente e a nova estrutura em madeira. Desta forma, tornou-se possível a fixação das vigas de madeira com seções uniformes e previamente dimensionadas, assegurando a padronização das peças, o correto alinhamento estrutural e a adequada distribuição das cargas. A chapa metálica desempenhou, portanto, um papel fundamental na calibragem da parede, conciliando as imperfeições do suporte original com as exigências geométricas e construtivas da nova solução estrutural, em conformidade com os princípios de compatibilidade e reversibilidade aplicáveis às intervenções em patrimônio edificado. As vigas de madeira laminada colada, com dimensões nominais de 21 × 136 × 3600 mm, constituíram o principal elemento estrutural do sistema de pavimento, tendo sido dimensionadas de modo a garantir a capacidade resistente, a rigidez adequada e a compatibilidade com o edifício existente (Figura 8). Sobre estas vigas foi executado o sistema de piso, concebido a partir de uma solução multicamada, visando o desempenho estrutural, acústico e de conforto de utilização.

Figura 6: Piso 1 – Chapa metálica chumbada na alvenaria

O acabamento final é composto por assoalho de madeira de pinho, acabado com verniz de proteção semimate, conferindo resistência ao desgaste superficial, facilidade de manutenção e adequada valorização estética do espaço. O assoalho foi aplicado por colagem sobre uma manta resiliente em aglomerado de borracha, com espessura de 4,5 mm, cuja função principal é a atenuação da transmissão de ruídos de impacto e a melhoria do isolamento acústico entre os pavimentos.

5.2 Cobertura

A cobertura em madeira maciça encontrava-se degradada, com perda de secção resistente devido à umidade e a agentes bióticos, provocando deformações, instabilidade e infiltrações, além de baixo desempenho térmico, o que justificou sua substituição integral (Lopes, Mário – Projetos Estruturais). A nova cobertura inclinada, em madeira laminada colada, foi concebida para garantir compatibilidade com o edifício e melhorar a estanqueidade e o desempenho térmico. Adotou-se um sistema multicamada, conciliando soluções tradicionais e contemporâneas, respeitando os princípios de mínima intervenção e reversibilidade. A estrutura inclui asnas, cumeeira e madres em MLC de pinho nórdico (GL24h) e varas em pinho nacional (C18), todos tratados contra agentes bióticos.

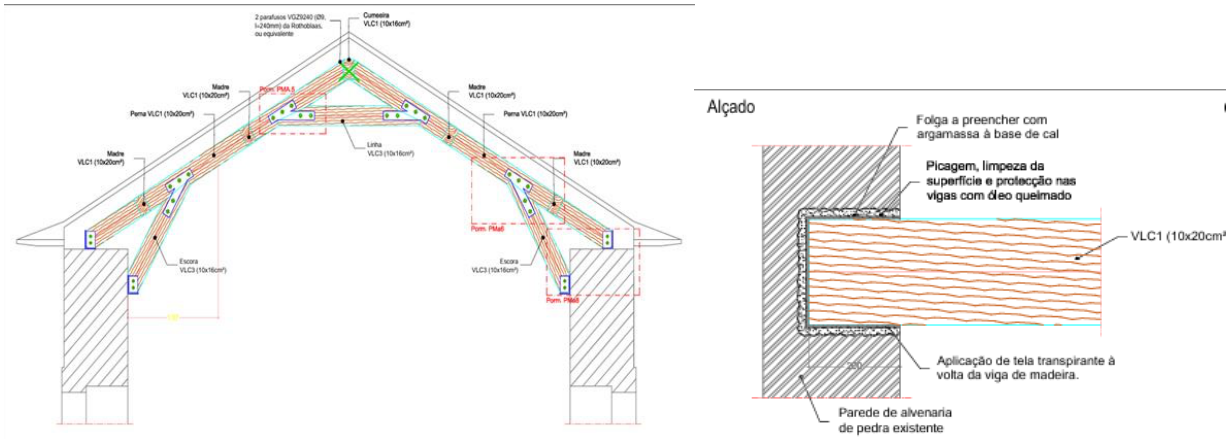

Figura 7: Alçado da estrutura da cobertura e detalhe do encastre da viga - (Lopes, M)

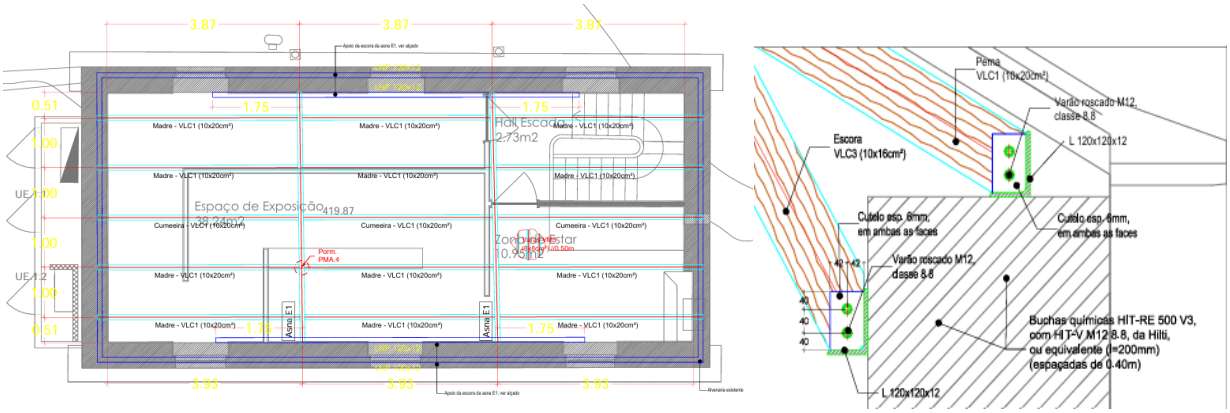

Figura 8: Planta estrutural da cobertura e pormenor apoio nas paredes de alvenaria - (Lopes, M)

Tomou-se o cuidado de garantir que o encastramento da viga de madeira à alvenaria de pedra portante recebesse tratamentos específicos, compatíveis com os materiais originais da edificação, de forma a assegurar a preservação dos elementos construtivos existentes. Inicialmente procedeu-se à picagem das zonas degradadas, seguida da limpeza cuidadosa da superfície de contacto e da aplicação de proteção nas

vigas por meio de óleo queimado, visando a redução da absorção de umidade (Figuras 7 e 8). Em seguida, realizou-se a colocação de uma tela transpirável envolvente à extremidade da viga, com o objetivo de permitir a difusão do vapor de água e evitar a retenção de umidade no contacto madeira–alvenaria. Posteriormente, o preenchimento da folga existente foi efetuado com argamassa à base de cal, garantindo compatibilidade físico-química e higrotérmica com os materiais tradicionais. Esta solução contribui para a durabilidade da madeira, minimiza o risco de patologias associadas à umidade e assegura a correta transmissão de esforços à alvenaria portante. (Figura 9)

Figura 9: Estrutura da Cobertura – Detalhe das ligações

5.2.1 Suporte da Cobertura

O suporte da cobertura é descontínuo e constituído por painéis de madeira, placas de OSB com espessura de 18 mm, devidamente fixadas às vigas de madeira laminada colada, assegurando a distribuição uniforme das cargas, assegurando a rigidez global do sistema e a adequada distribuição das cargas. Sobre este suporte foi aplicado isolamento térmico em poliestireno extrudido (XPS), com espessura de 80 mm, visando a redução das perdas térmicas e a melhoria do comportamento higrotérmico do edifício. Esta configuração multicamada contribui para a limitação das variações térmicas no interior, promovendo maior conforto ambiental (Figura 10). Adicionalmente, a utilização de materiais com estabilidade dimensional adequada permite acomodar deformações e variações higroscópicas da estrutura em madeira. A solução adotada revela-se compatível com intervenções em edifícios existentes, assegurando desempenho técnico e durabilidade adequada ao sistema de cobertura.

a) Execução da claraboia e placas de OSB b) XPS e DRS BT 50 c) Beirado português

Figura 10: Revestimentos da cobertura

A claraboia em edifícios históricos melhora iluminação e ventilação, mas sua introdução exige compatibilizar desempenho funcional com a preservação da cobertura, avaliando a estrutura existente e respeitando os princípios de mínima intervenção e reversibilidade. A sua localização e dimensão devem ser cuidadosamente estudadas, de modo a minimizar o impacto visual e a garantir a legibilidade da intervenção, em conformidade com os princípios de mínima intervenção e reversibilidade preconizados pelas cartas internacionais de conservação do patrimônio.

5.2.2 Impermeabilização da Cobertura

A impermeabilização foi garantida pela aplicação de placa subtelha asfáltica do tipo DRS BT 50, integrante do sistema ONDULINE, fixada mecanicamente ao suporte por meio de pregos apropriados, assegurando a continuidade da barreira impermeável e a proteção contra infiltrações. Este sistema contribui ainda para a durabilidade da estrutura de madeira, ao permitir uma adequada ventilação da cobertura. Trata-se de manta resiliente aplicada sobre a base contínua em placas de OSB. Esta base intermédia permite ainda uma correta interface entre a estrutura portante e o revestimento final, reduzindo tensões localizadas e acomodando pequenas deformações. A solução adotada alia eficiência estrutural, desempenho acústico e compatibilidade construtiva. Desta forma, garante-se não apenas a funcionalidade e durabilidade do pavimento, mas também a integração coerente entre técnicas construtivas contemporâneas e o contexto do patrimônio edificado.

5.2.3 Revestimento Final

O revestimento final foi executado com telhas cerâmicas do tipo lusa aba canudo, na cor vermelha, com dimensões de 43 × 26 cm, fixadas com massa de poliuretano, garantindo a estabilidade das peças face às ações climáticas. Foram igualmente previstos elementos de remate em madeira nas zonas de beirados e laterais, assegurando a proteção dos painéis e a coerência formal da solução adotada. A formação de beirado decorativo integrou-se na solução da cobertura, desempenhando simultaneamente funções técnicas e arquitetónicas, nomeadamente a proteção dos paramentos verticais contra a ação direta da chuva e a valorização da leitura arquitetónica do edifício. A solução adotada evidencia a viabilidade da integração entre sistemas construtivos contemporâneos e técnicas tradicionais.

5.3. Escada

A escada de madeira foi tratada, com substituição de revestimentos e limpeza dos elementos estruturais, incluindo reforços pontuais e tratamento contra agentes biológicos. Foram ainda verificadas as ligações e condições de segurança, visando garantir estabilidade, funcionalidade e preservação do seu valor histórico.

Figura 11: Escada de acesso ao pavimento superior antes das intervenções

6. Demais intervenções

As paredes de alvenaria de pedra existentes, foram alvo de picagem de rebocos, execução de lâmina de argamassa armada com 6cm de espessura pelo interior para consolidação e regularização do paramento, regularização e consolidação do coroamento das paredes de alvenaria de pedra existentes e contraventamento das paredes na direção fora-do-plano, através da melhoria da ligação aos pavimentos e coberturas. No nível do térreo, foi executado um novo piso, foram adotados o concreto C25/30 para pavimentos térreos, e o aço A500NR em armaduras ordinárias. tanto no edifício da estação quanto no edifício das instalações sanitárias.

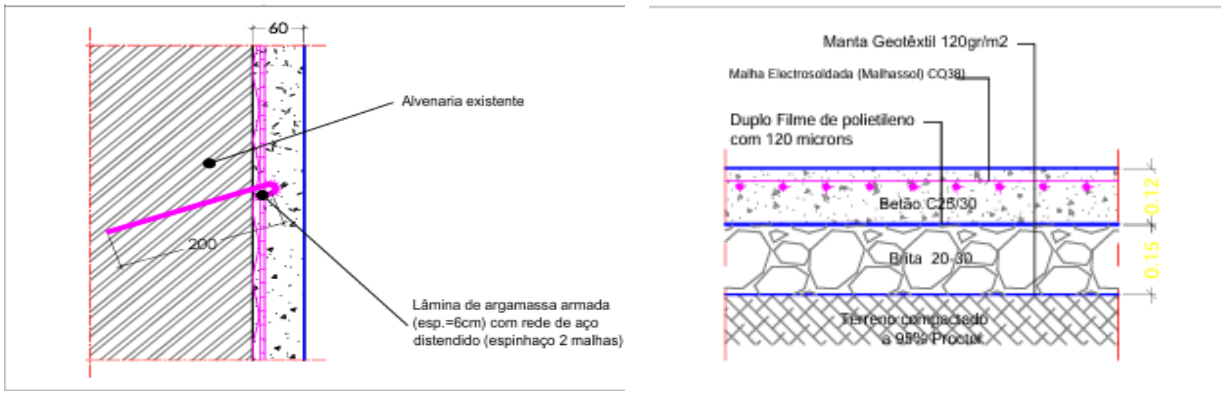

Figura 12: Pormenor do pavimento térreo e lâmina de argamassa armada (Lopes, M)

7. Materiais

As estruturas metálicas foram fabricadas em aço do tipo S275JR (EN 10025-2). As estruturas de madeira foram de madeira de pinho nacional (Pinus Pinaster) da classe resistente C18 e de madeira laminada colada de pinho nórdico (Pinus Sylvestris) da classe resistente GL24h. Todos os elementos novos receberam um tratamento contra insetos e fungos xilófagos. As características adotadas para cada um dos materiais são as especificadas no REBAP (Regulamento de Betão Armado e Pré-Esforçado) e no EC2 (EN 1992-1-1: Projecto de Estruturas de Betão), no EC3 (EN1993-1: Projecto de Estruturas de Aço), no EC5 (NP EN 1995-1-1 - Projecto de Estruturas de Madeira. Parte 1.1: Regras gerais e regras para edifícios) e na norma EN 338 (Structural timber - Strength classes). As ligações realizadas entre elementos de madeira apresentam características mecânicas e de resistência com especificação Rothoblaas®. As ligações foram realizadas com parafusos, todo roscado com ponta auto perfurante e suportes metálicos.

8. Conclusão

A madeira laminada colada (MLC), adotada pelo Engenheiro Calculista (Lopes, M0, afirma-se, neste estudo, como um material protagonista e estratégico no contexto da reabilitação de edifícios históricos, ao conjugar as vantagens inerentes à madeira enquanto material renovável com um desempenho estrutural superior e maior fiabilidade dimensional. A sua elevada relação resistência/peso e o controle industrial do processo de fabrico permitem responder de forma eficaz às exigências estruturais contemporâneas, sem comprometer a integridade dos sistemas construtivos tradicionais. A resposta favorável da MLC às variações térmicas e higrométricas, aliada à possibilidade de conceção de elementos estruturais de grandes vãos e geometrias controladas, revela-se particularmente relevante em intervenções sobre o edificado existente. Quando devidamente protegida contra agentes de degradação, nomeadamente a umidade e a ação biológica, e corretamente integrada em contacto com materiais históricos, a MLC demonstra um comportamento compatível do ponto de vista físico-mecânico e higrotérmico. Os resultados evidenciam que a utilização da madeira laminada colada contribui não apenas para a melhoria do desempenho estrutural, mas também

para a redução do peso próprio das estruturas e, consequentemente, das ações transmitidas às alvenarias portantes existentes. Adicionalmente, a sua aplicação favorece princípios fundamentais da conservação do património, como a reversibilidade das soluções, a legibilidade da intervenção e a minimização de impactos sobre os elementos originais. Conclui-se, assim, que a MLC constitui uma solução tecnicamente robusta e ambientalmente sustentável para intervenções de reabilitação estrutural, permitindo conciliar a preservação da autenticidade histórica com as exigências atuais de segurança, durabilidade e sustentabilidade. A sua adoção, quando sustentada por diagnóstico rigoroso e por critérios de compatibilidade material, reforça o papel da madeira engenheirada como elemento-chave na salvaguarda e valorização do património construído.

Abstract: Traditional earthen construction technologies represent a significant yet increasingly underutilized resource for sustainable and affordable housing development in Sub-Saharan Africa. This paper presents the outcomes of the PURSUE Project inception study, which benchmarks vernacular housing systems through detailed field investigations conducted in Mbulu District (Manyara Region) Kondoa District (Dodoma Region) and Makumbusho village Dar es salaam Tanzania. The study documents and analyses a range of indigenous dwelling typologies, including Mwera, Iraqw, Hehe, Bembe, and Nyakyusa houses, focusing on their spatial organization, which based on daily activities such as food preparation, livestock management, and communal living, material composition, construction techniques, and environmental performance. These housing systems are predominantly built using locally available materials such as earth, timber, bamboo, grass, stone, lime, and ash, resulting in structures with low embodied energy, high thermal mass, and strong climatic responsiveness. The findings highlight how traditional construction practices integrate architectural form, material selection, and settlement patterns with landscape, climate, and cultural knowledge, achieving durable and resource-efficient housing solutions. The paper also examines the ongoing transition from earthen and thatched construction to burnt clay brick masonry and corrugated metal roofing, driven by urbanization, market accessibility, and changing socio-economic aspirations. While this transition often retains traditional spatial layouts, it signifies a gradual shift away from vernacular building wisdom toward standardized materials perceived as more modern and permanent. By systematically documenting traditional earthen housing technologies and their contemporary transformations, this study establishes a technical and cultural knowledge base to inform future research, capacity building, and the development of sustainable construction and rehabilitation strategies rooted in local contexts.

Keywords: Earthen construction; Sustainable housing; Sub-Saharan Africa; Tanzania; Cultural landscape

1. Introduction

Green building materials and construction techniques are coming to the forefront whereas the impact of building materials on global warming frequently discussed these days (Mehra, ve diğerleri 2022). Structural green materials such as; bamboo, soil, recycled steel, engineered timber have been promoted more all over the world while traditional construction techniques and materials have been also gotten attention by end-users, architects and engineers. Vernacular building traditions refers to buildings created by local communities, where design choices are shaped by cultural traditions. It differs significantly across regions due to variations in climate, landscape, and cultural context. These technologies are grounded in the use of locally available materials and indigenous knowledge systems, resulting in building forms characterized by low embodied energy and high contextual suitability with minimal cost (Matos, Milheiro-Oliveira ve Varum

2025). The main factor influencing the development of the vernacular construction practices is depending on geographical location, climatic conditions, cultural practices, and the accessibility of locally available building materials such as adobe (i.e., mud blocks, whole walls), masonry (i.e., stone, clay) and timber (Sassu 2002). Over time, vernacular dwellings have adapted to environmental conditions, resource availability, and societal needs. These traditions emerged through long-term trial and error, guided by the practical expertise of local builders who possess deep, place-specific knowledge, an asset that is increasingly diminishing in today's era of globalization and remote practices. Therefore, studying and integrating the principles of traditional vernacular architecture into contemporary design holds considerable value. Building layout, like circular, rectangular and linear plans, is another factor usually related to cultural, historical, and urban planning traditions.

Vernacular building traditions fall under sustainable construction which emphasizes on reducing environmental impacts while ensuring economic and social viability. The structures align remarkably well with contemporary environmental goals. Their reliance on local materials reduces transportation impacts, while their typically low energy consumption and capacity for reuse or natural decomposition make them environmentally sensitive solutions. The study done by Mora-Ruiz et al., (2025) confirm that such construction practices significantly lowers greenhouse gas emissions compared to cement-based materials and supports circular construction practices. In addition, the study by Fouad et al., (2025) affirmed that vernacular construction practice offers a low-carbon alternative suitable for sustainable housing delivery. In this sense, vernacular architecture is not merely a record of past creativity but also a valuable source of inspiration for developing resilient and sustainable construction practices today. On the contextual of spatial studies also show that vernacular structures maintain strong links with cultural identity and local livelihoods, reinforcing their relevance in sustainable development discourse (Zhang et al., 2024). These practices symbolize an extremely refined intelligence that branches not from formal design rules but from the lived experiences accumulated over generations. By utilizing local materials and construction techniques, such as natural ventilation in warm climates or thermal mass in arid regions that perfectly adapt to regional climates, these structures are inherently sensitive to their surroundings. This enables the construction of buildings that typically achieve high levels of energy efficiency without relying on mechanical systems.

Furthermore, vernacular building traditions e reflects the identity, values, and social practices of the communities that build and inhabit it; it creates spaces that are not only functional but also meaningful. The construction process typically fosters community participation and knowledge transfer, thereby strengthening social cohesion and continuity. The characteristics and scale of buildings vary according to their region, geographical context, climatic conditions which differ considerably across locations and the availability of local resources. Despite their low cost and excellent thermal and acoustic performance, these buildings are associated with several challenges, particularly related to wall erosion caused by water and wind. Additional issues arise from vegetation growth and the presence of termites and other insects. Most structural deficiencies are linked to the foundations, which are typically constructed as shallow trenches, approximately 30-40 cm deep, from which the walls are erected. These foundations are often inadequate, as the erosive action of water can undermine the walls to greater depths. As a result, erosion at the base leads to a loss of cohesion among the wall components, causing gradual yet continuous structural deterioration (Fumo ve Di Nardo 2015).

In recent years, processes such as globalization and rapid urbanization, obvious by the growth of urban populations, have increasingly challenged the continuity of vernacular building traditions and urban forms specifically in Africa. These include increasing pressure on the environment, existing infrastructure, and urban building stock, as well as limited time and insufficient access to appropriate construction materials for new housing and services. At the same time, a more deeply rooted pattern in African development is the prioritization of non-African architectural models over vernacular traditions. Formal architectural practices across the continent have long been shaped by European influences, reflecting broader historical processes in which African societies were compelled to adopt European languages, governance systems, and cultural

norms during the colonial period. Although African cities existed and functioned effectively prior to colonization, their forms and structures did not align with European definitions of urbanity. Western concepts of urban form and building typologies continue to be regarded as superior, even when they conflict with local environmental conditions and cultural practices. Ones of the best examples of vernacular structures can be observed in Tanzania which is located on the Eastern coast of Africa and its population is over 61 million and one of the fastest growing countries in Africa. The total number of buildings is more than 14 million according to the CENSUS 2022 (The United Republic of Tanzania National Bureau of Statistics 2022). Urban population in Tanzania is 36% according to the World Bank data in 2024 (World Bank 2024). In Tanzania, homes are also built through self-help and/or community-based approaches. Most homes in the country do not comply with engineering standards, and informal settlements remain a major problem in the country. The 2011/12 National Population and Housing Census revealed that among more than 9 million households, the primary wall materials were cement bricks (20.3%), sun-dried bricks (26.3%), fired bricks (26.3%), and posts and mud (23.5%) (The United Republic of Tanzania National Bureau of Statistics 2022). The most common building types in Tanzania are traditional houses, unreinforced masonry structures made of adobe bricks, unreinforced masonry structures made of fired brick/concrete blocks, and reinforced concrete structures. The vast majority of residential buildings are vulnerable to damage and prone to collapse due to natural disasters (Silva, Tatar ve Henshaw 2021). Table 1 lists the common local building materials in Tanzania based on the region. Bamboo, grass, and mud are the most communal structural material in the country.

Table 1 - Tanzanian vernacular construction materials *(Runyoro 2020)*

Ethnic Group in Tanzania	Housing construction elements
Western Tanzania	Poles, sticks, bamboo, mud & grass, elephant grass roofing
South East Tanzania	Poles, sticks, bamboo, soil and grass
Southern Highlands	Bamboo (extensive), mud & grass
Coastal areas	Sticks, soil, palm leaves, mud & poles, grass thatch (common)
Central Tanzania	Bush poles, grass and soil
Inter lacustrine region	Poles, bamboo, sticks and grass
Nilo-Hamitics	Poles, sticks, grass and soil
Kosain&Luo	Mud and grass

This paper investigates the common vernacular building structures in Tanzania as a part of an EU funded project, PURSUE (PURSUE, PURSUE 2025). The PURSUE project aims to promote the usage of locally available, eco-friendly, and affordable construction materials, fostering collaboration among higher education institutions, professionals, and communities in Sub-Saharan Africa (SAR). The project involves collaboration between universities in Türkiye, Portugal, Mozambique, Tanzania, and Somalia, focusing on supporting sustainable development goals such as industry innovation, sustainable cities, responsible consumption, climate action, and partnerships for development. The main objectives of this study are:

- To document and benchmark traditional earthen construction technologies in Tanzania.
- To analyze the material systems and construction techniques used in vernacular dwellings.
- To evaluate the environmental and cultural significance of these housing systems.
- To identify lessons for sustainable and affordable housing development.

2. Vernacular Constructions in Tanzania

2.1 Cultural and Environmental Context

Traditional housing systems in Tanzania have evolved through long-term adaptation to climate, available resources, and social organization. Settlements often respond to topography, agricultural activities, and environmental conditions. In Mbulu District, for example, settlements are located in the Mbulu Highlands, characterized by undulating hills, volcanic soils, and seasonal water systems that influence building location and materials. Traditional communities such as the Iraqw people develop housing forms closely integrated

with their agricultural landscapes and collective settlement patterns. The main challenge the users face is the regular maintenance of dwellings, such as reapplying mud plaster to the walls three or more times per year to prevent the structural failure. Moreover, the rectangular plan of the dwelling may cause problems with wall separation at the corner and connections and out-of-plane collapse under lateral loading such as a strong wind or earthquake.

2.2 Traditional Building Materials

Natural materials such as stone, timber, straw, sheep's wool, plant-based fibers (e.g., hemp), cork, and clay have long formed the basis of traditional construction practices. However, over the past fifteen years, particularly in Europe and the United States, there has been a renewed and growing interest in both natural and unconventional building materials.

Traditional (natural) materials can generally be categorized according to their function within a building system. As structural components, materials such as timber, stone, rammed earth, straw bales, and clay bricks are commonly employed in load-bearing construction. For insulation purposes, materials like sheep's wool, hemp fibers, and cork are widely used due to their favorable thermal properties. Additionally, natural materials also serve complementary roles in finishing applications, including plastering, painting, and flooring, where clay and cork are frequently utilized (Spišáková ve Mačková 2015).

Among these materials, stone remains one of the most prominent. It is a highly durable and low-maintenance option, characterized by its significant thermal mass. Stone is also highly versatile, available in a wide range of shapes, sizes, colors, and textures, making it suitable for applications such as flooring, walls, arches, and roofing. Furthermore, it integrates harmoniously with the natural environment and can be readily reused or recycled for various construction purposes. Stone is often incorporated at the base of walls or within foundations. Its primary function is to protect earthen walls from moisture ingress and erosion, thereby enhancing the durability and longevity of the structure. Earth serves as the primary material for wall construction in many vernacular buildings (Matos, Milheiro-Oliveira ve Varum 2025). It is typically used either in the form of compacted mud or shaped into sun-dried blocks, providing both structural capacity and thermal mass. Timber is commonly employed for structural elements such as frames and roof beams. It is generally sourced from nearby forests, making it a locally available and renewable material that supports the overall framework of the building. Grass and thatch are widely used in roofing systems. These materials not only offer effective protection against rainfall by shedding water efficiently but also provide natural insulation, helping to regulate indoor temperatures. Lime and ash are occasionally added as stabilizing agents in construction. These materials improve the strength and resistance of earth-based mixtures, contributing to better performance against environmental effects. These materials offer:

- low embodied energy
- strong thermal performance
- environmental compatibility
- Often mixed with cow dung to improve cohesion and durability

Table *2* shows the comparison of the building materials in Tanzania based on labor, cost, time consumption, and distance to transport material. The locally available materials do not require laboring, have the minimum cost, necessitate less the construction time with limited needs of transportation in comparison with the other structural materials in the country.

Table 2 - Comparison of the building materials in Tanzania *(Buccellato ve Reineccius 2013)*

Type	Building Materials	Labor	Cost (0-$$$)	Time of Construction	Distance to Transport Material
Wattle and Daub	Mud with ash or manure as binding agent	Local, not hired	0	2 days	0
	Sisal poles	Local, not hired	0	5 days (to strip bark & trim)	Up to 15 km on foot

	Sisal split stalks for holding together walls	Local, not hired	0	5 days to prepare, 1 day to put in place	Up to 15 km on foot
	Corrugated metal with lumber wood trusses	Local, hired	$$ (for labor and material)	1 week	45 km by vehicle
Concrete Masonry Units	Concrete block units	Not local, hired	$$$ (for labor and material)	2 to 5 years (based on funding)	15 to 45 km by vehicle
	Poured concrete foundation	Not local, hired	$$$ (for labor and material)	1 week (depends on funding)	15 to 45 km by vehicle
	Corrugated metal and lumber wood trusses	Local, hired	$$ (for labor and material)	1–2 weeks (usually larger, complex structures)	45 km by vehicle
Compressed Earth Bricks	Walls: Soil (40% sand, 25% gravel, 25% clay, 10% silt and water), Concrete & mortar, Rebar (not always)	Local, hired	$$	Up to 2 years (based on funding)	0 (soil), 15 to 45 km by vehicle (concrete)
	Poured concrete foundation	Not local, hired	$$$	1 week (depending on funding and size)	15 to 45 km by vehicle
	Corrugated metal roof with wood trusses	Local, hired	$$$	1–2 weeks (usually larger, complex structures)	45 km by vehicle

3. Methodology

3.1 Research Design

This study adopts a qualitative multiple case study design to benchmark traditional earthen construction technologies across different geographical and cultural contexts in Tanzania. The case study approach is appropriate for investigating complex, context-dependent phenomena such as vernacular architecture, where boundaries between the phenomenon and context are not clearly defined (Yin, 2018). The qualitative approach allows for an in-depth understanding of material use, construction techniques, and socio-cultural influences that cannot be adequately captured through purely quantitative methods (Creswell, 2014). This design is widely applied in studies of traditional construction systems and sustainable architecture.

3.2 Study Areas

Field investigations were conducted in Mbulu District, Kondoa District, and Makumbusho Village. These sites were purposively selected to capture climatic and cultural diversity, as well as well-preserved vernacular housing systems. This purposive selection is justified in qualitative research aiming for information-rich cases rather than statistically representative samples (Patton, 2015).

3.3 Sampling Strategy and Sample Size

A purposive sampling strategy was employed to select between 15 and 24 dwelling units, with approximately 5–8 houses examined per study site. Purposive sampling is appropriate for studies that focus on specific characteristics, such as vernacular housing typologies and traditional material use, as it enables the selection of information-rich cases relevant to the research objectives (Patton, 2015). The chosen sample size is consistent with qualitative research standards, where depth of analysis is prioritized over statistical generalization (Creswell, 2014). This approach ensured the inclusion of representative housing typologies, variations in construction techniques, and different levels of structural condition. In Mbulu District and Kondoa District, Tembe houses were selected as the dominant vernacular typology. In contrast, at Makumbusho Village, a broader range of indigenous housing types was examined, including Mwera, Iraqw,

Hehe, Bembe, and Nyakyusa houses, reflecting the site's role as a cultural repository of diverse Tanzanian architectural traditions.

3.4 Selection Criteria

Selection criteria, guided by methodological rigor and relevance to research objectives, included: typological representation of dominant vernacular forms (Oliver, 2006); material authenticity focusing on traditional earthen systems (Houben & Guillaud, 1994); state of conservation for assessing durability; environmental context capturing climatic and geographical variations; and accessibility for detailed documentation.

3.5 Data collection methods

Data collection combined field and desk research: direct observation of construction, materials, and structural conditions; photographic surveys of building elements; measured sketches of spatial organization and construction systems; informal interviews with builders and occupants regarding construction practices and cultural context; and a literature review of earthen construction technologies and performance.

3.6 Analytical framework

This study uses a multi-criteria framework to holistically assess vernacular housing performance by integrating material (thermal, structural, durability), environmental (climatic responsiveness, embodied energy), socio-cultural (spatial organization, cultural practices), and construction technique (methods, adaptability) considerations. Multi-criteria analysis is a common method in sustainable construction research for evaluating complex systems (Kibert, 2016).

4. Vernacular Housing Typologies in Tanzania

4.1 Mwera (Banda) House

Mwera (Banda) House is traditionally built in a rectangular layout using natural, locally sourced materials, reflecting both environmental adaptation and cultural craftsmanship. Construction begins by digging small holes and placing sturdy wooden poles approximately two meters apart to form the main structural framework. Thinner miombo sticks are then woven horizontally between these poles at intervals of about 30 cm, creating a tight lattice that strengthens the walls and supports the clay render. Wet red clay mixed with water and sometimes small amounts of grass or cow dung for binding is applied over this woven frame to form thick, durable walls. A small window is intentionally left near the roofline to ensure sufficient ventilation and allow daylight into the interior without compromising security or heat control. The roof is supported by a network of wooden rafters and is meticulously thatched with layers of elephant grass. This type of thatching is not only lightweight but also provides excellent thermal performance, keeping the interior cool during hot seasons and warm during cold nights. The sloped form of the roof helps shed rainwater effectively, which is essential in the region's tropical climate. Figure 1 illustrates a typical Mwera house in Tanzania.

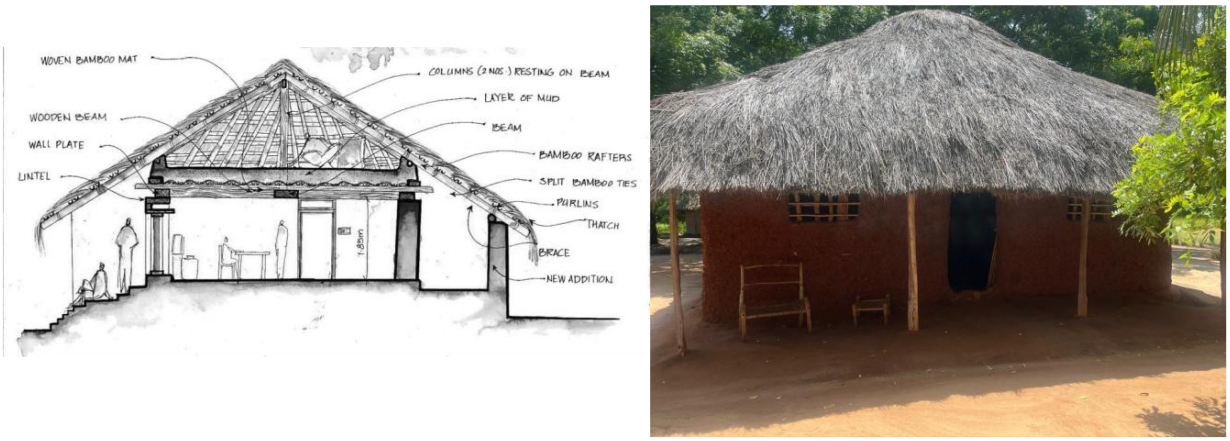

Figure 1 - Typical Mwera house in Tanzania

4.2 Iraqw House (Tembe)

Wa-Iraq Houses (Tembe) are traditionally rectangular dwellings characterized by their thick mud walls and distinctive flat earthen roofs. Built entirely from natural, locally available materials such as mud, clay, timber and cow dung. These houses demonstrate an efficient and sustainable architectural system well adapted to the Iraq tribe's environment. The walls are constructed either from sun-dried mud bricks or by applying layers of mud plaster over a simple wooden framework. This results in dense, thermally efficient walls that help keep the interior cool during the day and warm during cold nights. Cow dung is often mixed into the mud as a binding agent, improving the material's strength, durability and resistance to cracking. A defining feature of the house is its flat roof. Supported by strong timber beams laid across the main walls, the roof is topped with layers of compacted earth. This earthen roof is carefully tamped to enhance waterproofing and stability, allowing it to withstand wind, heat, and occasional rainfall. In some cases, grass or small branches are integrated beneath the mud layer to improve structural cohesion. Figure 2 displays a great example about Iraqw house in Tanzania.

Figure 2 - Typical Iraqw house in Tanzania

4.3 Hehe House

Hehe Houses (Tembe) are traditional rectangular or slightly oval structures built using wattle-and-daub techniques and natural local materials. Their construction begins with arranging strong wooden poles vertically into the ground to create the main frame of the house. Between these poles, smaller flexible sticks are woven horizontally to form a tight lattice that supports the wall structure. This woven framework is then plastered with layers of wet mud mixed with grass or cow dung, producing thick, sturdy walls that provide

excellent insulation against heat and cold. The walls are often smoothened by hand and left to dry naturally in the sun. The roof is typically constructed from wooden rafters covered with dense thatching made of long grasses, often elephant grass or similar locally available varieties. This thatched roof is designed with a gentle slope to shed rainwater efficiently and maintain a cool interior temperature. Figure 3 shows a sketch and one existing Hehe house in Tanzania.

Figure 3 - Typical Hehe house in Tanzania

4.4 Bembe House

Bembe House (Msonge houses) are traditionally constructed using a flexible framework that forms a rounded, dome-like structure. The building process begins with bending slender poles and securing them together to create a curved skeletal frame. This arched framework provides both strength and resilience, enabling the house to withstand heavy rains and shifting weather conditions. Once the main frame is set, the walls are woven with reeds, banana fibres, or other flexible plant materials to create a tight lattice.

This woven surface acts as a supportive base for the wall covering. Layers of mud are then applied over the lattice, forming a firm, smooth exterior that strengthens the structure and provides effective protection against rain and wind. The roof is traditionally thatched with bundles of dried grass or overlapping banana leaves. These materials are carefully arranged in thick layers to ensure water flows off easily, preventing leaks and maintaining a cool, well-insulated interior. Figure 4 displays a typical bembe house in Tanzania.

Figure 4 - Typical Bembe house in Tanzania

4.5 Nyakyusa House

Nyakyusa houses (Bamboo House) are traditionally constructed using bamboo as the primary structural material, reflecting the tribe's close connection to the forested landscapes of the Southern Highlands.

Building a house is a communal activity, where relatives and neighbors gather to assist, reinforcing social unity and cooperation. The construction process begins by assembling strong bamboo poles to form the main framework of the house. These poles are arranged vertically and horizontally, then tied securely to create a stable skeleton. Additional bamboo pieces are woven or lashed into the structure to strengthen the walls and support the roof. Because bamboo is lightweight yet durable, the completed structure remains flexible an advantage in areas prone to heavy rain or strong winds. A distinctive cultural characteristic of Nyakyusa housing is the attention given to decoration and finishing. Significant effort is spent smoothing the surfaces, arranging bamboo neatly, and sometimes embellishing entrances or edges to showcase craftsmanship. The quality of finishing often reflects pride, skill, and social identity within the community. Figure 5 illustrates Nyakyusa houses in Tanzania.

Figure 5 - Typical Nyakyusa house in Tanzania

The comprehensive comparative analysis of vernacular housing typologies in Tanzania is summarized in Table 3.

Table 3 - Comparative analysis of vernacular housing typologies in Tanzania

Typology	Structural System	Main Materials	Roof Type	Strength	Weakness	Environmental Performance
Mwera House	Timber frame + wattle and daub	Wooden poles, woven sticks, mud, grass, cow dung	Sloped thatched roof (elephant grass)	Lightweight structure; good airflow; adaptable construction	Vulnerable to erosion; weak wall cohesion; low durability against moisture	Good thermal insulation; effective ventilation; suitable for tropical climate
Iraqw House	Load-bearing earthen walls	Mud, clay, timber, cow dung, stone (foundation)	Flat earthen roof	Thick walls provide strength and insulation; compact layout	Poor resistance to water infiltration; heavy roof load;	High thermal mass; stable indoor temperature (day-night balance)

					foundation erosion risk	
Hehe House	Wattle and daub system	Wooden poles, sticks, mud, grass, cow dung	Sloped thatched roof	Flexible structure; easy to construct; low-cost materials	Weak structural integrity; prone to biological degradation (termites, vegetation)	Good thermal performance; efficient rainwater drainage
Bembe House	Flexible curved frame (dome-like)	Bent poles, reeds, banana fibers, mud	Thatched (grass/banana leaves)	Aerodynamic form improves resistance to wind; structural flexibility	Limited load-bearing capacity; high maintenance of organic materials	Good climatic adaptation; efficient rain shedding; stable internal environment
Nyakyusa House	Bamboo frame structure	Bamboo, grass, earth (foundation)	Thatched roof	Flexible and resilient to environmental loads; community-based construction	Low durability; susceptible to decay, insects, and moisture	Good ventilation; lightweight; suitable for humid environments

5. Results and Discussion

Cross-case comparison across typologies and regions evaluated using standardized indicators for thermal performance, durability, structural stability, and material efficiency via comparative benchmarking.

5.1 Thermal Performance of Earthen Materials

The findings indicate that traditional earthen construction systems across the study areas exhibit strong thermal performance due to their high thermal mass. Materials such as compacted earth walls and mud-plastered roofing systems absorb heat during the day and release it gradually at night, thereby moderating indoor temperature fluctuations.

In semi-arid environments such as Kondoa District and Mbulu District, this thermal behavior contributes significantly to indoor comfort by reducing daytime overheating and maintaining warmth during cooler nights. Similarly, in the coastal context of Dar es Salaam, earthen walls help buffer high ambient temperatures, although ventilation plays a more critical role due to humidity. These findings confirm that earthen materials provide an effective passive cooling strategy, reducing dependence on mechanical systems and supporting climate-responsive housing design.

5.2 Durability Performance and Degradation Mechanisms

Despite their environmental and thermal advantages, earthen structures are susceptible to several durability challenges. The most common form of deterioration observed across the case studies is surface erosion, primarily caused by rain impact, surface runoff, and wind action. This results in gradual material loss and weakening of wall sections over time.

Another critical issue is foundation-related failure, particularly in structures lacking adequate plinth protection. In several cases, direct contact between earthen walls and the ground led to moisture ingress through capillary action, causing rising damp, material disintegration, and eventual structural instability.

However, buildings incorporating stone foundations or raised plinths demonstrated improved resistance to moisture and longer service life. This highlights the importance of integrating basic protective measures to enhance the durability of earthen construction.

5.3 Structural Performance and Failure Modes

The structural assessment revealed several inherent weaknesses in traditional earthen construction systems, particularly in relation to lateral stability and wall integrity. These vulnerabilities are primarily attributed to the low tensile strength of earthen materials and the absence of effective reinforcement mechanisms.

5.4 Out-of-Plane Failure:

Out-of-plane wall failure was identified as a major structural risk, especially in buildings constructed with unreinforced earthen walls and weak roof-to-wall connections. Under lateral loads, such as wind pressure, walls tend to bulge and may eventually collapse outward due to insufficient tensile resistance and lack of proper anchorage. This type of failure is particularly evident in structures with large unsupported wall spans and inadequate structural integration between wall and roof elements.

5.5 Corner Separation:

Corner separation and cracking at wall junctions were also commonly observed across the case studies. These failures are typically associated with poor bonding between intersecting walls, often resulting from construction techniques that do not ensure adequate interlocking or continuity at corners. The absence of reinforcement elements, such as tie beams or corner strengthening, further exacerbates this weakness. Over time, progressive cracking at these junctions compromises the structural integrity and stability of the entire building. Overall, these findings highlight the need for incorporating simple and effective reinforcement strategies such as improved bonding techniques, timber ring beams, and corner stabilization methods. These will enhance the structural performance of earthen construction systems without undermining their sustainability advantages.

6. Conclusions

The findings of this study demonstrate that traditional earthen construction technologies in Tanzania embody a highly efficient and context-responsive approach to housing, shaped by centuries of adaptation to local climatic, environmental, and socio-cultural conditions. The investigated vernacular typologies, Mwera, Iraqw, Hehe, Bembe, and Nyakyusa houses, reveal a sophisticated integration of locally available materials, construction techniques, and spatial configurations, resulting in structures that are not only affordable and resource-efficient but also environmentally sustainable. These systems exhibit low embodied energy, strong thermal performance, and a high degree of compatibility with their surrounding landscapes, confirming their relevance within contemporary sustainability discourse.

However, the study also highlights a significant ongoing transition toward modern construction materials such as burnt bricks and corrugated metal roofing, driven by urbanization, changing socio-economic aspirations, and perceptions of durability and modernity. While this shift often preserves certain spatial and cultural characteristics, it simultaneously risks the gradual loss of valuable vernacular knowledge and practices. In this context, the results emphasize the necessity of adopting a balanced and integrative approach that does not disregard traditional systems but rather enhances them through scientific validation and technological innovation.

The PURSUE project provides a critical framework for this transition by bridging traditional knowledge with modern engineering practices through education, capacity building, and technology transfer. By equipping stakeholders with the necessary tools and knowledge to improve the performance of local materials, the project supports the development of resilient, affordable, and sustainable housing solutions tailored to regional needs. Ultimately, this research underlines that the future of housing in Sub-Saharan Africa lies not in the replacement of vernacular systems, but in their informed transformation, ensuring that cultural heritage, environmental sustainability, and technical advancement are effectively aligned.

Underground Intervention in a Historic Building: Structural Compatibility and Heritage Preservation at the Museu Paulista

Gabriel Juliani MENTONE[1], Drª Fabiana Lopes OLIVEIRA[2]

[1] Universidade de São Paulo, Brazil, gabriel.mentone@usp.br
[2] Universidade de São Paulo, Brazil, floliveira@usp.br

Abstract: Contemporary interventions in historic buildings often pose significant technical challenges, especially when involving pre-existing pathological conditions, strict heritage constraints, and the need for functional expansion. In this context, this paper presents a case study of the intervention carried out at the Museu Paulista in São Paulo, focusing on the structural connection between the historical load-bearing masonry building and an underground reinforced concrete extension constructed beneath its foundations. The objective is to critically analyze the design and construction solutions adopted to enable this interface, considering the risks related to settlement, vibration, and cracking, further aggravated by the presence of works of art integrated into the masonry and by pathological conditions resulting from previous interventions. The methodology is based on a case study, with the analysis of project documentation, construction records, field observations and a critical comparison with guidelines from international heritage charters, especially regarding the use of contemporary techniques and the functional adaptation of cultural assets. The results show that the initial planned execution had to be revised due to soil behavior and observed settlements, leading to the adoption of solutions such as micropiles, jet grouting, tunnel excavation using the NATM method, and continuous geotechnical monitoring, allowing safe excavation while preserving the structural and material integrity of the monument. The interventions resulted in controlled settlements, without inducing cracks in the historic masonry or damage to the artworks, although with significant impacts on the schedule. It is concluded that contemporary extensions to historic buildings are technically feasible when guided by criteria of minimal intervention, structural compatibility, reversibility, and rigorous risk management, demonstrating that techniques usually associated with large-scale projects can be fundamental for mitigating pathologies and supporting the preserving built heritage

Keywords: Foundation reinforcement, historic building, contemporary intervention, underground excavations, containment techniques

1. Introduction

The Museu Paulista building, located in the city of São Paulo and popularly known as the Ipiranga Museum, is one of the most significant architectural and symbolic landmarks of Brazil's cultural heritage. Designed by the Italian engineer and architect Tommaso Gaudêncio Bezzi and constructed between 1885 and 1890, the building was originally conceived as a monument commemorating the Independence of Brazil. It was later adapted to house a scientific and educational museum, consolidating its role throughout the twentieth century as an important cultural institution.

As is common in many historic buildings, the structure gradually developed pathological manifestations resulting from material aging, previous interventions, and the evolving functional and technical requirements associated with contemporary museum use. In 2013, following the worsening of structural and construction-related problems, the museum was closed to the public, initiating an extensive process of technical studies and planning aimed at its restoration, modernization, and functional expansion.

Within this context, the University of São Paulo launched, in 2017, a National Architectural Competition for the rehabilitation, restoration, and expansion of the Museu Paulista complex. The winning proposal,

developed by H+F Arquitetos (Hereñú + Ferroni Arquitetos), adopted an approach based on reconciling heritage conservation with the functional upgrading of the museum.

Construction works began in October 2019 and were carried out under conditions of considerable technical complexity, further intensified by the stringent restrictions imposed by heritage protection authorities. The Museu Paulista building and the Independence Park are protected simultaneously at the federal, state, and municipal levels, requiring that every intervention be carefully planned in order to preserve the material integrity and symbolic significance of the listed heritage property.

Among the principal design strategies adopted were improvements in functionality and accessibility, modernization of technical infrastructure systems, and, most notably, the construction of a new underground extension intended to accommodate reception facilities, temporary exhibition spaces, and visitor support areas. This extension was implemented beneath the front esplanade and connected directly to the historic building through vertical circulation cores constructed adjacent to the existing foundations.

The implementation of this intervention posed particularly complex technical challenges, primarily due to the need to carry out deep excavations and construct new structural elements in close proximity to the foundations of a historic load-bearing masonry building subject to strict heritage constraints and containing artistic elements integrated into the masonry fabric. In this context, balancing heritage conservation, structural safety, and construction feasibility became a central aspect of both the design and execution phases of the project.

Against this background, the present paper aims to analyze the planning and execution of the vertical connection between the historic Museu Paulista building and the underground extension, discussing the structural and geotechnical solutions adopted to enable interventions of this nature in sensitive historic buildings. In doing so, the study seeks to contribute to the technical discussion on underground excavations and complex structural interfaces between historic constructions and contemporary additions.

2. Construction System of the Museu Paulista

The building of the Paulista Museum presents a construction system characteristic of the late 19th century, predominantly based on load-bearing masonry made of solid ceramic bricks. Vertically, the building consists of four levels, including a continuous basement extending beneath its entire footprint, as well as additional levels within the towers. Horizontally, it is divided into three sectors. The central sector consists of a single tower that receives and distributes the flow of visitors to the upper floors and to the two lateral exhibition sectors. The lateral sectors, east and west, each comprise a side tower connected to the central one through a wing. Each lateral tower contains a wooden helical staircase that provides vertical circulation to the upper floors. The wings are composed of exhibition rooms connected by *loggias*[1]. Figure 1 presents the ground floor plan of the monument building, highlighting the sectioning axis that separates the front façade from the rest of the building body due to the intervention carried out in the basement.

The structural walls have variable thicknesses, approximately 50 cm in internal partitions and reaching up to 1.40 m in external façades or in areas subjected to higher structural demands. The floor systems are heterogeneous, including solutions in concrete, ceramic hollow blocks, and timber structures. Ceilings are made of either wood or stucco, while internal finishes consist of lime-and-sand mortars applied directly onto the masonry or onto vegetal fibre lath made from juçara palm.

[1] loggia is an architectural space typical of historic buildings, particularly widespread in Renaissance Italy, characterized as a covered gallery integrated into the body of the building. Unlike a projecting balcony, it is recessed and defined by columns or pillars, forming a laterally open area that enhances natural lighting and ventilation while providing protection from sun and rain. Derived from classical and medieval traditions, it constitutes a transitional element between interior and exterior, widely used in palaces and public buildings as a space for social interaction, circulation, and contemplation, while also contributing rhythm, lightness, and depth to façades.

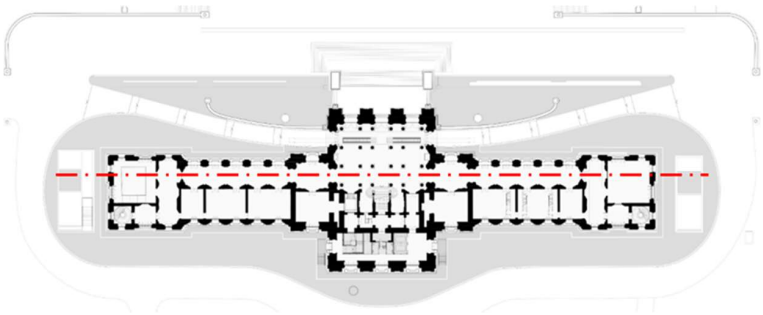

Figure 1 – Ground floor plan of the monument building Source: H+F Aquitetos (available at: https://hf.arq.br/projeto/museu-paulista/, accessed on April 5, 2026)

The foundations are composed of continuous strip footings in stone masonry bonded with mortar, approximately 2.00 m in height, consistent with the construction techniques of the period. Originally, the basement functioned as a ventilation and moisture-regulation space for the foundations, playing an important role in the hygrothermal balance of the building.

However, during a series of localized interventions in the 1990s, the basement was excavated and adapted for functional uses, coming to house sanitary facilities and administrative areas. This intervention led to the sectioning of the foundations along the front façade, particularly in the region beneath the loggias, resulting in structural movements and the emergence of cracks, especially in the front façade of the building.

This pre-existing condition constitutes a key factor in understanding the structural behavior of the monument within the context of contemporary interventions, revealing a history of modifications that have directly impacted its stability.

3. The Proposed Intervention

The architectural intervention proposed for the Paulista Museum was based on reconciling the preservation of the historic building with the need for functional expansion of the complex. In this context, a new underground volume was conceived beneath the front esplanade, with dimensions comparable to those of the monument building. The underground design strategy aimed to avoid interference with the monumental character of the historic structure, preserving its position and visual perspectives from all sides with minimal impact.

Figure 2 illustrates how the volumes relate within the landscape, without overlapping one another and with minimal intervention in existing elements. The intervention is only perceptible through the openings created in the existing granite balustrade, as no new architectural volume obstructs the pre-existing views or landscape.

The underground expansion was designed to accommodate visitor reception and welcoming functions, as well as exhibition spaces and support areas, establishing a direct connection with the monument through vertical accesses implemented adjacent to its foundations. This solution made it possible to preserve the volumetric integrity and the landscape reading of the complex, avoiding the insertion of visible elements that could compromise its historical perception. Figure 3 illustrates the scale of the reception hall proposed in the underground expansion, designed to distribute visitors throughout the cultural facility.

Figure 2 – Photograph of the façade of the extension and the monument building. Photo: Nelson Kon. Source: H+F Aquitetos (available at: https://hf.arq.br/projeto/museu-paulista/, accessed on April 4, 2026)

The connection between the underground structure and the historic monument was initially conceived through two main axes. The first, intended for primary circulation, consists of escalators installed beneath the former carriage access of the historic building, known as the via dos coxos. The via dos coxos was the monumental access route used by visitors attending events hosted in the building. It consists of two curvilinear ramped arms that enter through the sides of the central tower beneath the Noble Hall, as shown in Figure 1. In this way, carriages could stop inside the building itself, in a covered and protected area, for the boarding and disembarking of visitors.

Figure 3 – Photograph of the reception hall and ticketing area of the extension building. Photo: Nelson Kon. Source: H+F Aquitetos (available at: https://hf.arq.br/projeto/museu-paulista/, accessed on April 4, 2026)

With the intention of providing museum visitors with a sensory experience analogous to the historical arrival by carriage, this connection is composed of galleries that wrap around a soil mass responsible for supporting the loads of the monumental staircase, aligning beneath the axis of the via dos coxos. In this interpretation, the escalator functions as the “carriage” that transports visitors into the monument, directly to the ground-floor hall. Figure 4 presents a section along the axis of the via dos coxos, where the ramped accesses used by carriages and the underground intervention guiding visitors to the hall via escalators can be clearly observed.

The second axis, dedicated to elevator access, originates from the escalator axis and advances toward the interior of the building, crossing several foundation lines that support the main hall and the Noble Hall, which houses the painting Independência ou Morte.

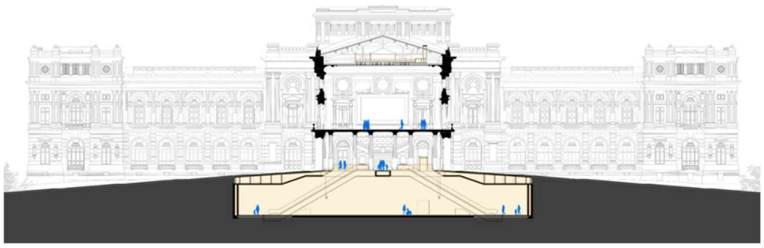

Figure 4 – Section of the main axis connecting the underground building to the monument. Source: H+F Arquitetos (available at: https://hf.arq.br/projeto/museu-paulista/, accessed on April 4, 2026)

The execution of these connections required excavations approximately 10.0 m deep in regions characterized by high concentrations of structural stresses, particularly near the central tower and the front façade. Furthermore, the proposed solutions involved the direct interaction between contemporary reinforced concrete structures and the historic load-bearing masonry system in stone. This was compounded by the structural fragility of the area due to previous interventions in the foundations carried out to adapt the basement for functional uses.

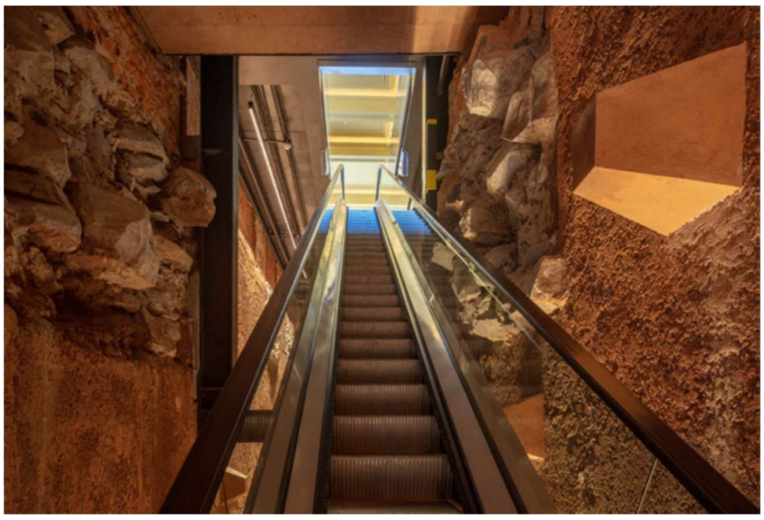

Figure 5 – Photograph of the reception hall and ticketing area of the extension building. Photo: Nelson Kon. Source: H+F Aquitetos (available at: https://hf.arq.br/projeto/museu-paulista/, accessed on April 4, 2026)

From a technical standpoint, the intervention posed significant challenges, mainly related to settlement control, soil stability, and vibration mitigation. These challenges were further intensified by the presence of artworks such as the portraits applied using the marouflage[2] technique on the central marble staircase, integrated into the masonry, whose integrity depended on extremely strict deformation limits.

Figure 5 materially illustrates the connection between the two buildings through the escalator emerging in the via dos coxos. It is possible to observe, in the lower part of the image, the pigmented concrete structures that form the anchored retaining walls at the levels of the underground expansion. Above, at the center of the figure, the rock masses that were demolished and originally composed the continuous foundation of the monument can be seen, along with soil nailing systems. Additionally, part of the vertical steel profile forming a metallic ring used to ensure continuity in load transfer within the shallow foundation system is visible, extending up to the emergence point within the ground-floor hall.

[2] *Marouflage* is a technique in which a painting executed on canvas is permanently adhered to a rigid support, such as a wall or panel, causing it to lose its mobility and become an integral part of the building's architecture.

Thus, the feasibility of the proposal depended not only on the adequacy of the adopted structural solutions but also on rigorous execution control and on strategies capable of reconciling technical requirements with the constraints imposed by heritage preservation.

4. Implemented Solution

The execution of the interventions was carried out based on a plan that incorporated continuous geotechnical monitoring and the adoption of progressive excavation and retaining strategies. As an initial measure, a line of micropiles with a diameter of 30 cm, spaced at 1.20 m intervals, was installed along the perimeter of the interface between the monument building and the extension, including both sides of the connection corridors. The primary function of this micropile line was to restrain potential movements of the sectioned foundation line of the basement and, consequently, of the front façade supported on it.

Simultaneously, the excavations were monitored through daily topographic surveys in order to detect any soil or structural movements. Preliminary geotechnical investigations, carried out under restrictions to avoid vibrations, indicated the presence of fill material in the area.

During the early excavation stages, still within the initial phases of the retaining system, differential settlements were identified in the region where the wing meets the west tower of the building. These displacements were associated with variations in the groundwater table level, which was found to be higher than initially indicated in the surveys.

In response to this scenario, excavation activities within the central area were suspended and the executive design was revised in order to mitigate the risks associated with excavation works in the most sensitive portion of the intervention.

As a result of this revision, the originally planned solution for the elevator access corridor—also based on excavation and anchored retaining walls—was replaced by the construction of a tunnel using the NATM (New Austrian Tunneling Method)[3], allowing for a more efficient redistribution of stresses within the soil mass and reducing the need for rigid retaining systems.

In addition, supplementary reinforcement was implemented through steel-cased micropiles (Schedule 80 steel pipes) installed side by side along the escalator corridor walls, the tunnel crown (see Figure 6), and the perimeter of the elevator shaft. These micropiles were interconnected by structural beams, providing additional stability to the system.

Figure 6 presents the cross-section of the tunnel excavated using the New Austrian Tunnelling Method (NATM), illustrating the stabilization system adopted to enable excavation beneath the foundations of the historic building. The scheme shows the semicircular arrangement of self-drilling steel-cased micropiles installed along the tunnel crown to provide pre-support of the soil mass prior to excavation advance.

The system was designed to reduce deformations around the excavation and control stress redistribution induced by material removal, thereby minimizing differential displacements in the foundations of the historic monument. The micropiles function as temporary retaining and ground-reinforcement elements, forming a resistant arch capable of transferring part of the loads to more stable zones of the ground.

The section also illustrates the sequential excavation procedure characteristic of the NATM, in which excavation advances are carried out in small increments and immediately followed by the application of shotcrete. This approach allows the reinforced ground itself to participate in the structural stabilization of

[3] The NATM (New Austrian Tunneling Method) is a tunnel construction methodology based on the principle that the excavated ground itself (soil or rock) should be mobilized as a structural support element. Instead of relying on immediate rigid linings, the method employs sequential excavation with continuous monitoring of deformations and the progressive application of flexible support systems—such as shotcrete, anchors, and steel ribs—adjusting the support measures according to the behavior of the ground

the tunnel, reducing the need for large rigid support structures and enabling progressive control of deformations.

In addition to the micropiles installed at the tunnel crown, lateral reinforcement elements can be observed in the support zones of the tunnel, contributing to the overall stability of the excavated section. The system was further complemented by soil nails, self-drilling spiles, and jet grouting reinforcement, installed according to excavation progress and the results obtained through continuous geotechnical monitoring.

The adoption of the ntion, as it provided greater constructior encountered during execution, especially uctural sensitivity of the historic building.

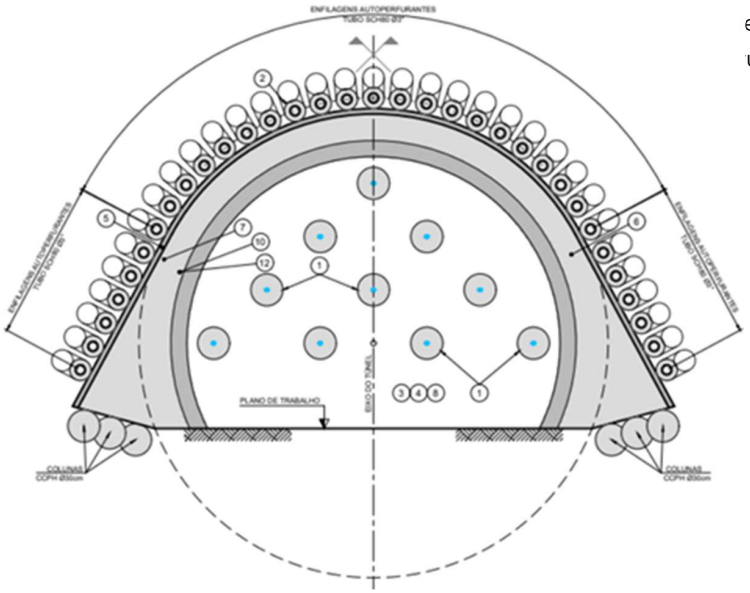

Figure 6 – Construction detail of the NATM tunnel design. Source: Maffei Engenharia e Consultoria Ltda.

Excavation activities in the central area resumed only after the completion of these reinforcement measures, including the simultaneous installation of jet grouting columns and the micropiles surrounding the elevator shaft. Subsequent excavation works were carried out in stages between April and September 2021, combining soil nailing and anchored retaining wall systems according to excavation depth and local ground conditions.

Construction of the NATM tunnel commenced only after stability conditions had been fully established, including the installation of self-drilling spiles and reinforced soil nails, and was completed by the end of November 2021. Continuous monitoring made it possible to assess the behavior of the soil–structure system throughout all stages of the intervention. A total of twelve settlement monitoring pins were installed on the lateral columns of the Via dos Coxos within the historic building to track displacements during the excavation process. In addition, fifteen monitoring pins were installed along five cross-sections of the NATM tunnel following the commencement of tunnel excavation works.

Figure 7 shows the location of the settlement monitoring pins installed along the side of the Via dos Coxos within the historic Museu Paulista building. These instruments were used for the continuous monitoring of vertical displacements induced by excavation activities and retaining interventions carried out during construction. The monitoring points identified as PR-44 to PR-55 were strategically distributed in areas considered particularly sensitive from a structural perspective, especially near the interface between the historic monument and the new underground connections.

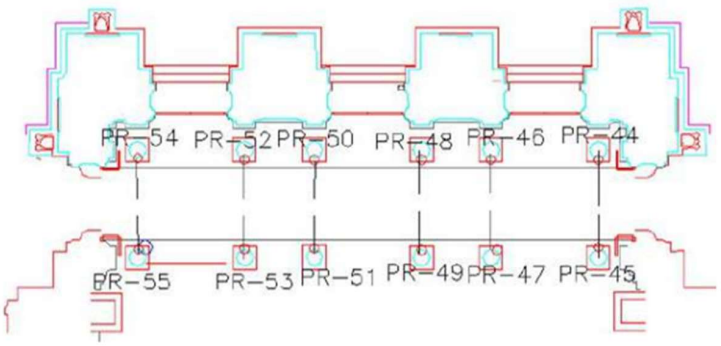

Figure 7 – Layout of settlement monitoring pins PR-44 to PR-55 installed along the side of the Via dos Coxos. Source: Museu Paulista Instrumentation Monitoring Report.

For the analysis of structural behavior, particular attention was given to monitoring points PR-52, PR-53, PR-54, and PR-55, located near the NATM tunnel portal and in regions subjected to the most significant changes in the stress state of the soil mass. These points exhibited a greater potential for differential displacements due to the combined effects of deep excavations, the presence of previously weakened historic foundations, and the execution of successive retaining structures within a confined area.

The monitoring system made it possible to track the temporal evolution of settlements throughout the various construction stages, providing essential data for assessing the stability of the historic structure and supporting decision-making during the execution of the works. Systematic analysis of the instrumentation readings enabled the identification of changes in soil–structure interaction during the early phases of excavation, allowing the revision of the originally proposed solutions before more significant displacements could compromise the integrity of the monument.

Beyond its role as a safety control measure, the monitoring program was instrumental in validating the effectiveness of the adopted reinforcement techniques, including steel-cased micropiles, jet grouting, and the NATM tunnel. The instrumentation data demonstrated that, following the implementation of the supplementary stabilization measures, displacement rates progressively decreased and the structural behavior of the monitored area became stabilized.

Therefore, Figure 7 not only illustrates the distribution of the monitoring instruments but also highlights the importance of continuous geotechnical monitoring as an essential risk management tool for underground interventions carried out beneath sensitive historic structures.

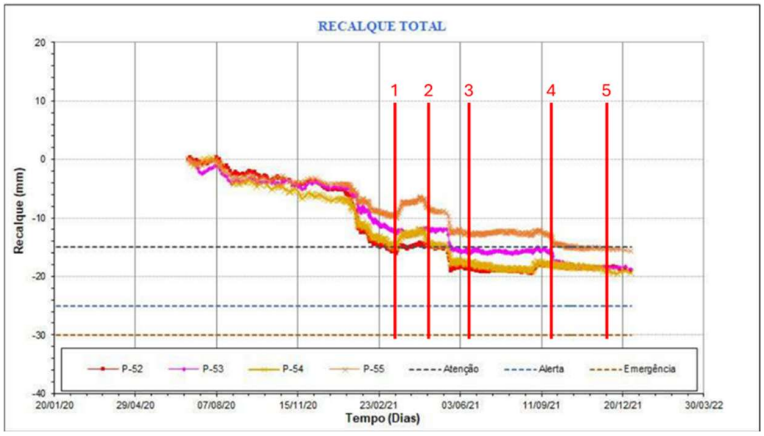

Figure 8 – Graphical record of the monitoring results for points PR-52, PR-53, PR-54, and PR-55 during the excavation and retaining works at Museu Paulista. Source: Museu Paulista Instrumentation Monitoring Report

The records presented in Figure 8 illustrate the progressive development of settlements throughout the various stages of excavation and structural reinforcement. During the initial phases of excavation for the underground extension, monitoring points PR-52 to PR-55 exhibited gradual vertical displacements, reaching an accumulated settlement of approximately 10 mm by Point 1 on the graph.

This initial behavior indicates the direct influence of deep excavations on both the redistribution of stresses within the soil mass and the response of the foundation system, which had previously been weakened by interventions carried out in the basement during the 1990s. Despite the occurrence of measurable displacements, the observed values remained within acceptable limits for historic masonry structures, and no new cracks or deterioration of existing pathological manifestations were identified.

From Point 1 onward, corresponding to the commencement of excavation works for the escalator corridor, a more pronounced increase in the slope of the settlement curves can be observed, indicating a greater sensitivity of the building's front section to the underground works carried out along the axis of the Via dos Coxos. This behavior prompted a revision of the originally proposed construction solutions and the adoption of additional stabilization measures.

At Point 2 on the graph, corresponding to the beginning of the underground works associated with the escalator corridor and the implementation of supplementary reinforcement measures, a gradual reduction in displacement rates can be observed. The progressive stabilization of the settlement curves following the installation of steel-cased micropiles, self-drilling spiles, and jet grouting reinforcement demonstrates the effectiveness of the adopted measures in controlling ground movements and redistributing stresses within the soil mass.

The monitoring results indicate that the combination of construction solutions adopted was effective in controlling differential settlements despite the considerable geotechnical and structural complexity of the intervention, which involved deep excavations adjacent to sensitive historic foundations and artistic elements integrated into the masonry fabric. Continuous monitoring proved essential in guiding design revisions and allowing construction strategies to be adapted to the actual behavior of both the structure and the ground during execution.

During specific stages of construction, some monitoring points reached threshold values classified as an "attention level," requiring increased caution during excavation and enhanced monitoring procedures. However, no interruption of construction activities was required. Temporary cross-bracing systems were installed between the excavation sides to relieve lateral earth pressures and reduce settlement levels, ensuring that none of the monitoring points reached the established "alert level," which would have required suspension of activities and could potentially have led to cracking within the historic masonry.

The temporary bracing system proved effective in stabilizing the settlement process. It can be observed that during excavation at the deeper levels, where anchored retaining walls had already been installed, ground movements became virtually negligible. Point 3 on the graph indicates the beginning of the construction of the anchored retaining walls, consisting of two levels of anchors. The interval between Points 4 and 5 corresponds to the construction period of the NATM tunnel.

Following the commencement of the horizontal excavation of the NATM tunnel, monitoring data indicate displacements of approximately 2 mm at points PR-53 and PR-55, both located near the tunnel portal. Nevertheless, no significant movements were recorded during tunnel excavation, demonstrating the effectiveness of the stabilization measures that had been implemented.

Monitoring of the horizontal tunnel excavation was carried out by measuring the distances between three monitoring pins installed along the tunnel crown at five monitoring sections distributed throughout the excavation advance. The pins were located at the highest point of the crown (P1) and at its lateral extremities (P2 and P3). The monitored distances between these points were designated C1–2, C1–3, and C2–3, as illustrated in Figure 9.

Figure 9 presents the monitoring results for sections S1, S3, and S5. With the exception of Section S3, all sections exhibited similar behavior. During the initial stages of excavation, compressive effects caused convergence between the monitoring points until structural stabilization was achieved. In other words, the tunnel opening tended to close slightly as stresses were redistributed.

In Section S1, the greatest displacements occurred between points P2 and P3 relative to P1, indicating that vertical displacement at the crown was more significant than horizontal displacement at the side points. This behavior is attributed to the proximity of the anchored retaining wall system. In contrast, Section S5 exhibited its greatest displacement through convergence between the lateral points P2 and P3, indicating that lateral earth pressures had a greater influence on tunnel closure than the direct vertical loading acting on point P1.

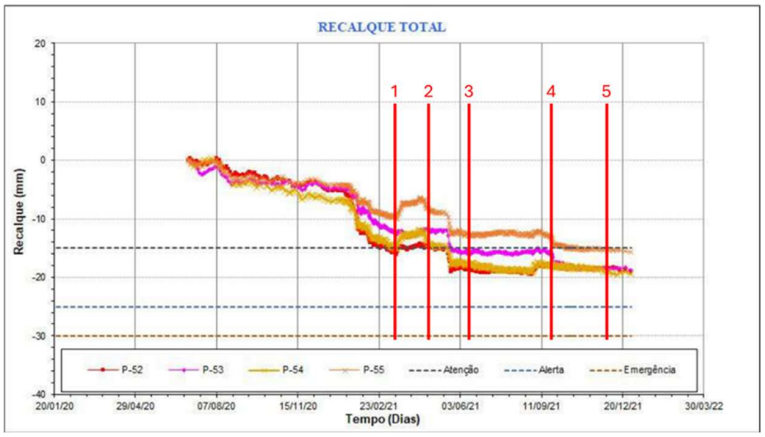

Figure 9 – Superimposed convergence monitoring data for NATM tunnel sections S1, S3, and S5. Source: Museu Paulista Instrumentation Monitoring Report.

The behavior observed in Section S3, however, differed from that of the other monitored sections. In this case, the distances between the monitoring points increased until stabilization was achieved, with the largest displacement occurring between lateral points P2 and P3. This behavior is opposite to that observed in Section S5, indicating that, at this location, the tunnel section experienced vertical compression that tended to induce lateral expansion prior to stabilization.

By correlating the monitoring data obtained from the tunnel sections with the measurements recorded at the monitoring points located directly above them, as presented in Figure 8, it can be observed that most of the deformations occurring within the tunnel did not directly affect the historic building. Instead, these movements resulted primarily from the redistribution and re-equilibration of stresses within the surrounding soil mass.

The revision of the original design and the implementation of the solutions described above had a significant impact on the project schedule, extending the duration originally planned for the retaining works in the central area by approximately one year. Nevertheless, the construction schedule was adjusted to allow progress on other work fronts, thereby minimizing the impact on the overall completion time of the project.

5. Results and Discussion

The design revisions and solutions adopted throughout the execution proved to be essential for enabling the proposed intervention, ensuring the preservation of the structural and material integrity of the historic building.

Although settlements occurred during the excavation process, they remained within controlled limits and did not result in cracking of the masonry or damage to the artworks integrated into the monument. The

impact on the construction schedule was significant; however, it was mitigated through adjustments in the execution planning and the reorganization of work fronts.

In light of international heritage charters, the intervention can be analyzed from two main perspectives: the use of contemporary techniques and the functional adaptation of the historic building.

Regarding the use of new materials and techniques, an evolution can be observed in the interpretation of heritage guidelines over time. The Athens Charter adopts a more permissive stance, encouraging the use of modern techniques as a means to prevent the degradation of historic elements. The Venice Charter, in turn, takes a more cautious position, recommending their use only when traditional techniques prove inadequate and provided that their effectiveness is well established.

This understanding is reinforced by later documents, such as the Amsterdam Declaration and the Nairobi Recommendation, which emphasize the importance of maintaining traditional techniques and preserving intangible knowledge, while also recognizing the need for systematic studies on the application of contemporary methods.

The Burra Charter consolidates this approach by accepting the use of modern techniques, provided that they effectively contribute to the preservation of the cultural value of the asset, while also emphasizing the importance of reversibility whenever possible.

In the case analyzed, the adoption of techniques such as micropiles, jet grouting, and excavation using the NATM method can be understood as a response to the limitations of traditional techniques when faced with the complexity of the intervention. These solutions were employed with the objective of minimizing vibrations, controlling deformations, and ensuring the overall stability of the system, in accordance with preservation principles.

With regard to functional adaptations, heritage guidelines converge in recognizing functionality as a key condition for the preservation of cultural assets. The maintenance of the exhibition use within the historic building, combined with the relocation of incompatible functions to the underground extension, demonstrates alignment with these principles.

The adopted solution allowed for the preservation of the spatial configuration and significant elements of the monument, while simultaneously enabling its adaptation to contemporary demands.

The combined analysis of these aspects indicates that the design and construction decisions sought to balance technical and functional requirements with the principles of heritage preservation, even though revisions and adjustments were necessary throughout the process.

6. Conclusion

The analysis of the intervention carried out at Museu Paulista demonstrates that the construction of underground extensions beneath historic load-bearing masonry buildings is technically feasible, provided that it is guided by rigorous criteria for risk management, structural compatibility, and the preservation of the cultural significance of the heritage asset.

The case study shows that the adoption of contemporary engineering and construction techniques may be not only appropriate but also necessary in situations of high technical complexity, particularly when pre-existing instability conditions or severe intervention constraints are present.

The design revisions implemented throughout the construction process highlight the importance of flexible and adaptive approaches capable of responding to actual site conditions without compromising conservation objectives. As a result of these adjustments, the maximum monitored displacements remained below the thresholds generally considered critical for crack initiation in historic masonry structures, ensuring the structural and artistic integrity of the monument throughout all stages of construction.

Finally, it is important to emphasize that the successful integration of heritage conservation and contemporary intervention depends not only on technical solutions but also on a critical understanding of the principles that guide the conservation of cultural heritage, allowing them to be applied in a contextualized and informed manner.

In light of the foregoing, and in accordance with the principles established by international heritage charters, it can be concluded that the incorporation of contemporary construction technologies into restoration projects is not only possible but may also be essential for safeguarding the physical, functional, and symbolic integrity of cultural heritage assets. As demonstrated by the Museu Paulista case study, the use of solutions such as micropiles, jet grouting, and controlled excavation techniques showed that, when guided by the principles of minimum intervention, compatibility, reversibility, and respect for authenticity, such technologies do not compromise the values that justified the heritage designation of the property. On the contrary, they contribute to the rehabilitation and continued use of the building, enabling its adaptation to contemporary requirements without altering its original character. Thus, this study reaffirms that a balanced integration of tradition and innovation constitutes both a legitimate and necessary approach to the conservation of built heritage, ensuring its continuity and relevance for future generations.

Acknowledgments

The authors would like to express their gratitude to Carlos Eduardo Moreira Maffei, from Maffei Engenharia e Consultoria Ltda., for providing access to technical materials related to the foundation reinforcement project of the Paulista Museum (Ipiranga Museum), including soil analysis data, design calculations, and monitoring records. Access to this material was essential for the development of this research.

The authors also thank the Paulista Museum of the University of São Paulo for authorizing and supporting this study, thereby making a significant contribution to its development. Due acknowledgment and proper credit are given to the aforementioned firm for the project and the materials utilized.

Resumo: No contexto do desenvolvimento da tecnologia em todos os setores da atualidade, muito se discute acerca do potencial da aplicação de estratégias de modelagem digital no patrimônio histórico edificado no âmbito nacional e internacional. Em contrapartida, os cenários de desaparecimento da materialização da cultura brasileira são cada vez mais recorrentes. Dessa forma, essa pesquisa surge dentro dos esforços para desenvolver e aplicar metodologias inovadoras que cruzem dados geométricos com informações construtivas, históricas e de gestão, num modelo integrado, objetivando a documentação digital do acervo arquitetônico cearense por meio da aplicação dos princípios do *Heritage Building Information Modeling* (HBIM) e levantamento com *laser scanner* terrestre. Buscou-se refletir sobre o processo de aplicação da metodologia e novas perspectivas, visando fazer uma reconstrução digital que facilite a tomada de decisões para a gestão e a manutenção. O método, que adota a abordagem do estudo de caso no edifício anexo do Museu da Imagem e do Som Chico Albuquerque em Fortaleza, Ceará, permite a execução dos processos de captura da edificação aplicados a geometria e particularidades individuais do objeto arquitetônico, promovendo uma análise focada e pontual do processo. A metodologia foi dividida nas etapas de: levantamento com nuvem de pontos, modelagem digital, integração de informações adicionais como detalhes construtivos e revestimentos aplicados. Como produto final, obteve-se material de documentação técnica da edificação para auxiliar na gestão e manutenção do bem, além de resultados que confirmam a eficiência dos métodos e sua aplicabilidade para o registro das demais obras do acervo arquitetônico cearense, mantendo um memorial do processo de digitalização e modelagem do Museu da Imagem e do Som Chico Albuquerque. Por fim, conclui-se que o levantamento através da nuvem de pontos para modelagem digital mostrou-se eficiente e aplicável para demais bens.

Palavras Chave: HBIM. Modelagem digital, Nuvem de pontos.

1. Introdução

O patrimônio histórico edificado e edifícios de uso cultural e turístico nas cidades são alvos de diversas discussões no âmbito acadêmico e social, principalmente no que tange às estratégias de conservação, manutenção e gestão. Em contrapartida, os cenários de desaparecimento da materialização da cultura brasileira são cada vez mais recorrentes, estes, muitas vezes agravados por fatores naturais, mudanças climáticas e até geopolíticas (Kuroczyński e Argasiński 2025; Fatorić e Seekamp 2017). Meios que divulguem e apoiem a tomada de decisão do ponto de vista construtivo para a conservação desses bens exigem trabalhos custosos e enfrentam desafios em manter as documentações existentes de fácil acesso e organizadas. Para além disso, as instituições e órgãos de proteção do patrimônio enfrentam diversas limitações que levam a atuação no visível e urgente, deixando de lado planos e alternativas estratégicas que identifiquem riscos e ameaças de forma preventiva (Campos e Corrêa 2021), o que evidencia a necessidade de estratégias que identifique prioridades e alinhe custos a um processo otimizado (Freire 2026). Assim, os esforços para o desenvolvimento e implementação de meios de representação eficientes que atendam as particulares dos edifícios para fins de documentação, são fundamentais.

Com o desenvolvimento de tecnologias, novas ferramentas como a fotogrametria e o *laser scanner* surgiram para dar suporte ao processo de documentação do patrimônio construído, inclusive no cenário brasileiro, a exemplo dos trabalhos de Gonçalves e Inojosa (2022), Vieira et al. (2024), Ribeiro et al (2025), que por meio de nuvem de pontos alcançam níveis elevados de detalhamento, seja para simulação estrutural, modelagem de objetos e arquitetura. Além disso, outra metodologia consolidada que auxilia no processo de documentação é o *Building Information Modeling* (BIM), que possibilita a criação de modelos compatíveis para diversas disciplinas e inserção de informações paramétricas, o que vem constituindo um paradigma para o processo de projeto de novos edifícios com maior precisão. A inclusão da dimensão informacional e paramétrica na metodologia BIM permite anexar informações de materiais e custos num ambiente colaborativo e multidisciplinar, além de possibilitar, se usado de forma contínua, o monitoramento e gestão com dados atualizados (Rubens 2023) e (Freire 2026). Entretanto, a documentação de edifícios já existentes, seguindo a metodologia BIM, encontra restrições ao analisar geometrias complexas e com documentação dispersa ou inexistente (Ribeiro 2025).

Contornando esta problemática, o *Heritage Building Information Modeling* (HBIM) proposto por Murphy *et al.* (2009) diferente do BIM, se desenvolve com o objetivo de documentar e preservar o patrimônio histórico edificado, surgindo para levantar estruturas já existentes, unificar e sistematizar informações ao modelo, sejam elas históricas ou de construção, permitir o acompanhamento da obra ao longo do tempo e monitorar manifestações patológicas (Monteiro 2024). O HBIM possibilita que estratégias de conservação, manutenção e restauro sejam mais agilizadas e eficientes num ambiente integrado, por meio de uma modelagem digital 3D gerada por engenharia reversa que, segundo Yang *et al.* (2020) pode ser sistematizado em 4 tipos, sendo eles: o modelo geométrico, que reconstroi a entidade original numa forma holística; o semântico, que atribui significado; o paramétrico que permite modificação dos elementos com base em parâmetros; e o informacional que constroi um banco de dados com os atributos, materiais e demais informações dos componentes. Ou seja, para além de um modelo geométrico, o HBIM funciona como um repositório de informações que podem ser úteis para intervenções, reformas e restauros.

Aliado a tecnologias otimizadas de levantamento já amplamente utilizadas como o laser scanner e a integração com software de modelagem BIM, esse trabalho visa aplicar os princípios da metodologia HBIM na modelagem digital do edifício anexo do Museu da Imagem e do Som Chico Albuquerque em Fortaleza, Ceará. O objetivo é registrar o processo de reconstrução, fortalecer o método e avaliar sua aplicabilidade, além de manter a documentação do acervo arquitetônico cearense, atendendo a demanda da Secretaria de Cultura do Estado do Ceará (Secult CE) para gestão e manutenção do ativo. Essa pesquisa se mostra relevante ao partir de uma demanda real e integrar tecnologias digitais de levantamento, modelagem e processamento para a manutenção dos edifícios cearenses de uso turístico e cultural.

2. Metodologia

2.1 Estudo de caso: Museu da Imagem e do Som Chico Albuquerque

O Museu da Imagem e do Som Chico Albuquerque (MIS), atualmente localizado na Avenida Barão de Studart, 410, na cidade de Fortaleza, Ceará é um instrumento da Secretaria de Cultura do Estado do Ceará (Secult-CE) e funciona na antiga residência Fausto de Cabral (Figura 1a), prédio tombado em âmbito estadual definitivamente desde 2016 (Secult 2016). Datado de 1951 e com projeto atribuído a José Barros Maia, “Mainha”, a construção de traços ecléticos foi executada para ser a casa do senador Fausto Cabral, o edifício já abrigou a residência oficial do Governo do Estado em 1963, o Museu Histórico e Antropológico do Estado em 1972, a sede do Departamento de Patrimônio Histórico (Depac) e desde 1996 passou a ser a sede do Museu da Imagem e do Som (Governo do Estado 2015) e (Azevedo 2012). Durante o ano de 2018 o MIS passou por uma grande reforma e restauros, onde ganhou um prédio anexo de 5 andares, com mais salas de exposição, laboratórios de mixagem, áudio, e imagem, centros de pesquisa e biblioteca. Chamado agora de Complexo do Museu da Imagem e do Som, o prédio antigo e o novo, além da praça que existe entre eles, compõem um importante atrativo cultural e turístico para a cidade.

Este trabalho aplicou o processo de modelagem e estudo para o prédio novo anexo do museu (Figura 1b e 1c). Com as obras finalizadas em 2022 e projeto assinado pelo arquiteto portugês José Manuel Carvalho Araújo, o edifício já se consagra como importante marco turístico e arquitetônico da cidade. A obra priorizou

o afastamento do edifício para o limite posterior do terreno e a criação de uma generosa praça com arquibancadas para assistir apresentações ao ar livre e projeções que ocorrem na grande fachada de concreto aparente do edifício, possibilitando uma relação de plateia e tela entre o prédio e a cidade (Archdaily 2023). O programa sofisticado aliado a tecnologia de ponta coloca o museu em níveis excepcionais de qualidade em serviços e exibições. São cinco pisos, sendo um o térreo e dois no subsolo, o prédio conta com sala imersiva, laboratórios de audiovisual, salas de exposição e biblioteca.

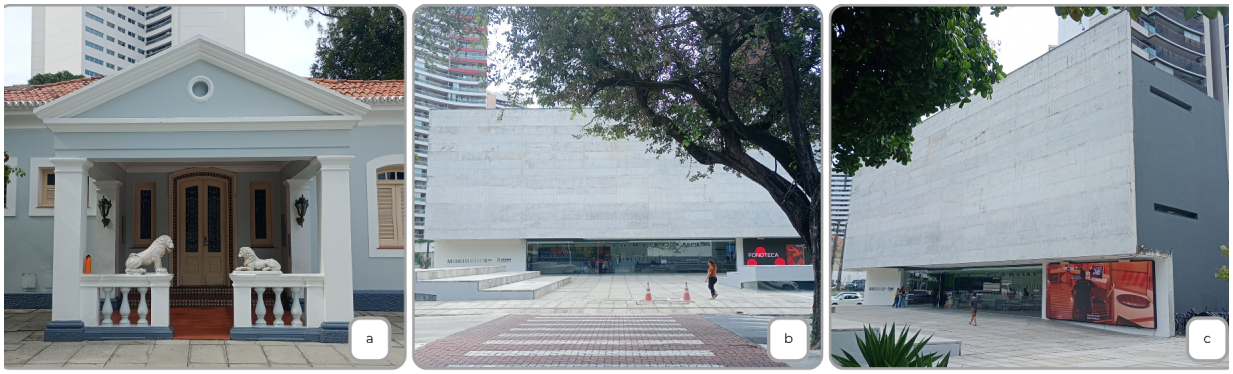

Figura 1. Museu da Imagem e do Som Chico Albuquerque

2.2 Levantamento e modelagem digital

O levantamento para captura de dados geométricos foi feito usando *laser* scanner terrestre visando chegar ao *Scan-to*-BIM, processo que visa a obtenção de um modelo BIM preciso e de alta qualidade a partir de uma nuvem de pontos (León 2018). Em seguida, os *setups* de cada captura realizados por um *scanner* Leica® BLK360 foram processados e unidos para gerar um modelo 3D da nuvem de pontos, a fim de se incorporar ao ambiente BIM para modelagem dos elementos construtivos. Na etapa de levantamento também foram coletadas fotos 360 para montagem de passeios interativos pelo edifício de forma virtual disponibilizados no site do DocumentaCe (www.documenta.com.br).

O processo de modelagem digital utilizou o formato protocolado pela prática do Documenta CE, grupo em rede ligado ao projeto Cientista Chefe da Cultura da Secult-CE que já conta com exemplares de bens digitalizados com métodos validados e publicados, como a Casa José de Alencar (Rubens *et al.* 2023) a Igreja Matriz de Nossa Senhora do Rosário (Ribeiro 2023) o Theatro José de Alencar (Vieira *et al.* 2023), e o Sobrado Doutor José Lourenço (Ribeiro 2025). O protocolo de modelagem HBIM sistematizado por Ribeiro (2025) busca uma uniformização de processos e linguagens de representação, reunindo todos os processos de modelagem em cinco etapas: o plano de execução BIM (PEB), que visa organizar ferramentas, prazos, nível de detalhes e objetivos; a modelagem digital, que modela os elementos construtivos; a precisão geométrica, que garante coerência dimensional entre o levantado e modelado; o enriquecimento semântico, que atribui significado e informações aos elementos; e a documentação e reconstrução digital que visa a produção de material gráfico arquitetônico e de divulgação.

O software de modelagem BIM adotado foi o Autodesk® Revit®, permitindo uma visualização tridimensional detalhada do modelo e uma variedade de funcionalidades que auxiliam no gerenciamento de dados. Segundo Penjor *et al.* (2024) é o software mais utilizado para criação de modelos HBIM com cerca de 60% de uso, consagrando suas ferramentas como as que melhor se adequam na construção digital. A nuvem de pontos foi importada e deu-se início a modelagem dos elementos primários como pisos, paredes, forros, escadas, cobertura e platibanda, em seguida, elementos construtivos secundários como portas, janelas, guarda-corpo, canteiros, arquibancadas e revestimentos foram incorporados. A Figura 2 ilustra de forma esquemática as etapas do processo da captura do edifício à modelagem final.

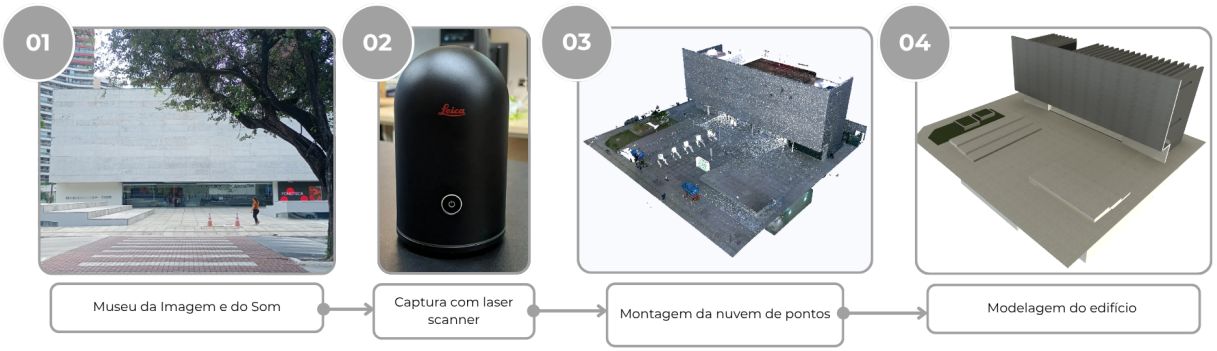

Figura 2. Esquema do processo de captura à modelagem final

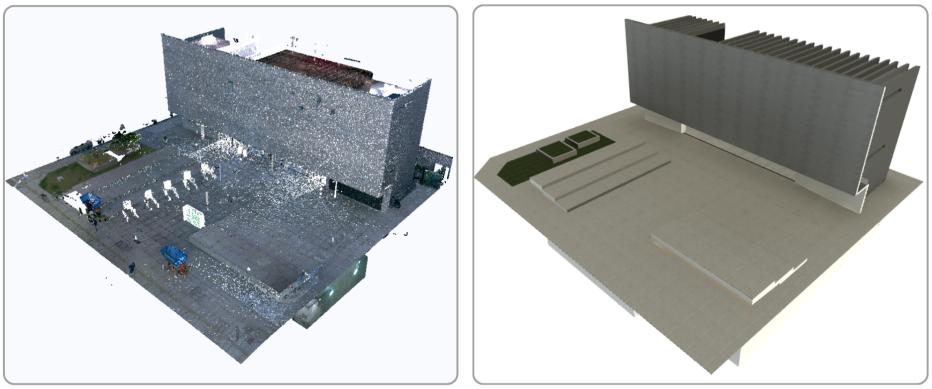
2.3 Enriquecimento semântico

A etapa de enriquecimento semântico visa agregar informações dos elementos construtivos ao modelo, por meio de considerações de acabamento, nível de ornamentação, particularidades construtivas, camadas, dentre outros, seguindo o proposto por Magalhães *et al.* (2024) no HBIMPath. O HBIMPath é um protocolo de documentação desenvolvido para otimizar e organizar o levantamento de informações acerca de materiais, acabamentos e ornamentação que muitas vezes são característicos de edifícios históricos e que nem sempre são contempladas em modelos tridimensionais convencionais. Seu objetivo, em diálogo com o aspecto semântico e informacional de Yang *et al.* (2020), é complementar os modelos geométricos com informações como: acabamento, questões de aspecto e superfície, espessura de camadas, quando disponível essa informação, além de demais comentários e acréscimos que se julgue necessário ser incluído ao modelo na forma de texto ou imagem. Essa metodologia permite acrescentar informações especialmente nos casos em que o nível de detalhe exigido da representação não seja tão rigoroso ou necessário, ou seja, um alto nível de ornamentação de um elemento pode ser somente descrito, enquanto seu modelo geométrico é simplificado.

As informações foram levantadas *in loco* e por meio de *tours* virtuais disponíveis na plataforma DocumentaCE (www.documenta.com.br) posteriormente organizadas em fichas de catalogação externas por elemento construtivo para depois serem integradas nos atributos de materiais e componentes no modelo geométrico, assim, o enriquecimento semântico se dá na transformação de dados documentais ou de texto alfanumérico em informação paramétrica no modelo (Ribeiro 2025). Por se tratar de uma construção recente e de arquitetura contemporânea, essa etapa é facilitada, afinal, os métodos construtivos são os usuais e existem registros de construção, além disso os materiais de revestimento são facilmente reconhecíveis.

2.4 Reconstrução digital e documentação

A reconstrução digital propõe a criação de imagens a partir do modelo, de forma a recriar seu contexto, gerando uma ambientação sensível ao entendimento e apropriação do espaço para leigos. Essa etapa se utiliza de qualidades fotográficas para a apresentação e comunicação de iluminação, materiais de revestimento, acabamentos e superfícies de uma forma geral. Ribeiro (2025) afirma que a renderização de imagens é o recurso mais direto e rápido para entender a aparência atual ou histórica de um edifício e Miao (2021) aponta para o uso de renderização como meio de divulgação do edifício pelo seu alto nível de detalhes e alcance de imagens para milhares de pessoas.



Visando criar imagens de renderização de modo otimizado, este trabalho propõe o uso de inteligência artificial para melhoramento e refinamento de imagem diretamente a partir do modelo tridimensional, por mais que ainda pouco usual, esse cenário é promissor e vem sendo cada vez mais estudado dentro da representação em arquitetura (Muslo e Koçyiğit 2024 e Nabizadeh Rafsanjani e Nabizadeh 2023). Foi usado o ChatGpt® e o Gemini® para renderizações gerais e a Inteligência Artificial do D5 Render® para criação de mobiliário a partir de imagens. Os prompts foram estruturados de modo a especificar o nível de qualidade da Imagem e estilo de renderização, adicionar contexto urbano semelhante ao entorno do edifício do MIS, presença humana para efeitos de escala e iluminação externa ou interna conforme fosse necessário.

Já a etapa de documentação visa a elaboração de pranchas técnicas da arquitetura do edifício contendo as informações e desenhos de: implantação, planta dos pisos, planta de cobertura, cortes, elevações, tabelas entre outros. A modelagem na metodologia BIM permite que os desenhos técnicos sejam construídos de forma concomitante ao modelo tridimensional, dessa forma, após a modelagem finalizada, as vistas são salvas e configuradas de acordo com os padrões gráficos desejados e exportadas para formatos de documento, como PDF.

3. Resultados e Discussões

3.1 Levantamento e modelagem digital

A aplicação da metodologia proposta permitiu a criação da modelagem digital a partir da estrutura existente do prédio anexo do Museu da Imagem e do Som Chico Albuquerque em Fortaleza, Ceará, com enfoque nos elementos captados pela nuvem de pontos. A Figura 3 ilustra o resultado dos dados do levantamento da edificação com o *laser scanner* terrestre formando a nuvem de pontos completa do edifício e o paralelo com a modelagem geral finalizada, ou seja, a inserção de pisos, paredes, escadas, revestimentos e demais componentes construtivos na interface BIM do Revit. Do ponto de vista geométrico o resultado mostrou-se fiel à nuvem de pontos, atendendo de forma precisa o nível de detalhes exigido e as dimensões do objeto arquitetônico.

Nuvem de pontos | Modelagem do edifício

Figura 3. Perspectiva da nuvem de pontos e do modelo HBIM

3.2 Enriquecimento semântico

O enriquecimento semântico que objetiva agregar informações alfanuméricas ao modelo BIM mostrou-se de fundamental importância para a integração de dados construtivos, e que muitas vezes não estão disponíveis na nuvem de pontos. Dessa forma, o uso de *tours* virtuais e visitas presenciais complementaram a aquisição de informações ao permitirem uma análise mais detalhada dos materiais e acabamentos empregados nos elementos construtivos. A Figura 4 mostra os resultados da aplicação da ficha de catalogação para a esquadria de acesso à biblioteca do museu, partindo do preenchimento das informações da planilha à inserção das informações no modelo. Ao final da análise da esquadria, foi possível adicionar por texto o tipo de abertura, posição da maçaneta, forma de fixação, materialidade, acabamentos e cor dos caixilhos. Ficou evidente a relação entre o HBIMPath e a linguagem arquitetônica da edificação. Diferentemente do estudo de Magalhães et al. (2024), desenvolvido no edifício eclético do Theatro José de Alencar, caracterizado pela maior variedade de materiais e acabamentos, o MIS apresenta uma arquitetura com menor diversidade material, o que simplificou o estudo dos componentes e de suas superfícies. Vale ressaltar que estudos futuros mais aprofundados esperam uma caracterização mais ampliada utilizando ensaios não destrutivos que determinem constituição de camadas e composição dos elementos construtivos com maior exatidão.

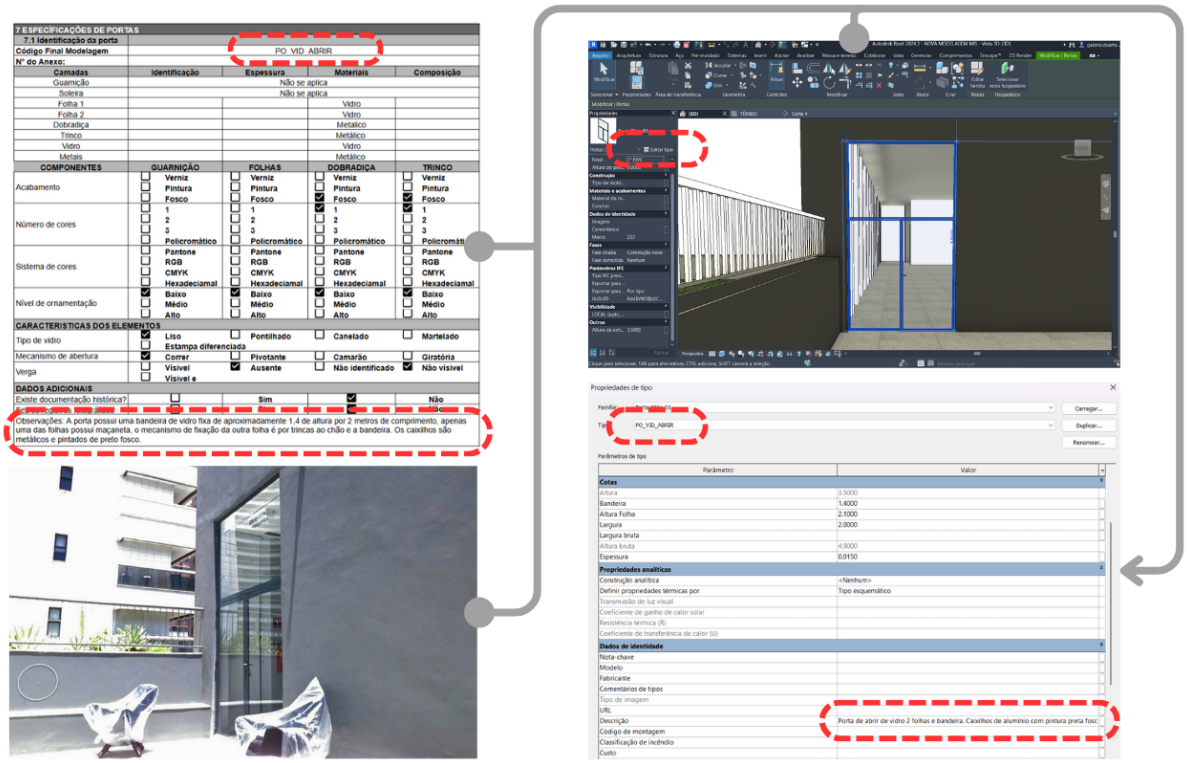


Figura 4. Fluxo de aquisição de dados para enriquecimento semântico

3.3 Reconstrução digital e documentação

Como produto final da etapa de reconstrução digital e documentação obteve-se os *renders* para fins de divulgação e ambientação e a elaboração das pranchas técnicas da arquitetura do museu contendo plantas, vistas, cortes, elevações e detalhes construtivos, permitindo uma leitura atualizada das condições do edifício. A Figura 5 reúne as imagens para reconstrução digital geradas com inteligência artificial (ChatGPT® e Gemini®) a partir do modelo tridimensional do museu. Para ambientação do espaço interno na Figura 5b utilizou-se a inteligência artificial do D5 Render® que permitiu a recriação do mobiliário 3D a partir de fotos. Já na Figura 5e, o mobiliário do espaço interno foi sugerido pelo ChatGPT® para simular uma possível exposição. Os resultados mostraram-se consistentes e fiéis as proporções originais da nuvem de pontos e do edifício, além de ter sido considerado um método fácil, rápido, replicável e muito eficiente.

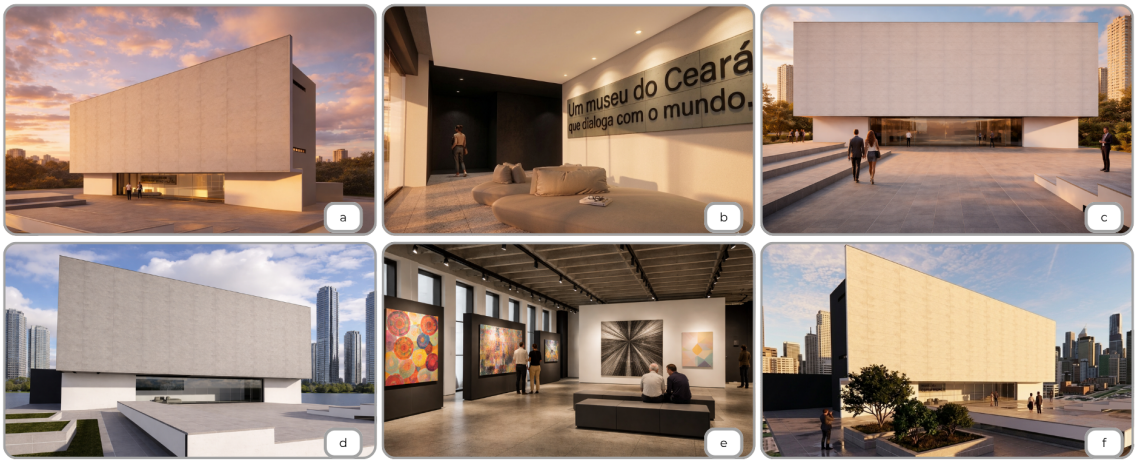

Figura 4. Renderizações externas e internas do museu

A Figura 5 sistematiza os prompts utilizados para geração das imagens e as modificações dos resultados obtidos, de modo a facilitar reproduções e documentar o processo.

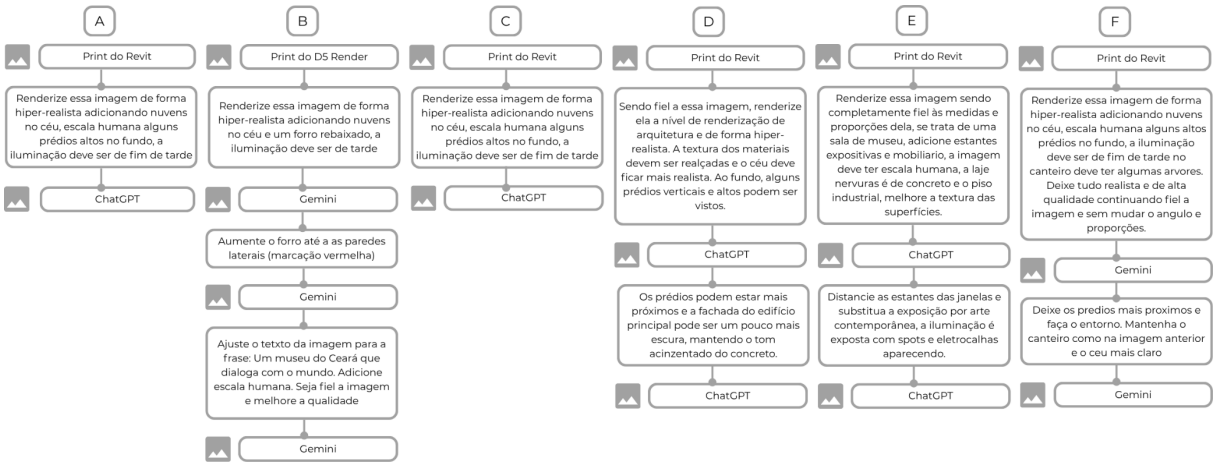

Figura 5. Sistematização dos prompts referentes a Figura 4.

Do ponto de vista da documentação técnica, a Figura 6 exemplifica os resultados ao apresentar a prancha de elevações do museu, contendo os desenhos da fachada norte, sul, leste e oeste. Devido o sistema BIM, a montagem de documentos técnicos mostrou-se otimizada, visto que uma vez tendo o modelo completo, a extração de vistas no *software* acontece de forma automática, além disso, possibilita o uso de diferentes gráficos de modo instantâneo, permitindo personalização e padronização dos esquemas de representação.

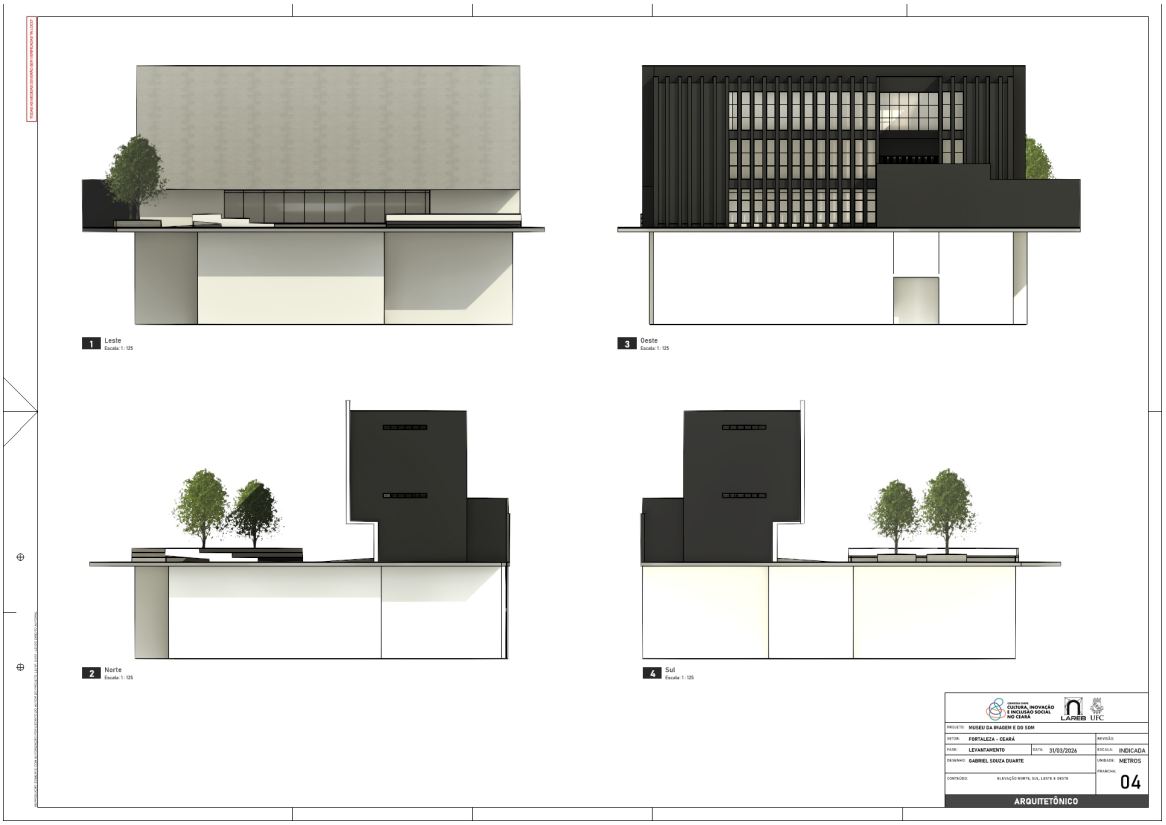

Figura 6. Prancha de elevações do museu

4. Conclusão

O trabalho realizado no edifício anexo do Museu da Imagem e do Som Chico Albuquerque em Fortaleza, Ceará, propôs e validou a aplicação dos princípios da metodologia HBIM a partir de levantamento com nuvem de pontos esperando discutir e produzir material acerca de métodos inovadores, precisos e eficientes de documentação de edifícios históricos de uso cultural e turístico para o desenvolvimento da cidade. A utilização do software Revit como ferramenta capaz de integrar os dados levantados por nuvem de pontos com a construção do modelo geométrico pela adição dos elementos construtivos, mostrou-se de alta eficiência chegando a níveis de representação de alta qualidade, além da otimização na criação de material técnico de arquitetura como plantas, cortes e vistas. O levantamento de dados que atribuiu significado ao modelo geométrico mostrou-se fundamental para a inserção de informações que auxiliem na gestão e manutenção do ativo, como se propõe o HBIM. Nesse momento, observou-se que o preenchimento das planilhas de catalogação pela visualização dos elementos no *tour virtual* tornou o processo fácil e intuitivo, além disso, a transposição das informações no software de modelagem permitiu o agrupamento de dados textuais descritivos sobre o observado nos elementos do edifício. As renderizações realizadas com inteligência artificial (ChatGPT®, D5IA® e Gemini®) apontaram para um método novo e promissor de geração de imagens de alta qualidade, com o tempo otimizado quando comparado aos processos tradicionais de renderização e que mostraram resultados muito satisfatórios.

Vale ressaltar as dificuldades e limites da pesquisa, a começar pela etapa de levantamento que requer dispositivos de alto processamento para operação dos dados, além de limites no âmbito de caracterização e composição de sistemas, que exigem estudos mais aprofundados. Quanto a expectativas para trabalhos futuros, espera-se superar os limites deste e avançar com o modelo à nível de modelagem de sistemas complementares, protocolos de gestão, detalhamentos de componentes construtivos, simulações térmicas, monitoramento de estruturas entre outros.

Por fim, a modelagem digital desenvolvida neste estudo validou o processo de reconstrução virtual de edifícios de uso cultural e turístico para fins de documentação, usando tecnologia de ponta e métodos de alta precisão geométrica. A metodologia abre caminho para ferramentas futuras de gestão, integrando e agilizando processos num ambiente virtual colaborativo. O estudo de caso no Museu da Imagem e do Som confirma o processo e demonstra a replicabilidade para outros contextos, abrindo caminho para novas experiências de implementação.

Social Tourism and Modern Heritage: Digital Documentation and Conservation of the SESC Garanhuns Holiday Camp (1956), Brazil

Ricardo Alexandre PAIVA[1], Francisco Canuto LINS NETO[2]

[1] Federal University of Ceará, Fortaleza-CE, Brazil, ricardopai@gmail.com
[2] Federal University of Ceará, Fortaleza-CE, Brazil, canutolins@arquitetura.ufc.br

Abstract: Social tourism in Brazil gained strong momentum through state action, particularly with the creation of the Social Services in the 1940s—employer-funded institutions aimed at promoting vocational training and the health, culture, and leisure of workers. In this context, infrastructures aligned with the principles of modernism were conceived, among which holiday camps stand out as important spatial manifestations of social tourism. The initiatives of the Social Service of Commerce (SESC) in providing leisure and tourism facilities for the working class are exemplary, such as the SESC Garanhuns Holiday Camp in Pernambuco, designed by architect José Armando Farias (1927–1974) and inaugurated in 1956. However, socio-spatial transformations over time have compromised the complex's material and immaterial integrity, as it has undergone successive alterations and expansions that have affected its original architectural characteristics. Thus, this paper investigates how the digital modeling of the original SESC Garanhuns Holiday Camp building, through HBIM (Heritage Building Information Modeling) processes, can support actions for documentation, conservation, and management of modern heritage. The methodology is grounded in the theoretical and practical assumptions of digital redrawing in historical research, articulating the use of HBIM with the concept of the Digital Twin, understood as strategic platforms for the documentation, conservation, and analysis of the built heritage. As a main result, the study highlights a parametric HBIM model conceived as a virtual matrix capable of integrating analog and digital data and information, as well as multiple representations and analyses. Finally, this model constitutes a relevant instrument for the documentation, management, and conservation—albeit in a digital environment—of the building, contributing to the preservation of the memory of social tourism and modern heritage in Brazil.

Keywords: Heritage Building Information Modeling, BIM model, HBIM, Heritage, Digital Twin

1. Introduction

The establishment of Social Services throughout the 1940s stimulated social tourism activities across the country, primarily by creating institutions dedicated to improving health, culture, and recreation for the working class. Against this backdrop, various structures were designed in accordance with the principles of the modern movement, notably the summer camps, which exemplify an architectural program crucial to the consolidation of social tourism in Brazil. The Social Service of Commerce (SESC), through its initiatives aimed at promoting leisure and tourism, was one of the key drivers behind the development of facilities that contributed to the spread of modernism in the country. Among these facilities, the SESC Garanhuns Holiday Camp stands out, designed by Ceará-born architect José Armando Farias (1927–1974) and inaugurated in 1956.

However, successive socio-spatial changes have compromised the physical and intangible integrity of the building, given the gradual alterations and expansions carried out over time, which ultimately led to the loss of the original design's distinctive character. This scenario reflects a lack of awareness regarding the heritage, historical, and cultural value of works with modernist attributes, both on the part of society and of the agencies responsible for safeguarding and preserving them (PAIVA; DIÓGENES, 2018). The SESC

Garanhuns holiday camp is one of countless examples that, due to a lack of awareness of its intrinsic values, result in what is known as “architectural death,” understood as the total disappearance when the building is completely destroyed, or partial, when the building loses the original characteristics that gave it its architectural identity (AMORIM, 2007).

Within this scenario, heritage documentation, conservation, and management activities are often rendered impossible or compromised due to the lack of a systematic architectural inventory. The body of information available regarding a site of cultural and heritage interest tends to be lost over time and in the face of constant physical alterations, reflecting the inability to manage and integrate data related to architectural heritage. According to Simeone et al. (2014), a large volume of information is lost in isolated files, such as 2D CAD technical drawings and photographic surveys, generating a set of data that is not integrated and limited to various unconnected “islands of knowledge.”

An effective strategy for dealing with this issue is the application of BIM technology combined with the concept of a Digital Twin (a precise virtual replica of a physical object, system, or environment) to develop a parametric three-dimensional digital model capable of capturing, organizing, and systematizing information related to cultural heritage in an integrated manner. This approach enables the implementation of management and conservation actions—even in a digital environment—for a heritage site. Thus, the use of BIM for heritage recording, conservation, and management—referred to as Heritage Building Information Modeling (HBIM)—enables the creation of a reliable and unified inventory of a subject of study, allowing different users to consult, update, and manage information related to the architectural asset (SIMEONE et al., 2014).

Accordingly, this study investigates how the digital modeling of the original SESC Garanhuns holiday camp building, through the application of HBIM, can support heritage documentation, conservation, and management efforts. The theoretical framework is based on the principles of HBIM, linked to the concept of the Digital Twin, for the documentation and redrawing of the building. The practical assumptions, on the other hand, refer to the process of parametric digital modeling, based on a documentary survey comprising original architectural drawings, 2D CAD drawings, and historical photographs, which enabled the creation of an integrated digital inventory and a three-dimensional model, contributing to the memory of social tourism and modern heritage in Brazil.

2. The SESC Garanhuns Holiday Camp

Institutions such as the Social Service of Commerce (SESC) were pioneers in promoting social tourism in Brazil around the 1940s, an activity that was new at the time, given that taking annual vacations was a rare practice among retail workers (SESC DEP. PERNAMBUCO, 1965). The inauguration of the SESC Bertioga Vacation Center in 1948, considered the first facility of its kind in the country, marked the institution’s initial effort to promote the well-being of its beneficiaries through activities focused on education, health, leisure, culture, and assistance (CHEIBUB, 2011).

Similarly, the SESC Regional Department in Pernambuco was working to consolidate plans to establish a holiday camp in the municipality of Garanhuns, located in the Agreste region of Pernambuco, initially through lease and lodging agreements with local hotels. This strategy proved advantageous for the institution’s activities, as it enabled the organization of a vacation program focused on collective social service. Thus, the initiative was not limited to traditional recreational activities but also served as a means to promote the physical and mental well-being of the beneficiaries, while fostering a stronger sense of community among the participants (SESC DEP. PERNAMBUCO, 1965).

Throughout the 1950s, the holiday camp established itself as one of SESC’s most successful and widely promoted activities in Pernambuco. However, the need arose to install the service in its own building. Given the years of experience gained through lease and lodging agreements, the SESC Regional Department in Pernambuco launched, in 1952, a design competition for the headquarters of the SESC Garanhuns Holiday

Camp (Figure 1), with the winner being the then-recently graduated architect from Ceará, José Armando Farias (1927–1974), who had obtained his degree in Recife.

Figure 1 – SESC Garanhuns Holiday Camp
Source: José Armando Farias Memorial

Inaugurated on May 6, 1956, the SESC Garanhuns Holiday Camp stands as a striking example of Modernist architecture in northeastern Brazil. The building is situated on a slightly undulating site, seeking to establish a direct relationship between the built space and the outdoors, with a focus on the natural landscape. Its primary geometric composition consists of a gentle curve that follows the topography of the lot and opens to the exterior through a system of pilotis, creating a continuous veranda. The most striking visual element of the structure is a large panel of *"cobogós"* in a trapezoidal shape, which follows the curvature of the building. The Holiday Camp had an initial capacity to accommodate 82 people distributed across 12 apartments. It featured a library, game room, meeting room, auditorium for theatrical performances and cinema, as well as a large garden of tropical plants with a pond (SESC DEP. PERNAMBUCO, 1965).

Over the course of its nearly 70 years, the complex has undergone numerous renovations and expansions that have almost completely altered the original design, with the construction of new apartment buildings (Figure 2). According to Amorim (2007), there are several types of architectural deaths, among them death by "external architectural parasites," which occurs with the incorporation of elements extrinsic to the original compositional concept of the architectural design, introduced due to new demands of human activities. Given this, even though the building retains its original use and activities, its compositional logic has been completely altered, compromising its material and immaterial integrity and rendering it almost unrecognizable.

Figure 2 – Current Status of the SESC Garanhuns Holiday Camp
Source: www.sescpe.org.br

In addition, active public participation is a key factor in the preservation of heritage assets, given that when the public lacks a connection to the building or its surroundings—a reflection of a lack of identification—the preservation process becomes more difficult and complex, especially when it comes to architectural works of the Modern Movement (DOĞAN, 2020). From this perspective, the SESC Garanhuns Holiday Camp stands as a clear example of the invisibility of Modern Movement works, reflecting a lack of recognition by society and the agencies responsible for safeguarding and preserving their heritage and cultural value.

The original building underwent successive renovations and expansions (Figure 3) driven by SESC's need to expand the facilities of the former Holiday Camp, due to partnerships established by the Pernambuco department with other regional units in neighboring states (SESC DEP. PERNAMBUCO, 1965). Currently, the complex has 101 apartments, with eight times as many beds as the original building. In addition, the former garden has given way to new annexes, which house a variety of recreational activities, such as swimming pools, a restaurant, a convention center, and a gym, among other facilities.

3. Methodology

3.1 Theoretical Assumptions: Redrawing and Documentation in a BIM Environment

The development of documentation for an architectural object is a complex process that draws upon various fields of knowledge within the disciplines of architecture and urban planning to compile, clarify, and supplement the historical, formal, and structural characteristics of a building (Waisman, 2013). In this context, redrawing establishes itself as a fundamental methodology in the documentation of historical and cultural heritage, as it enables an in-depth analysis of the building and contributes to the systematization and transmission of knowledge regarding its materiality and significance over time.

The use of redrawing as a method of historical research and analysis is not a recent practice. It is a technique that gained prominence during the Renaissance, when artists and architects used representational media —such as drawings and other iconographic records—to document the legacy of classical architecture, conducting studies, research, and the construction and reconstruction of works that no longer existed or were disappearing. This approach ensures a deeper connection with the architectural work, allowing the creation of documentation to go beyond a mere collection of data about a project, becoming a means of transmitting knowledge (VÁZQUEZ RAMOS, 2016).

The redrawing of documentation has become one of the most important tools for preserving the memory of a heritage site, whether through traditional methods or new resources. From this perspective, even if a building disappears entirely or partially, its visual record can be restored, albeit with limitations, access to the work, perpetuating its legacy and the way in which human beings connect to it (OLIVEIRA, 2008).

In addition, digital technologies open up new possibilities for documentation, particularly through the creation of parametric 3D models capable of emulating specific aspects of the architectural object. Among these technologies, BIM (Building Information Modeling) has been driving significant changes in representation methods in Architecture and Urban Planning, marking a gradual transition from traditional analog methods to an integrated data environment. According to López et al. (2018), BIM has been expanding its scope of application to the field of cultural heritage, enabling its representation in a virtual environment to contribute to documentation and management activities.

HBIM (Heritage Building Information Modeling)—where "Historical" has recently been replaced by "Heritage"—has emerged as a branch of BIM that is not limited to the design process for new buildings, but extends to initiatives involving the digital redesign and documentation of existing structures. In HBIM, it is possible to create interactive parametric elements that represent the historic structure, developed based on documentary sources and other historical records (MURPHY; MCGOVERN; PAVIA, 2013).

Thus, the concept of the Digital Twin reinforces this approach by enabling the creation of a realistic model of a physical object through a dynamic virtual representation, capable of continuously aggregating updated data and reflecting its characteristics, behaviors, and transformations throughout its life cycle (MADNI; MADNI; LUCERO, 2019). Concerning architectural objects, the digital twin of a heritage site allows for the integration of construction and historical information associated with this digital model, fostering a deeper understanding of the physical space, encompassing aspects such as materiality, construction techniques, and progressive modifications, such as expansions and renovations, in addition to guiding potential decision-making regarding heritage management (MESEGUER; VALLDECABRES, 2023).

3.2 Practical Assumptions: Parametric 3D Modeling

To create the 3D model, it was first necessary to conduct iconographic research, given that, in order to build a parametric model faithful to the original building, as much information as possible must be gathered (original technical drawings (Figure 4), photographic records (Figure 5), texts, etc.). Only through this survey is it possible to adequately understand the building under study. In this work, sources and documents provided by the family of architect José Armando Farias were used; the family preserves a large part of his collection, which contributed to the creation of a memorial housed in the architect's former office. The "José Armando Farias Memorial" brings together personal objects (furniture, drawing boards, drawing materials, books); photographs of works and travels; paintings and engravings created by him; as well as some originals and heliographic copies of studies and working drawings of projects, as well as perspectives (PAIVA; DIÓGENES, 2014).

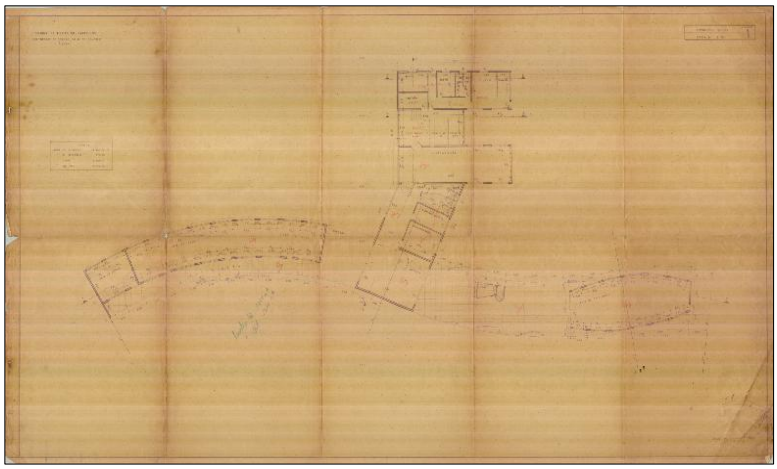

Figure 4 – Original Technical Floor Plan Drawing
Source: José Armando Farias Memorial

Figure 5 – Photo Gallery of the recently inaugurated Holiday Camp
Source: José Armando Farias Memorial

The modeling process for the SESC Garanhuns Holiday Camp was carried out using Graphisoft Archicad 28 BIM software. Following an initial analysis, the modeling began by importing the original technical drawings—which had already been digitized in .pdf format—into the software and organizing them into different worksheets that served as a guide for creating the model using the vectorization tool. In total, there were five digitized drawings, containing floor plans, sections, elevations, and construction details. During data collection, 2D CAD drawings of the most recent renovation of the SESC Garanhuns Tourism and Leisure Center (the current name of the former holiday camp) were made available, which served to fill in some information gaps, such as the absence of certain metric data.

In Archicad, the architectural model was created using parametric elements already available in the platform (walls, slabs, beams, columns, window frames, etc.), adapted to the specific requirements of the original project, which contributed to a more efficient development of the model. It was necessary to individually model some more complex elements, such as the *"cobogó"* curtain on the upper floor (Figure 6). During this process, it was found that using the original technical drawings would not be sufficient to vectorize the project in a way that would ensure an accurate reconstruction, given the distortions the drawings had undergone during digitization. To resolve this issue, .dwg files containing the 2D CAD drawings of the building's current configuration were used. These files were transferred from Autodesk AutoCAD to Archicad.

Figure 6 – 2D CAD technical drawings of the building's current configuration
Source: PROJEBRÁS LTDA

Although the original technical documents for the project were readily available in excellent condition—thanks to the architect's family's efforts to preserve his work—no information regarding the site's topography was found. Topographic data proved essential to the modeling process, since the way the building is situated on the lot reveals the architect's concern with creating a volumetry that respects the existing surroundings. To generate a topographic approximation, the Quantum Geographic Information System (QGIS) software was used to obtain the contour lines with their elevations in .dxf file format. Following this procedure, it was possible to transfer this information to Archicad and model the lot according to its topography, using the mesh element associated with the generated file.

Furthermore, by comparing the 2D CAD technical drawings, photographs of the project as it was newly completed in the 1950s and 1960s, and the original drawings, it was possible to determine that certain changes were made during construction. The original design called for a flat slab waterproofed with an asphalt membrane, which was later replaced by a low-slope tile roof concealed by a small parapet, in addition to some windows with different numbers of panes.

4. Results and Discussion

The main product is the three-dimensional parametric model, provided in .pln format, which compiles the data and information from the historical documentation inventoried for the preparation of this study. In conjunction with this product, digital documentation was developed, consisting of redrawn floor plans (Figure 7), sections, and elevations (Figure 8) of the Holiday Camp reconstruction. Furthermore, using the features provided by Archicad itself, it was possible to create rendered perspectives (Figure 9). This set of traditional information, combined with the graphic representations produced, contributes to the architectural analysis of the building, enabling a better understanding of aspects such as zoning, the building's layout on the site, floor distribution, enclosures (window frames and "*cobogó*" panels), and, above all, spatiality, serving as a foundation for future initiatives in education, research, and heritage intervention.

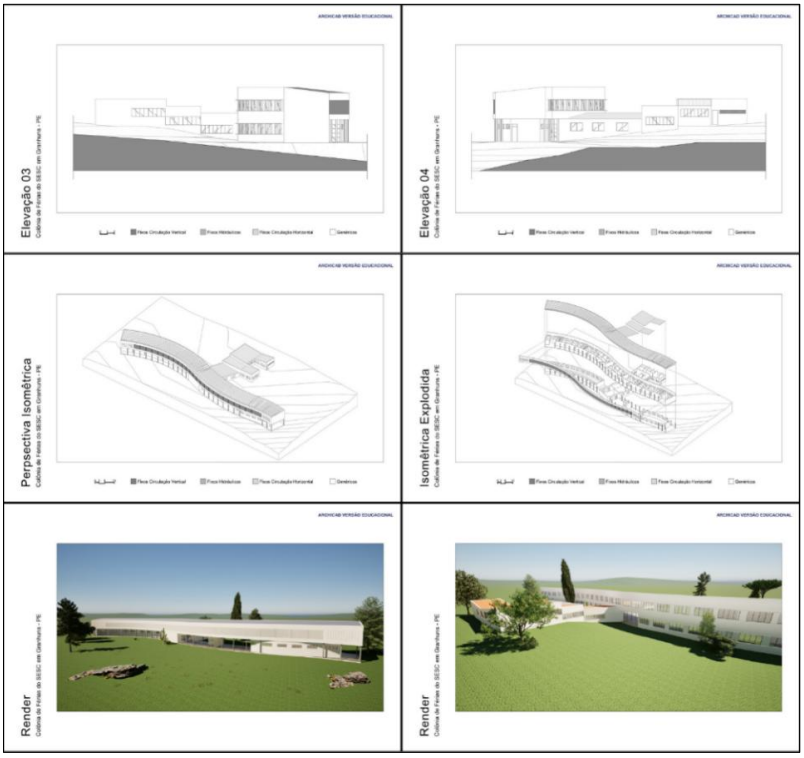

Figure 9 – Digital documentation
Source: Produced by the authors

This process, aimed at creating a digital twin using BIM as a tool, reaffirms the versatility and ability of this methodology to integrate data from different sources, such as photographic records, digitized documents, and files based on various programming languages. Such integration helps streamline operations, making them more agile and reliable. In this specific context, the application of HBIM strengthens the use of new technologies aimed at preserving the legacy of buildings that have undergone processes of historical erasure, as well as at enhancing their potential as cultural heritage.

5. Conclusions

This study sought to demonstrate how the digital reconstruction of the SESC Garanhuns Holiday Camp (1956), through the application of BIM combined with the Digital Twin concept, can support architectural documentation, heritage conservation, and information management. The results confirm that the integration of original drawings, historical photographs, CAD files, and topographic data into a single parametric three-dimensional model made it possible to reconstruct the spatial, formal, and structural logic of José Armando Farias's modernist design, despite the profound alterations that compromised its integrity over time.

The research demonstrates that HBIM goes beyond the realm of mere graphic representation, serving as an effective methodological tool for organizing, systematizing, and preserving scattered documentary information that would otherwise remain fragmented across isolated archives. In this sense, the resulting digital model functions simultaneously as a heritage inventory and a digital obituary, capable of safeguarding the architectural memory of a modern work subjected to processes of partial "architectural death" resulting from successive expansions and parasitic additions. Beyond its documentary function, the model also offers a consistent foundation for preservation strategies, educational activities, critical historical interpretation, and potential restoration or redevelopment efforts.

From a broader perspective, the study contributes to the debate on the preservation of modern heritage linked to the history of social tourism in Brazil, highlighting how digital technologies can revitalize the cultural significance of buildings that have been physically altered or rendered socially invisible, bridging the fields of architectural and urban theory and history with technology. The case of SESC Garanhuns thus reinforces the relevance of the HBIM as a link between memory, management, and conservation, especially in contexts where the original project survives only partially. As a corollary, possibilities are identified for expanding this digital twin to interactive management platforms, allowing for continuous data updates, maintenance protocols, and greater public dissemination of the legacy of Brazilian modern architecture.

Acknowledgments

The authors would like to thank CNPq (the National Council for Scientific and Technological Development) for the financial support provided for the research project "Social Tourism and Modern Architecture in Brazil," as well as for the PIBIC fellowship also awarded by CNPq as part of that project.

Abstract: The inspection and diagnosis of pathological manifestations in historic buildings, fundamental for planning conservation and maintenance actions and are traditionally based on manual visual assessments. Although widely adopted, this approach presents limitations related to evaluating subjectivity, inconsistency of records, and difficulties in systematizing the collected information. In this context, this study proposes the application of Computer Vision (CV) and Machine Learning (ML) techniques for the automated detection of pathological manifestations in structural and architectural elements of the historic asset José de Alencar Teatre (TJA), located in Fortaleza, Brazil. The research was based on the construction of an image dataset obtained during inspection campaigns carried out at the TJA. The images were organized, pre-processed, and manually labeled according to damage classes associated with structural and architectural components, including cracks, corrosion, moisture stains, coating detachment, and surface degradation. Based on this dataset, an image classification model was developed using supervised learning techniques and implemented on the Microsoft Custom Vision platform, which applies Convolutional Neural Network (CNN) architectures for visual pattern recognition. The methodological procedure comprised image acquisition and preprocessing, definition of damage classes, iterative model training, validation, and performance evaluation using classification metrics. The results indicated satisfactory model performance in identifying the analyzed damage classes, with accuracy values above 85%. In the application stage, the probabilistic responses generated by the model showed correspondence with the visible damage patterns observed in the submitted images, indicating consistency between automated classification and field inspection records. The proposed method showed technical applicability as a support tool for damage mapping, organization of diagnostic information, and incorporation of image-based analysis into digital documentation environments for historic building maintenance and conservation.

Keywords: Computer vision; Machine learning; Pathological manifestations; Built heritage; Building inspection.

1. Introduction

The conservation of historic buildings depends directly on the proper identification of damage manifestations affecting their architectural and structural elements over time. These assets are subject to the combined effects of natural aging, environmental exposure, moisture, inadequate interventions, and lack of maintenance, factors that contribute to the occurrence of cracks, detachments, superficial losses, oxidation processes, and other forms of material deterioration [1,2]. For this reason, the inspection stage plays a central role in diagnosis and intervention planning, especially in buildings whose historical and cultural value requires procedures compatible with the preservation of their physical and documentary integrity [1,3].

Although widely employed, conventional visual inspection still presents limitations related to evaluator subjectivity, variability between records, the high time required, and the difficulty of systematizing information collected in the field [4,5]. On extensive surfaces with complex geometries, ornamentation, and

the coexistence of multiple pathological manifestations, exclusive reliance on manual observation tends to hinder the comparison between inspection campaigns and to compromise the standardization of diagnoses [4,6]. This issue becomes even more critical in historic buildings, where the assessment of pathological conditions must be technically consistent and compatible with documentation and long-term monitoring processes [2,3].

In this context, computer vision has been established as a promising alternative for the systematic processing of inspection images, allowing photographic records to be treated not only as visual documentation, but also as data suitable for segmentation, pattern recognition, classification, and automated tracking [3,4]. In the field of damage detection, methods based on machine learning and deep learning have been applied to the identification of cracks, surface defects, localized degradation, and the classification of failure types in several materials and components [7–10]. These advances demonstrate that the automation of visual interpretation can reduce dependence on manual assessment and increase objectivity in anomaly evaluation [7,8].

In the context of historic heritage, the application of these techniques is of particular interest, as it allows photographic surveys to be used as the basis for the construction of labeled image datasets and for the training of models aimed at recognizing pathological manifestations in façades and building elements. Recent studies have shown that systems based on artificial intelligence can support the production of deterioration maps from façade images and assist in monitoring the evolution of cracks and other damage in heritage buildings [2,11]. In addition, the quality and diversity of training images, the definition of classes, and the consistency of labeling directly influence model performance, especially when different types of damage present similar morphological characteristics [12].

Similar methods have been applied to the automated identification of damage in underwater concrete [8], steel cables [7], internal equipment profiles [9], drilling components [10], and aquaculture nets [16], as well as to damage monitoring in civil infrastructure [13–15]. Although developed in different contexts, these studies demonstrate the applicability of classification and detection algorithms to reduce inconsistencies in manual inspection and support image-based assessments [8,13].

At the same time, computer vision has been increasingly incorporated into broader building inspection and management workflows. Approaches based on three-dimensional reconstruction, association between 2D images and digital models, augmented reality, and BIM integration have been used to locate defects, record their position, and structure inspection data in digital environments [4–6]. This type of integration is particularly relevant in technical documentation strategies, as it enables the results of automated visual analysis to be related to the spatial representation of the building and to information storage and retrieval systems [5,6].

In the field of civil construction, there is also evidence of the practical application of supervised classification platforms to building inspection tasks. Staffa et al. [17] demonstrated the feasibility of using Microsoft Custom Vision for the automated identification of nonconformities in building roofs, based on an image dataset collected with an unmanned aerial vehicle. This type of application is particularly relevant to the present research, as it demonstrates the possibility of employing an accessible supervised learning platform for the classification of damage recorded during technical inspections [17].

Despite these advances, a gap still remains between the development of computational models and their systematic application to the inspection of historic buildings, especially in assets with high architectural complexity, material diversity, and the need for continuous documentation [1,2]. A significant portion of existing studies is focused on civil infrastructure, industrial components, or specific surfaces, whereas historic buildings require models capable of dealing with diverse pathological manifestations, overlapping damage, ornamental interference, and variations resulting from material aging [1,2,11].

In this context, the present study proposes the application of computer vision and machine learning (ML) techniques for the automated detection of pathological manifestations in structural and architectural elements of the Teatro José de Alencar, located in Fortaleza, Ceará. The research is based on the construction of an image dataset obtained during inspections of the building, followed by the organization, preprocessing, labeling, and supervised training of the algorithm on the Microsoft Custom Vision platform. The study investigates the feasibility of automated damage classification as a support tool for technical inspection activities, damage mapping, and the systematization of diagnostic records in historic buildings.

2. Methods and materials

The methodological procedure adopted in this research was structured into five sequential stages, comprising the selection of the heritage building, data acquisition through field inspections and photographic records, the development of the image dataset for training the Machine Learning (ML) model, the supervised training and validation of the computer vision model, and the application of the validated model for automated damage detection. This workflow was defined to support the organization, classification, and interpretation of the pathological manifestations identified in the architectural and structural elements of the Teatro José de Alencar, as summarized in Figure 1.

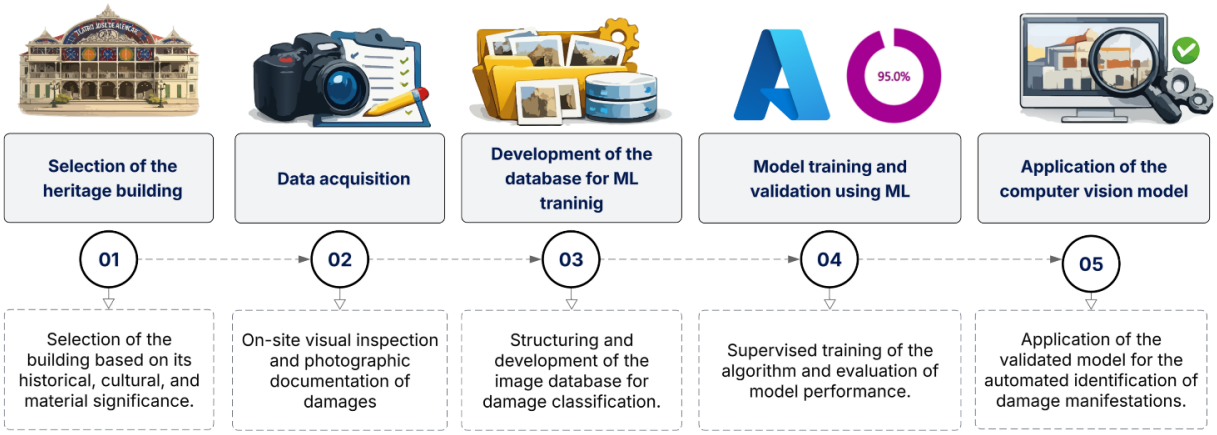

Figure 1 – Workflow of the methodological procedure adopted in the research.

2.1. Selection of the heritage building

The Teatro José de Alencar (TJA), located in Fortaleza, Ceará, was defined as the object of study of this research due to its historical, cultural, and architectural relevance, as well as its material and constructive complexity. It is a listed building, inaugurated in 1910, whose configuration combines masonry elements, ornamental cast-iron metallic components, and characteristics associated with the neoclassical and art nouveau styles, giving the asset a high degree of uniqueness for studies focused on inspection, documentation, and conservation.

The selection of the TJA is also justified by the existence of an HBIM model previously developed by Vieira et al. (2023), based on digital documentation strategies using scan-to-BIM, with terrestrial laser scanning and aerial photogrammetry [18]. This model already constitutes a consolidated geometric and informational basis for the asset, which favors the expansion of analyses related to maintenance and diagnosis. In this context, the application of computer vision to the TJA is inserted as a direct complement to the workflow under development for the building, contributing to the organization of the image dataset, the automated identification of damage, and the improvement of the analysis tools applied to its architectural and structural elements.

Figure 2 – 3D digital model of the Teatro José de Alencar developed by Vieira et al. (2023).

2.2. Data acquisition

The data acquisition stage was developed from visual inspections carried out at the Teatro José de Alencar, with a focus on the systematic photographic documentation of the conditions observed in the architectural and structural elements of the building. Image capture was carried out strategically, prioritizing areas with a greater concentration of visible damage, different exposure conditions, and a variety of constructive elements, in order to provide a broader visual reading of the condition of the building.

As a result, an archive of approximately 1,200 digital photographs was established, obtained in the field and organized as the basis for the damage mapping of the building. These records were used to identify, locate, and document the damage observed during the inspection, supporting the enrichment of the 3D digital model of the Teatro José de Alencar under development. For this purpose, the mapping information was structured through parameters inserted in Autodesk Revit, using the Project Parameters feature in the Manage tab, allowing the creation of specific fields for associating the data with the analyzed elements. From this set, a specific selection of images corresponding to the masonry elements was carried out, defined as the focus of interest for subsequent submission to the computer vision analysis stages. After the analysis, the corresponding images and results were intended to be inserted into and mapped within the model according to their respective locations, allowing the photographic record, damage identification, and its spatial position to be associated within the digital environment.

2.3. Development of the database for Machine Learning

The development of the database for model training was based on the collection of images with visual patterns representative of recurring damage on masonry surfaces, following the stages of collection, screening, and labeling presented in Figure 3. To compose this dataset, both images obtained during the surveys carried out on the asset and complementary images available on the web were used, selected in order to enrich the visual variability of the classes and increase the model's generalization capacity. This strategy made it possible to gather different lighting conditions, textures, scales, framings, and damage intensities, contributing to the formation of a more consistent basis for supervised training.

Figure 3 – Workflow for image database preparation.

After the initial constitution of the dataset, a database of approximately 500 images was structured for training the algorithm to recognize seven damage classes: mold, efflorescence, detachment, degradation, cracks, dampness, and spalling. From this set, a data cleaning stage was carried out, aimed at screening and refining the images by excluding redundant records, images with low sharpness, inadequate framing, or low visual representativeness. Subsequently, the data labeling stage was performed, in which the selected images were organized and labeled according to their respective classes, allowing each visual pattern to be associated with its corresponding diagnostic category.

This process was necessary to provide the model with a base set of previously classified visual examples, from which the algorithm could learn to recognize regularities, differences, and characteristic patterns of each type of damage. In this way, the database was structured not only as an image repository, but also as a supervised training base prepared to support the development of automated damage classification in digital images.

2.4. Model training and validation using AI

The training of the computer vision model was carried out on the Microsoft Custom Vision (Azure AI) platform, adopted as a supervised learning environment for the automatic classification of damage in digital images. The methodological workflow used at this stage comprised the phases of platform configuration, image submission, model training, metric evaluation, performance validation, and final application of the algorithm, as presented in Figure 4. This structure was defined to allow the learning process to occur sequentially, from the initial organization of the project to the obtaining of a model capable of classifying the submitted images.

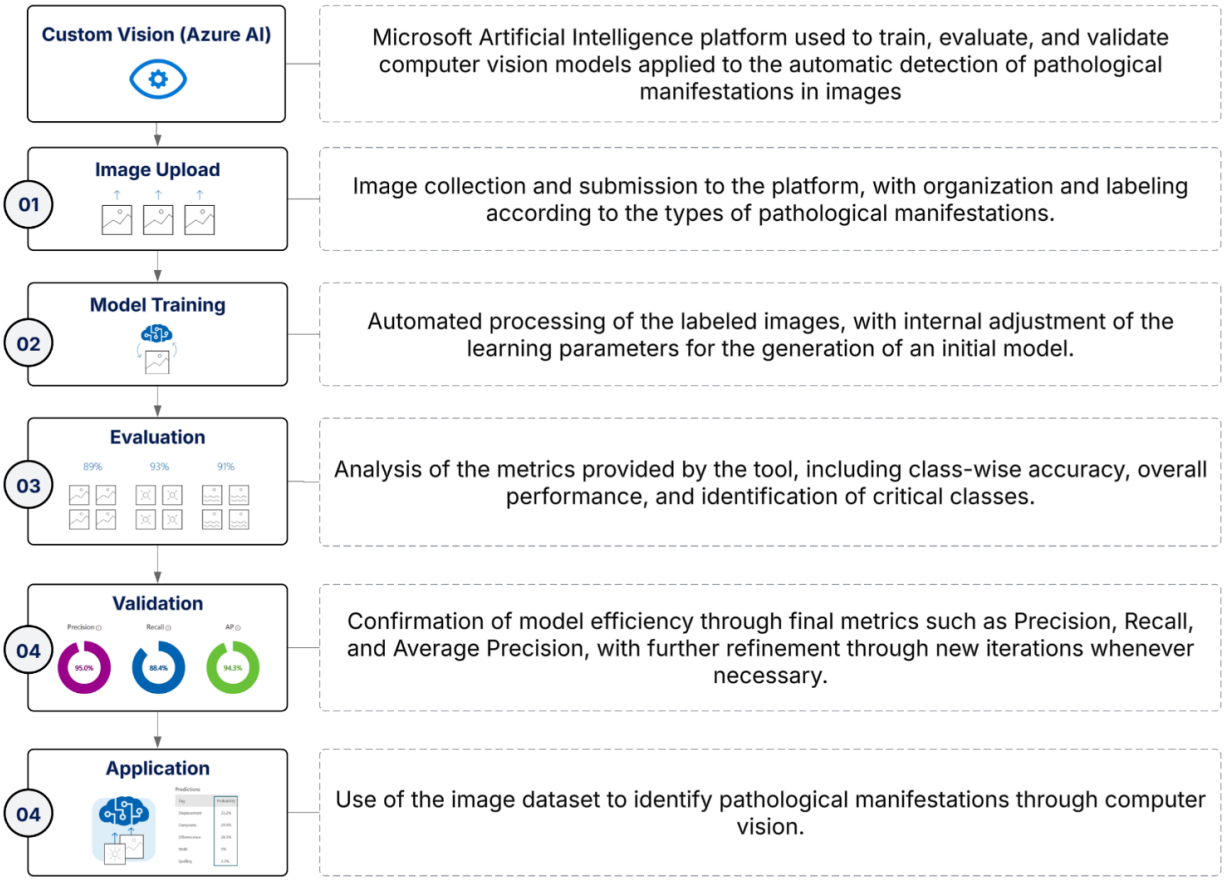

Figure 4 – Workflow of model training, evaluation, and validation.

Initially, a specific project was created on the platform, configured for the classification of masonry damage images. At this stage, the project name, the description of the analysis scope, and the classification domain to be used in the Custom Vision environment were defined, in addition to the type of classification adopted for the training. Next, the previously structured image database was submitted, with the samples organized according to their respective pathological classes. After the image upload, supervised training of the model was initiated. At this stage, the algorithm began to process the visual patterns present in each labeled class, seeking to recognize regularities, morphological differences, and recurring characteristics among the analyzed damage types. This processing occurred automatically on the platform itself, based on the provided examples, allowing the internal adjustment of the learning parameters and the generation of an initial classification model.

In the following stage, the metrics produced by the system were analyzed to verify the performance of the trained model. This evaluation considered the indicators presented by the platform for each class and for the model as a whole, making it possible to observe the behavior of the algorithm in relation to the learned patterns and to identify possible critical classes, with greater visual overlap or lower distinction between them. Based on this assessment, new refinement iterations were carried out whenever necessary, with the aim of improving training consistency and reducing ambiguities in classification. Figure 5 illustrates the project configuration and the visual organization of the training images according to their respective damage classes.

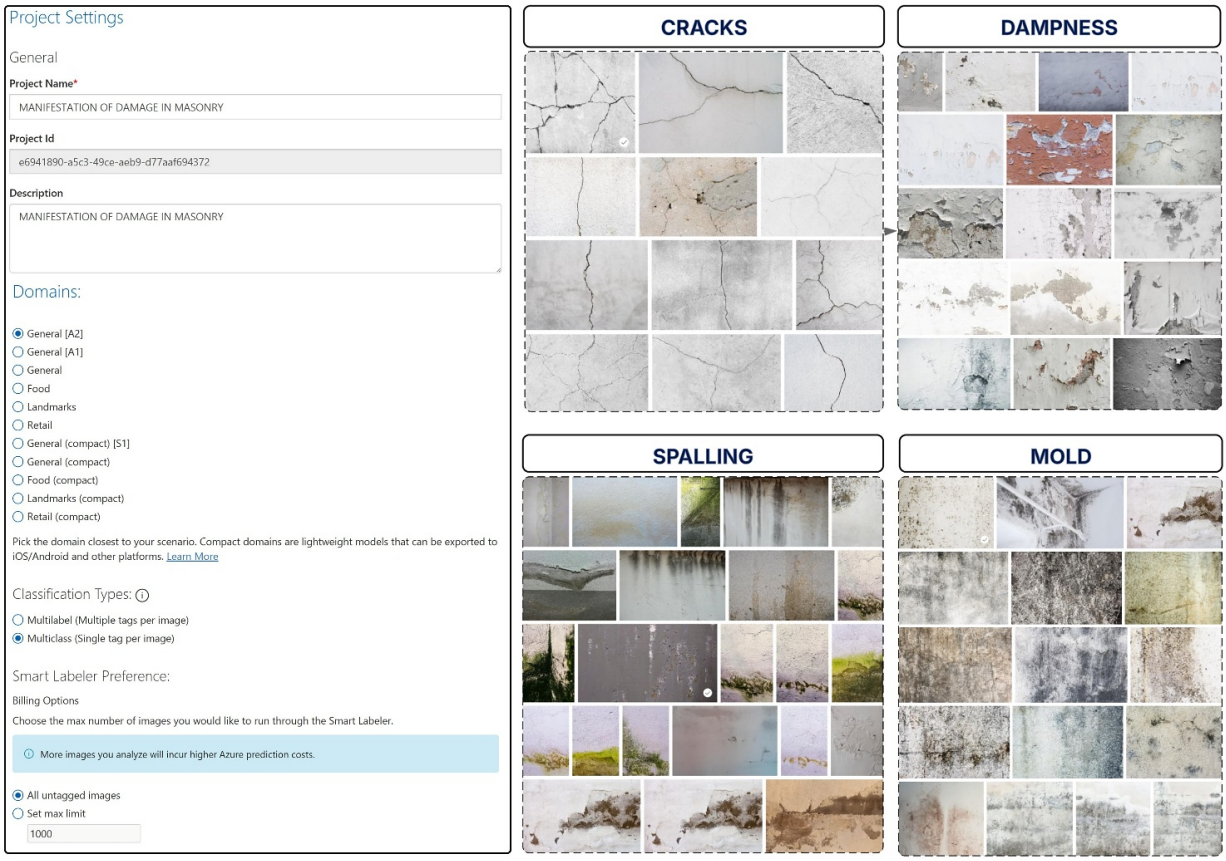

Figure 5 – Project configuration and organization of damage classes.

Model validation was carried out based on the final metrics provided by the platform, with emphasis on Precision, Recall, and Average Precision, adopted as parameters to confirm the efficiency of the algorithm. These indicators made it possible to verify the model's capacity to correctly recognize the visual patterns associated with each damage class, as well as to assess the balance between sensitivity and precision in

classification. Once satisfactory performance was achieved, the validated model proceeded to the final application stage.

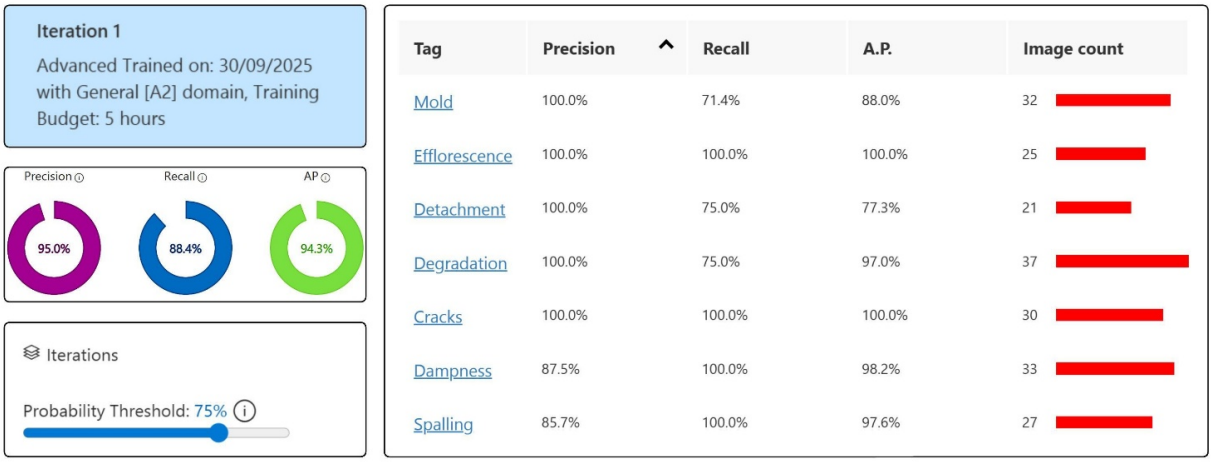
Finally, the trained and validated model was used for the automated analysis of digital images, allowing the identification of pathological patterns based on the classes learned during training. At this stage, the algorithm began to function as a support tool for the technical interpretation of images, providing classificatory outputs based on the previously structured database. In this way, the use of Custom Vision made it possible to operationalize the supervised classification of damage in masonry images, establishing a continuous methodological workflow between database development, training, validation, and model application.

2.5. Application of Computer Vision model

After the training, evaluation, and validation stages, the computer vision model was applied to the automated analysis of digital images, with the aim of identifying visual patterns associated with the previously defined damage classes. At this stage, the images submitted to the algorithm were processed on the Microsoft Custom Vision platform, which began to provide, for each analyzed record, the probabilities of association between the image and the classes trained in the model. The application was carried out on representative images of the architectural and structural elements of the building, allowing verification of the algorithm's ability to recognize damage patterns under real inspection conditions.

The analysis of the results was performed based on the classification probabilities assigned to each class, making it possible to identify the predominance of certain damage patterns and to analyze the coherence between the model's output and the visual characteristics observed in the images. After the computer vision analysis stage, the information resulting from damage classification was added to the building's 3D digital model, allowing the photographic records, the identified damage patterns, and their spatial location to be associated within the same representational environment.

Thus, the methodology was concluded with the application of the validated model to the photographic records, establishing a continuous workflow between data acquisition, image database organization, supervised training, and automated analysis. This procedure made it possible to structure a methodological sequence aimed at identifying damage in digital images, based on the recognition of visual patterns learned from the previously developed dataset.



3. Results and discution

3.1. Image database development and model training

The image database structured for model training enabled the development of a first iteration of supervised classification on the Microsoft Custom Vision platform, using the General [A2] domain. Training was completed in approximately 5 hours, with a probability threshold set at 75%, resulting in global metrics of 95.0% precision, 88.4% recall, and 94.3% average precision (AP). These results indicate that the model presented satisfactory performance in identifying the trained classes, with a high success rate in positive classifications and a good overall balance between sensitivity and precision (Figure 6).

The class-by-class analysis (Figure 6) showed consistent performance for most of the evaluated damage patterns. The efflorescence and cracks classes presented the best results, with 100.0% precision, 100.0% recall, and 100.0% AP, indicating a high visual distinction of these patterns in the training set. The degradation, dampness, and spalling classes also showed high performance, with AP values of 97.0%, 98.2%, and 97.6%, respectively. On the other hand, the mold and detachment classes presented the lowest recall values, at 71.4% and 75.0%, respectively, although they maintained 100.0% precision. This behavior indicates that, for these classes, the model correctly classified the recognized images but still showed lower sensitivity in recovering all available examples in the analyzed set. In terms of sample distribution, the database used

in training showed moderate variation among classes, with counts ranging from 21 to 37 images per tag, suggesting that the model was trained with a relatively balanced dataset, although still subject to the influence of visual variability and the number of examples available in certain categories.

Tag	Precision	Recall	A.P.	Image count
Mold	100.0%	71.4%	88.0%	32
Efflorescence	100.0%	100.0%	100.0%	25
Detachment	100.0%	75.0%	77.3%	21
Degradation	100.0%	75.0%	97.0%	37
Cracks	100.0%	100.0%	100.0%	30
Dampness	87.5%	100.0%	98.2%	33
Spalling	85.7%	100.0%	97.6%	27

Figure 6 – Evaluation of model performance by damage class.

3.2. AI-Based Computer Vision for Damage Detection in Masonry

The application of the computer vision model to images of the external façades of the Teatro José de Alencar showed correspondence between the probabilistic outputs provided by the platform and the visible damage patterns on the analyzed surfaces. The photographs submitted to the algorithm correspond to sections of masonry with visible damage identified by visual inspection, allowing comparison between automated classification and the condition observed in the field (Figure 7).

In Figure 7a, the highest probability was assigned to the detachment class (64.7%), compatible with the localized loss of coating observed at the base of the wall. In Figure 7b, the predominant class was dampness (78.8%), consistent with the presence of continuous dark stains and surface alteration associated with moisture. In Figure 7c, the model indicated the highest association with spalling (34.2%), followed by degradation (30.8%) and detachment (30.0%), a result compatible with the simultaneous presence of material loss, surface degradation, and coating detachment. In Figure 7d, the highest probability was attributed to dampness (40.3%), followed by efflorescence (24.5%) and detachment (22.7%), reflecting the overlap of distinct visual patterns on the same analyzed surface.

The images submitted to the model present variations in natural lighting, texture heterogeneity, surface alterations, geometric elements, and coexistence of damage, conditions that directly influence the classification process. Even so, the outputs provided by the algorithm-maintained correspondence with the predominant visual patterns identified on the external façades of the building. In addition to indicating the class with the highest probability, the model also presented secondary classes with relevant percentages, allowing the simultaneous presence of more than one damage pattern in the same image to be recorded.

The results obtained in this stage show that probabilistic classification made it possible to identify visible damage patterns in the masonry based on the classes trained in the model. In the analyzed examples, the classes with the highest probability assigned by the system coincided with the predominant patterns visible in the images. The interpretation of the probabilities provided a hierarchy among competing classes and allowed comparison between the automated output and the visual records obtained during inspection. In this way, the application of the model to the TJA photographs established an analytical stage based on supervised classification, using real façade images for the recognition of visual patterns associated with the mapped damage.

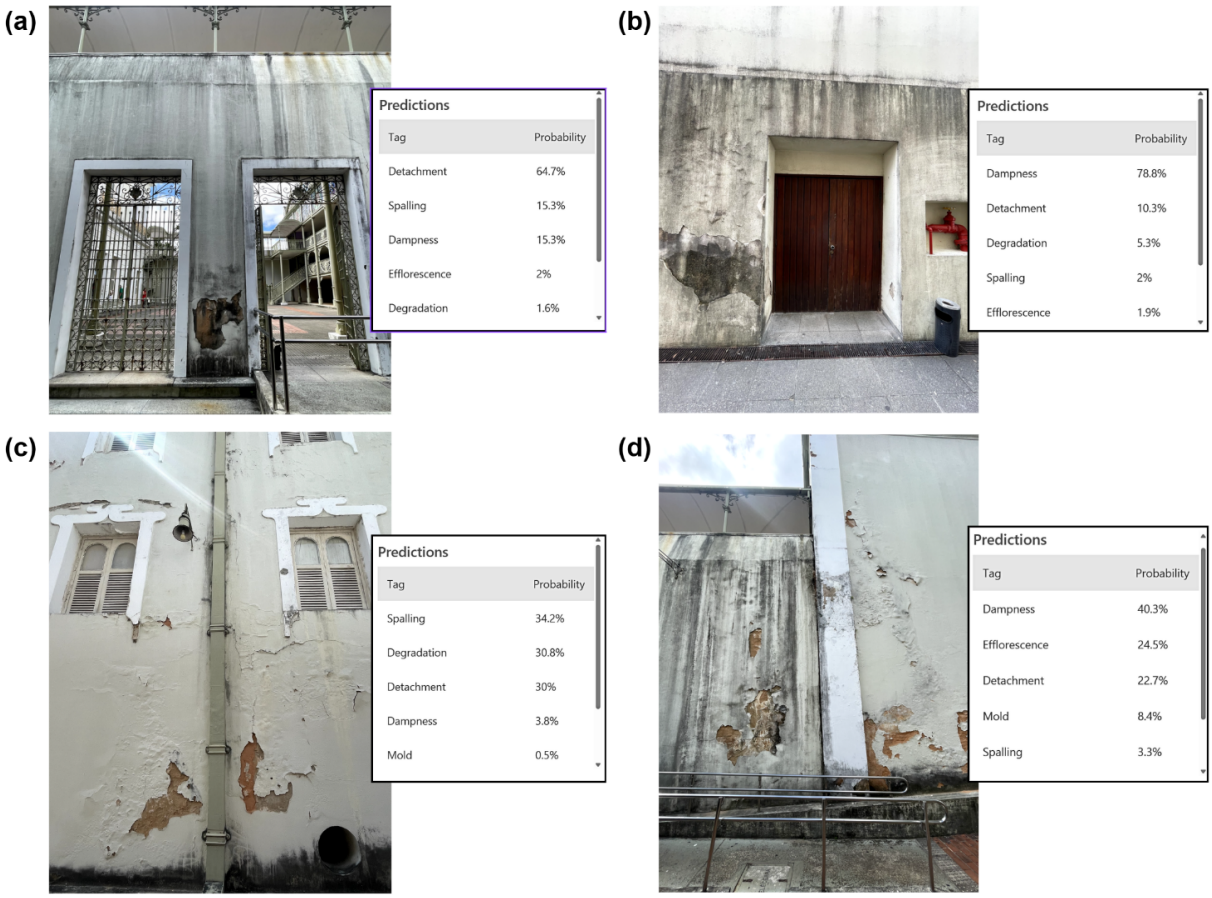


Figure 7 – Predictions of damage manifestations in masonry using computer vision.

3.3. Integration of Damage Data into the 3D Digital Model

The analyzed sections of the façades and internal environments were linked to the respective elements of the model, enabling the visual mapping of damaged regions and the organization of the information obtained during inspection and automated classification. In this process, the data were inserted through parameters associated with the modelled elements, allowing the recording of information such as visual inspection description, element code, location, and reference to the corresponding image.

The insertion of this information into the digital model made it possible to structure a visual and informational basis linked to the analyzed architectural elements, bringing together in the same environment the field-observed damage records, the images used in the analysis, and the data resulting from computer vision classification. In this way, the model came to concentrate not only the geometric representation of the building, but also the location and identification of the mapped damage, establishing a direct correspondence between the modelled element, the photographic evidence, and the associated diagnostic information. This procedure consolidated the workflow developed in the study, integrating photographic survey, supervised classification, and spatial organization of the data in the 3D digital model of the Teatro José de Alencar.

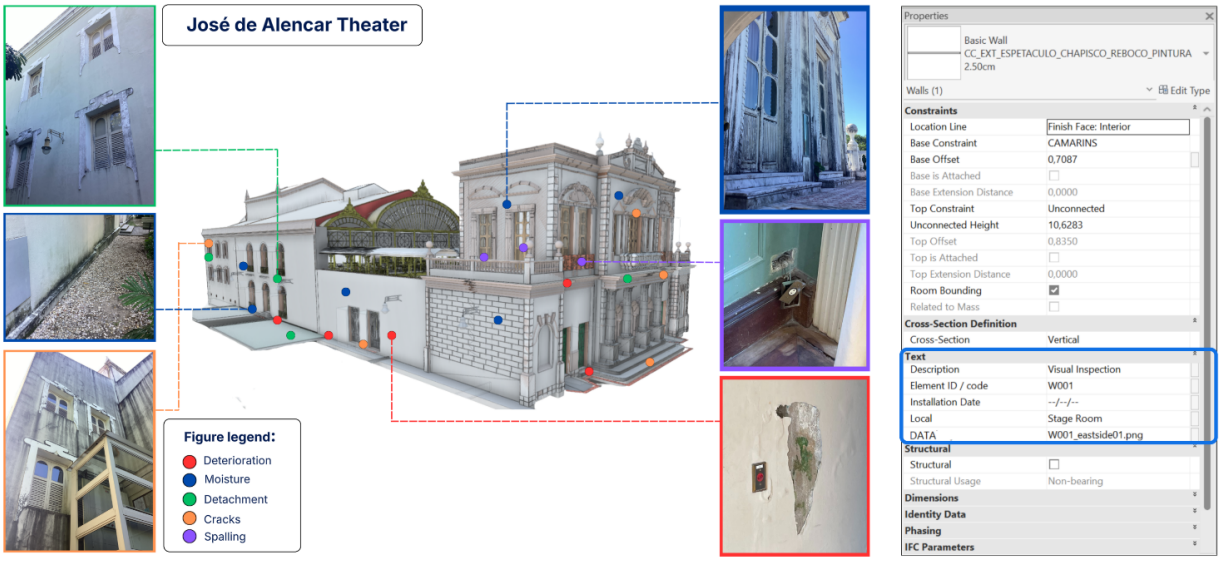

Figure 8 – Damage mapping and data insertion into the 3D digital model.

4. Conclusion

This study investigated the application of Computer Vision (CV) and Machine Learning (ML) techniques for the automated detection of damage patterns in structural and architectural elements of the Teatro José de Alencar, a historic building located in Fortaleza, Ceará. The methodological workflow comprised field photographic survey, the development of a labeled image dataset, the supervised training and validation of a classification model on the Microsoft Custom Vision platform, and the subsequent insertion of the resulting information into a 3D digital model. The trained model presented satisfactory performance, with global metrics of 95.0% precision, 88.4% recall, and 94.3% average precision, indicating adequate recognition capability for the damage classes adopted in the research.

The application of the validated model to façade images of the building showed correspondence between the probabilistic outputs provided by the algorithm and the visible damage patterns identified during field inspection. In addition to the classification of the predominant damage in each image, the model also indicated secondary classes with relevant probabilities, allowing the overlap of visual patterns on the same masonry surface to be recorded. The subsequent insertion of this information into the 3D digital model made it possible to associate photographic records, identified damage types, and mapped building elements within the same representational environment. The obtained results show that the proposed workflow is technically applicable as a support tool for damage mapping, the organization of diagnostic information, and the integration between automated image classification and digital documentation processes for historic buildings.

Abstract: This study investigates the electromechanical self-sensing behavior of lime mortars modified with carbon nanotubes (CNTs) and carbon microfibers (CMFs) for potential Structural Health Monitoring (SHM) applications in heritage-compatible materials. A hydrated lime mortar was produced with CNT contents of 0.20 and 0.40 wt.% of binder and CMF contents of 0.05, 0.10, and 0.20 wt.% of binder, in addition to a reference mixture. The mortars were evaluated for workability, compressive strength, electrical resistance, and electromechanical response under cyclic compressive loading using a biphasic measurement method. As expected, the incorporation of conductive additions reduced the workability of the fresh mixtures, with a more pronounced effect observed in mortars containing CMF. The mechanical performance improved in mixtures with both CNT and CMF, with optimal contents identified at 0.20 wt.% CNT and 0.05 wt.% CMF. Electrical resistance decreased in all modified mortars, with CMFs proving more effective in reducing the resistance of the lime matrix within the investigated range of filler content. Under cyclic compression, the mixtures exhibited different levels of piezoresistive behavior. The mortar containing 0.20 wt.% CNT showed the highest electromechanical sensitivity, while the mixture with 0.20 wt.% CMF also demonstrated a stable and significant response. In contrast, the reference mortar and the mixture containing 0.10 wt.% CMF exhibited limited self-sensing performance, as indicated by λ values of 4.52 and 6.41 and R^2 values of 0.01 and 0.12, respectively, although the latter showed one of the lowest electrical resistance values among the investigated mixtures. The results indicate that the self-sensing performance of lime mortars depends not only on increased electrical conductivity but also on the balance between filler dispersion, matrix integrity, and the sensitivity of the conductive network to deformation.

Keywords: Lime mortars; Carbon nanotubes; Carbon microfibers; Self-sensing materials, Structural health monitoring

1. Introduction

Historic buildings are frequently subjected to risks associated with the development of damage over time, resulting from actions such as earthquakes, settlements, the introduction of additional loads, usage conditions not foreseen in the original design, and deficiencies in maintenance, factors that may compromise their structural integrity and, consequently, the safety of users (Matos et al., 2025; Oliveira, 2015; Pringopoulos et al., 2024). In this context, the early identification of damage, combined with the timely adoption of safety measures, can prevent or mitigate the progression of structural pathologies. Although periodic inspections remain essential for assessing the performance of these buildings, Structural Health Monitoring (SHM) stands out as an effective tool for continuous or quasi-continuous detection and diagnosis of damage at early stages, as well as for assessing structural risks (E. F. T. Mesquita, 2019).

In recent decades, the development of SHM systems has been closely linked to advances in sensing technologies, particularly those based on electrical, mechanical, and optical measurements. Devices such as strain gauges (Biswal et al., 2016), linear variable differential transducers (Andreades et al., 2020), and optical sensors (Liao et al., 2020) have been widely applied in the instrumentation of different types of structures, enabling the continuous acquisition of data related to their in-service behavior (Gao et al., 2018; Kot et al., 2021; Mesquita et al., 2023; Sakiyama et al., 2019). However, the application of these sensors presents several challenges, including installation difficulties in hard-to-access locations, the need for numerous wired connections, costs, and long-term operational limitations.

Considering these limitations, the development of smart sensing materials has emerged as a promising alternative for SHM applications. These materials consist of structural composites that become electrically conductive and exhibit piezoresistive properties through the incorporation of carbon-based fillers, such as carbon microfibers (CMFs), carbon nanotubes (CNTs), and graphite, which enable variations in electrical resistivity in response to mechanical deformations (Meoni et al., 2018; Nalon et al., 2020; Ubertini et al., 2018). Studies reported in the literature have predominantly focused on developing self-sensing cementitious mortars for SHM applications (Cholker, 2021; Ding et al., 2021; Meoni et al., 2021; Rao et al., 2020). However, in the context of heritage conservation and sustainable construction practices, lime-based mortars play a fundamental role due to their physical and mechanical compatibility and greater affinity for the materials used in historical buildings (Dalalbashi et al., 2025). Despite this relevance, the application of lime-based matrices with self-sensing properties remains in the early stages of development.

Based on recent literature, although still in an early stage of development, studies investigating lime-based matrices with self-sensing properties are increasing. Dimou et al. (2020) demonstrated that the addition of 0.15 wt.% of CNTs promoted an approximately 12% reduction in the electrical resistivity of lime-based pastes. Xu et al. (2021) observed that the incorporation of CMFs at the highest investigated dosage (1 wt.% by volume) allowed the preservation, or even slight improvement, of mechanical properties, with increases of 11.24% in compressive strength and 3.69% in tensile strength. In addition, Drougkas et al. (2023) highlighted the effectiveness of incorporating CNTs into lime mortars, showing that adding 0.4 wt.% CNTs reduced electrical resistivity. Moreover, the incorporation of graphite and CMFs resulted in reductions in electrical resistivity of approximately 50% and 70%, respectively, along with a slight increase in flexural and compressive strengths, thereby reinforcing the potential of these materials for SHM applications.

Despite recent advances, additional studies are still needed to investigate the effectiveness of lime-based matrices in the context of SHM, particularly in developing analyses that correlate states of mechanical deformation, the occurrence of damage, and variations in the electrical parameters of these matrices. In this regard, the present study aims to contribute to enabling the effective use of self-sensing lime mortars for the monitoring and preservation of historical heritage. To this end, lime mortars were produced with different concentrations of CNTs and CMFs. The mixtures were evaluated for workability and mechanical properties. The electrical and electromechanical capabilities were evaluated using the biphasic measurement method.

2. Materials and methods

2.1 Materials

A commercial hydrated lime (CL 90-S) with a density of 2.24 g/cm³ was used as a binder. According to the manufacturer's chemical analysis (non-volatile basis), the combined CaO + MgO content exceeded 90%, CO_2 was below 10%, and unhydrated oxides were negligible, as indicated in EN 459-1 (2015). The aggregate used was a siliceous sand with a nominal particle size distribution of 0–3 mm. It presented a density of 2.63 g/cm³, a maximum grain size of 2.36 mm, and a fineness modulus of 2.71. Tap water was used and CNTs functionalized with carboxyl (-COOH) groups via acid treatment were incorporated into the mortar mixtures. The CNTs were supplied as a powder by Nanoview® Nanotecnologia, with diameters ranging from 10 to 30 nm and lengths between 1 and 10 µm. The CMFs used in this study presented a diameter of 7 µm and a length of 6-8 mm.

2.2 Experimental design and production of specimens

Mortars were prepared following EN 196-1 (2005) mixing procedures, according to conservation and masonry practice. Although the standard specifies the binder-to-aggregate proportion by weight, the dry components were mixed at a 1:3 volume ratio, a common practice in the production of mortars for masonry and conservation applications (Drougkas et al., 2023). This adoption results in a mortar with a lower binder content compared with that specified by the standard. Nevertheless, this proportion remains suitable for application as a repointing mortar in conservation contexts. The water-to-binder ratio was fixed at w/b = 1.00 (considering the total water, including the water used for CNT dispersion). Six mixes were produced, including a reference mortar and mortars modified with CNTs or CMFs, with the filler contents and mix proportions summarized in Table 1. The selected contents were defined within ranges commonly investigated in the literature (Dalalbashi et al., 2025; Danoglidis et al., 2016; Dimou et al., 2022).

Table 1 – Mix proportions of lime mortars with CNT and CMF additions.

Filler type	Filler content (wt.% of binder)	Lime (g)	Sand (g)	Water (g)	CNT (g)	CMF (g)
REF	0.00	443.52	1562.22	439.08	-	-
CNT	0.20	443.52	1562.22	439.08	0.89	-
CNT	0.40	443.52	1562.22	439.08	1.77	-
CMF	0.05	443.52	1562.22	439.08	-	0.22
CMF	0.10	443.52	1562.22	439.08	-	0.44
CMF	0.20	443.52	1562.22	439.08	-	0.89

Prismatic specimens (40x40x160 mm) were cast in triplicate, incorporating four metallic electrodes embedded within the samples and spaced 4 cm apart in the central region, following the configuration of strain gauges used in structural monitoring (Materazzi et al., 2013). These specimens were used for electrical and electromechanical tests. In addition, cubic specimens (40x40x40 mm) were prepared for compressive strength tests. The fresh mixture was poured into molds previously coated with oil, in two layers, each layer being compacted with 30 strokes of a metallic rod. Finally, the specimens remained in the molds for 72 h at 24°C under controlled conditions.

To reduce agglomeration and promote homogeneous distribution, the CNTs were previously dispersed in deionized water following methodological procedures like those reported by Vasconcelos et al. (2024). A fixed ratio of 0.033 g of CNT per mL of water was used. The suspension was sonicated for 15 min using a probe sonicator (VCX 750 Sonics®, 750 W) operating in cyclic mode (20% amplitude), with temperature

control maintained at 24°C, providing adequate dispersion in the aqueous solution, as reported by Matos et al. (2025), prior to incorporation into the mixtures. Figure 1 illustrates the experimental process flow, covering the stages from material dispersion to specimen casting.

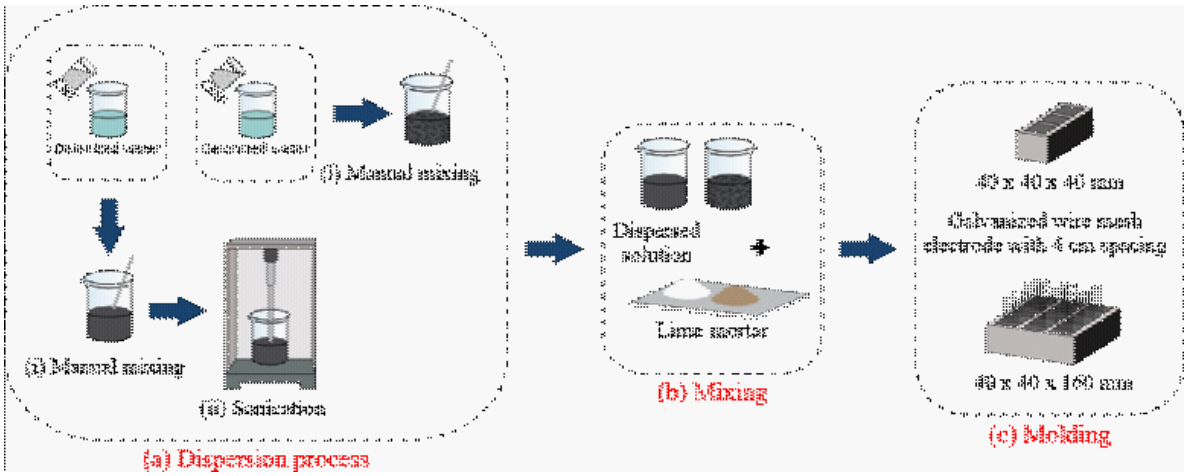

Figure 1 – Schematic representation of the process from dispersion to specimen casting.

2.3 Experimental tests

2.3.1 Workability

The consistency of the mortars was evaluated using a flow table test with a Kantro cone, in accordance with NBR 13276 (2016), similar to EN 1015-3 (1999).

2.3.2 Compressive strength

Compressive strength was determined using cubic specimens (40x40x40 mm) at 56 days, employing a universal testing machine (EMIC, model GR048, Instron, Norwood, USA), following procedures equivalent to EN 196-1 (2005), with adaptations for the present study.

2.3.3 Biphasic measurement

Electrical tests were performed to investigate the percolation threshold and characterize the material's electrical properties. For this purpose, a biphasic electrical measurement approach proposed by Downey et al. (2017) was used, which applied an alternating square signal. In the present study, a square wave signal with an amplitude of ±10 V, a frequency of 1 Hz, and a peak-to-peak voltage of 20 V was applied using a function generator. The experimental setup was configured in a four-electrode system, in which the external electrodes were responsible for applying the electrical current to the specimen, while the internal electrodes were used to measure the potential difference (V_{in}), following the reading scheme illustrated in Figure 2. Furthermore, a reference resistor (Rg) was connected in series with the sample, allowing the indirect determination of the electrical current through Ohm's law, according to Eq. (1), based on the voltage drop (V_{Rg}) monitored across (Rg). Finally, the sample's electrical resistance was obtained using Eq. (2) from the voltage measured between the internal electrodes. The measurements were taken when the specimens were 56 days old.

$$i = \frac{V_{Rg}}{Rg} \quad (1)$$

Thus, the electrical resistance of the specimen was calculated according to:

$$R = \frac{V_{in}}{i} \quad (2)$$

where i is the electrical current, V_{Rg} is the voltage drop across the reference resistor Rg, V_{in} is the voltage measured between the internal electrodes, and R is the electrical resistance of the specimen.

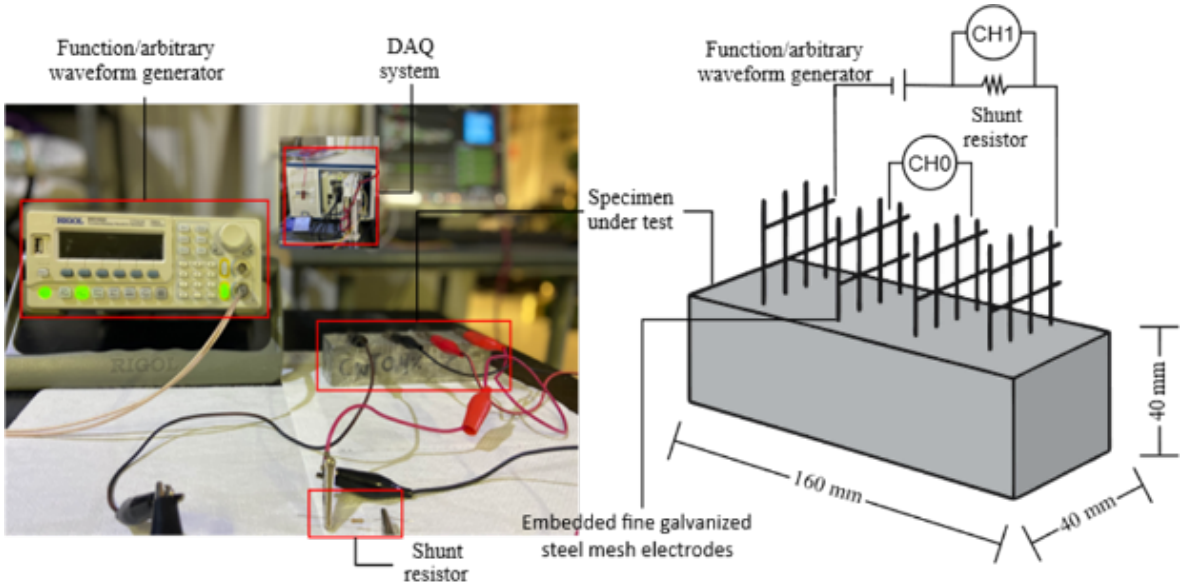

Figure 2 – Experimental setup adopted for the determination of electrical resistance using the biphasic measurement method.

2.3.4 Electromechanical test

For the electromechanical test, prismatic specimens were subjected to cyclic compressive loading, with two cycles at each stress level. Maximum stress levels of 0.125 MPa, 0.1875 MPa, and 0.25 MPa were adopted, with a minimum stress of 0.0125 MPa, as illustrated in Figure 3, with a loading and unloading rate of 50 N/s.

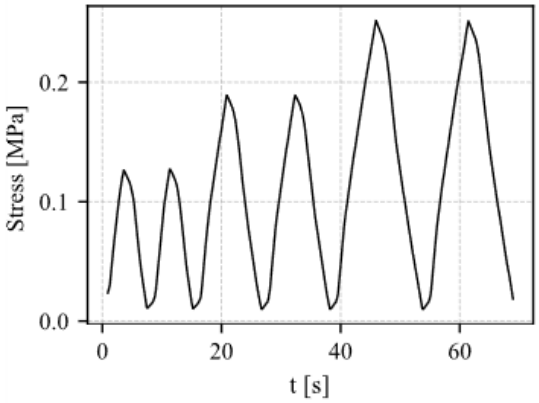

Figure 3 – Cyclic compressive loading protocol for electromechanical tests.

During the test, the electrical resistance was monitored simultaneously using the biphasic electrical measurement system previously described to correlate the imposed deformation with the material's electrical response. Thus, the electrical response was quantified through the fractional change in resistance (FCR), defined by Eq. 3:

$$\frac{\Delta R}{R_0} = \frac{R - R_0}{R_0} \tag{3}$$

where R is the measured electrical resistance and R_0 is the reference resistance, taken before the beginning of cyclic loading (or at the initial instant of the analyzed segment). The gauge factor (λ), used as a parameter of electromechanical sensitivity, was calculated according to Eq. 4:

$$\lambda = \frac{\Delta R/R_0}{\varepsilon} \quad (4)$$

Where ε is the axial strain, estimated from the axial displacement recorded by the testing machine and normalized by the initial specimen height (160 mm), corresponding to nominal strain. Gauge factor λ was determined as the slope coefficient of a linear fit of the FCR vs ε relationship, applied to the selected data segment used for analysis. Thus, the experimental setup of the electrical and mechanical tests is illustrated in Figure 4.

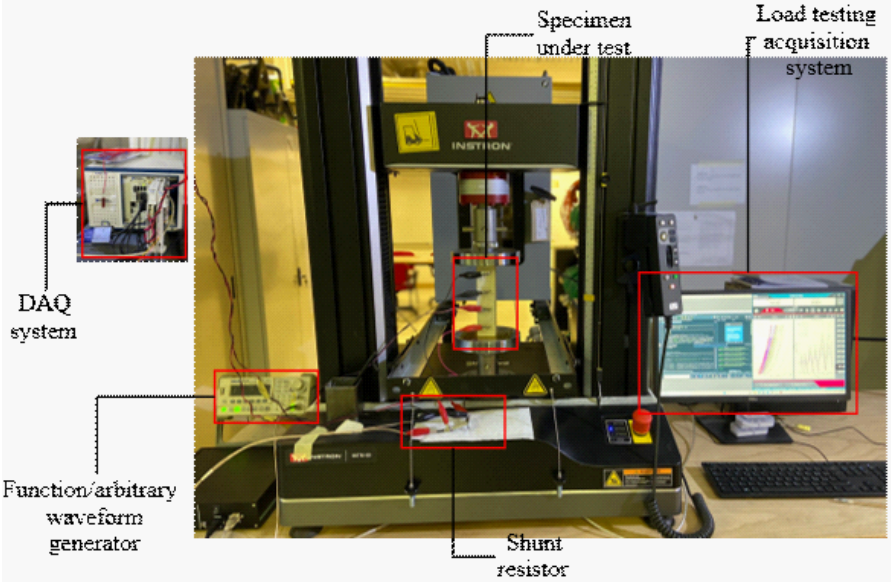

Figure 4 – Schematic overview of the experimental setup used for electromechanical testing.

3. Results and discussion

The incorporation of conductive additions modified the fresh-state behavior, mechanical performance, electrical properties, and electromechanical response of the lime mortars. As observed in previous studies, linear behavior was not observed: instead, the results indicated the existence of optimal contents, defined by the balance between dispersion, matrix integrity, and the formation of a conductive network within the material (Dalalbashi et al., 2025; Drougkas et al., 2023).

The workability analysis of lime mortars with varying CNT and CMF contents showed a reduction in the flow diameter of the fresh mixtures, as illustrated in Figure 5. The REF mixture exhibited high fluidity, with a spread of 290 ± 2 mm, whereas the mortars containing CNTs showed a reduction to 257 ± 7 mm at 0.20 wt.%, followed by a partial recovery to 282 ± 5 mm at 0.40 wt.%. This behavior indicates a strong influence of the dispersion state. The results suggest that the rheological response is highly sensitive to both the dispersion state and the high specific surface area introduced by the nanotubes in the lime matrix, which may lead to changes in the degree of agglomeration and in the microstructural organization of the system depending on the addition content (Nalon et al., 2024).

In contrast, the incorporation of CMF led to a notable reduction in workability, with the most pronounced effect observed at 0.10 wt.% (234 ± 3 mm), while 0.05 wt.% and 0.20 wt.% reached 241 ± 4 mm and 244 ± 3 mm, respectively. This behavior is generally associated with increased internal friction and the mechanical interlocking effect resulting from the fibrous morphology, which tends to restrict the relative mobility of particles (D'Alessandro et al., 2024; Safiuddin et al., 2018). Nevertheless, a consistent reduction in workability with increasing CMF content was not observed, which may be attributable to factors such as variations in

dispersion and homogenization, localized agglomerate formation, and non-uniform fiber distribution within the mixture. These aspects can alter the rheological response even when the mass content is increased.

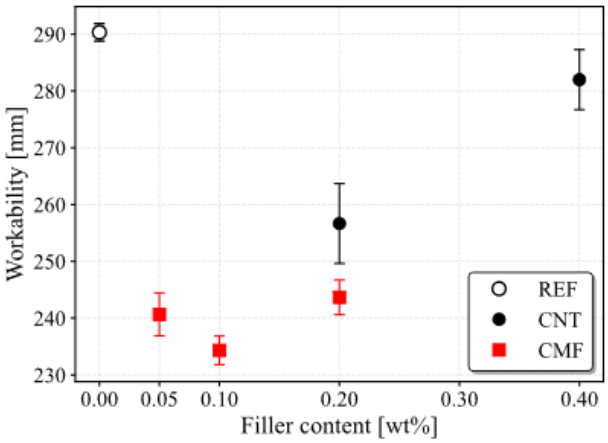

Figure 5 – Workability values of lime-doped mortars.

The results presented in Figure 6 show that this modification in the fresh state affects the mechanical performance, although not in a directly proportional manner to the flow spread. While the REF sample exhibited a compressive strength of 0.86 MPa, the mixtures containing CNTs showed their best performance at 0.20 wt.%, with a nearly twofold increase in mechanical strength, reaching a value close to 1.70 MPa. Increasing the CNT content to 0.40 wt.%, although still higher than the reference mixture, resulted in a strength of 1.15 MPa. This behavior suggests the existence of an optimal incorporation content, possibly associated with the balance between adequate dispersion and the onset of nanotube agglomeration, which may generate discontinuities or stress concentrations within the matrix (Konsta-Gdoutos et al., 2010; Thomoglou et al., 2023). Similarly, the mortars containing CMF exhibited significant strength gains, particularly at a content of 0.05 wt.%, reaching approximately 2.10 MPa, corresponding to an increase of 143% compared with the reference mixture. A progressive reduction in strength is observed with increasing fiber content (0.10 wt.% and 0.20 wt.%), which may be related to the greater difficulty in achieving adequate dispersion and to the possible formation of voids or fiber concentration zones at higher contents (D'Alessandro et al., 2024).

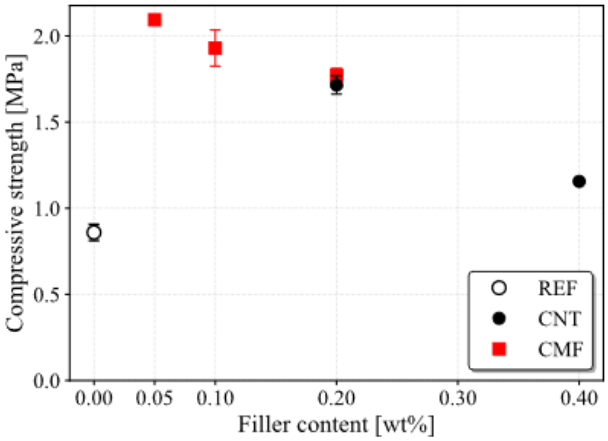

Figure 6 – Compressive strength results of lime mortars with CNTs and CMFs.

Figure 7 shows that incorporating conductive additions reduced the electrical resistance of the lime matrix, confirming the formation of internal conductive pathways. For the CNT series, the electrical resistance decreased

from 16.88 MΩ in the reference mixture to 10.09 MΩ at 0.20 wt.%, representing a reduction of approximately 40 wt.%, but increased again to 15.91 MΩ at 0.40 wt.%, corresponding to a decrease of 5.75% relative to the reference. This behavior indicates that the 0.20 wt.% content provided a more efficient conductive network, whereas the increase to 0.40 wt.% likely impaired effective connectivity due to less homogeneous dispersion and a greater tendency toward agglomeration (Dimou et al., 2022).

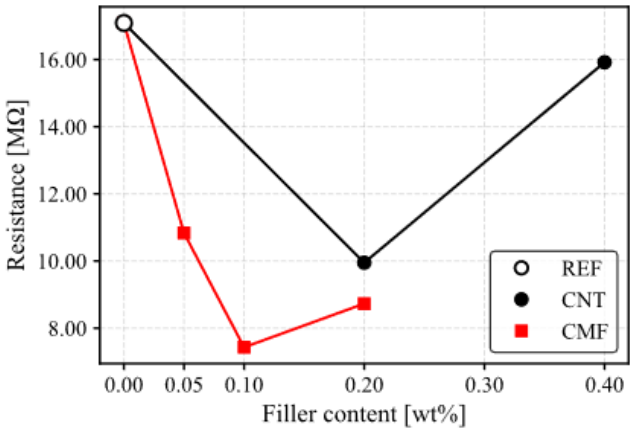

Figure 7 – Electrical resistance variation of lime mortars with different CNT and CMF contents.

In the case of mortars containing CMFs, a greater reduction in electrical resistance was observed, particularly in the samples with 0.10 wt.% and 0.20 wt.% microfibers. The 0.10 wt.% content reached 7.30 MΩ, followed by a slight increase at 0.20 wt.% to 8.59 MΩ, corresponding to reductions of 56.75% and 49.11%, respectively. Moreover, even the lowest evaluated content, 0.05%, already reduced electrical resistance to 10.84 MΩ, equivalent to a 35.72% decrease. These results indicate that, in terms of electrical performance, CMFs were more efficient than CNTs. This behavior may be associated with the geometry and dimensions of the microfibers, whose length favors the formation of more extended conductive pathways throughout the matrix (Drougkas et al., 2023). This behavior shows partial coherence with the mechanical results, since this series exhibited the highest compressive strength among the contents studied. Therefore, these contents combine mechanical improvement with reduced electrical resistance. In addition, CMF-modified mortars exhibited satisfactory mechanical performance relative to the reference mixture, despite a progressive reduction in strength with increasing fiber content. Thus, the incorporation of conductive functionality through CMF did not compromise mechanical performance.

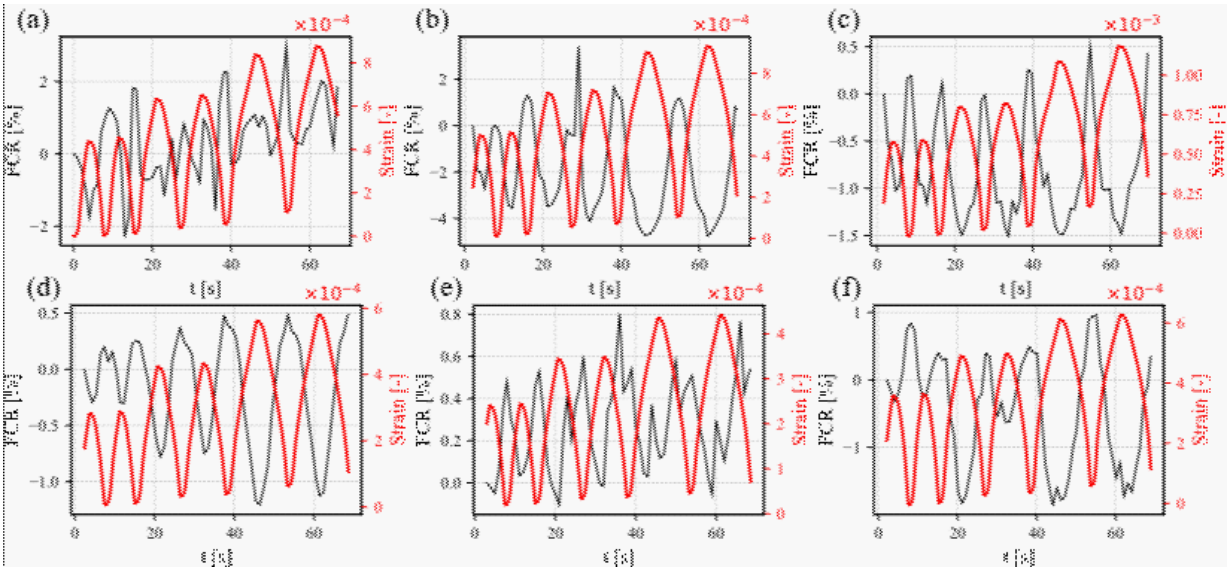

Figure 8 – Time-dependent FCR and Strain response of lime mortars under cyclic compressive loading: (a) REF, (b) CNT 0.20 wt.%, (c) CNT 0.40 wt.%, (d) CMF 0.05 wt.%, (e) CMF 0.10 wt.%, and (f) CMF 0.20 wt.%.

Figure 8 presents the electromechanical behavior of the mortars, monitoring the variation in electrical resistance during the application of compression cycles, thereby enabling evaluation of their sensing performance. The mixtures containing 0.20 wt.% CNT, 0.40 wt.% CNT, 0.05 wt.% CMF, and 0.20 wt.% CMF, corresponding to graphs (b), (c), (d), and (f), exhibited FCR oscillations that generally followed the strain cycles, indicating a higher sensitivity to the applied loading. In contrast, the reference mixture (a) and the mixture containing 0.10 wt.% CMF (e) showed more scattered signals with lower and less regular amplitudes, suggesting a weaker and less stable electromechanical response, as also indicated by their R^2 values of 0.01 and 0.12, respectively.

The results of the electromechanical tests are summarized in Table 2, which presents the main associated parameters, including sensitivity and fitting quality. The reference mortar (a) showed $\lambda = 4.52$ and $R^2 = 0.01$, indicating that the lime matrix without conductive additions did not develop a reliable electromechanical response under the evaluated conditions. This behavior is consistent with the observed scattered signal, indicating low sensitivity to the applied load. The mixture containing 0.20 wt.% CNT (b) showed the highest absolute sensitivity value ($\lambda = 74.77$), associated with $R^2 = 0.78$, representing the best performance among the compositions evaluated. This result shows a trend similar to that reported by Drougkas et al. (2023), who, despite using a different matrix based on natural hydraulic lime (NHL 3.5), also observed higher sensitivity at lower CNT contents, followed by a reduction in performance as the reinforcement fraction increased. Consistently, the composition with 0.40 wt.% CNT (c) maintained piezoresistive behavior, but with significantly lower sensitivity ($\lambda = 18.56$), suggesting the formation of a conductive network that was less responsive to loading-induced variations.

Table 2 – Electromechanical parameters.

Filler type	Filler content (wt.% of binder)	λ [-]	R^2
REF	0.00	4.52	0.01
CNT	0.20	74.77	0.78
CNT	0.40	18.56	0.68
CMF	0.05	29.79	0.85

CMF	0.10	6.41	0.12
CMF	0.20	45.80	0.78

Among the mixtures containing CMF, the best performance was obtained for 0.20 wt.% (f), with λ = 45.80 and R^2 = 0.78, followed by 0.05 wt.% (d), with λ = 29.79 and R^2 = 0.85. In contrast, the composition with 0.10 wt.% CMF (e), despite showing one of the lowest average electrical resistance values among the investigated mixtures, resulted in λ = 6.41 and R^2 = 0.12, indicating limited sensing performance. Although Figure 8 indicates a response to load application, despite the scattered signal observed for this mixture, Figure 9 shows that the CMF 0.1 wt.% mixture presents less defined hysteresis loops, with less consistent trajectories throughout the loading cycles. This behavior reinforces the instability of the electromechanical response, in agreement with the low λ and R^2 values. Results reported by Dalalbashi et al. (2025) using hydraulic lime matrices (NHL 5) indicate a similar trend, with good performance at CMF contents, although the best result was observed at 0.10 wt.%. In addition, this set of results demonstrates that higher electrical conductivity does not necessarily imply greater electromechanical sensitivity, showing that self-monitoring performance depends not only on the formation of conductive pathways but also on the ability of the network to respond effectively to strain variations, in line with the trend observed by these authors.

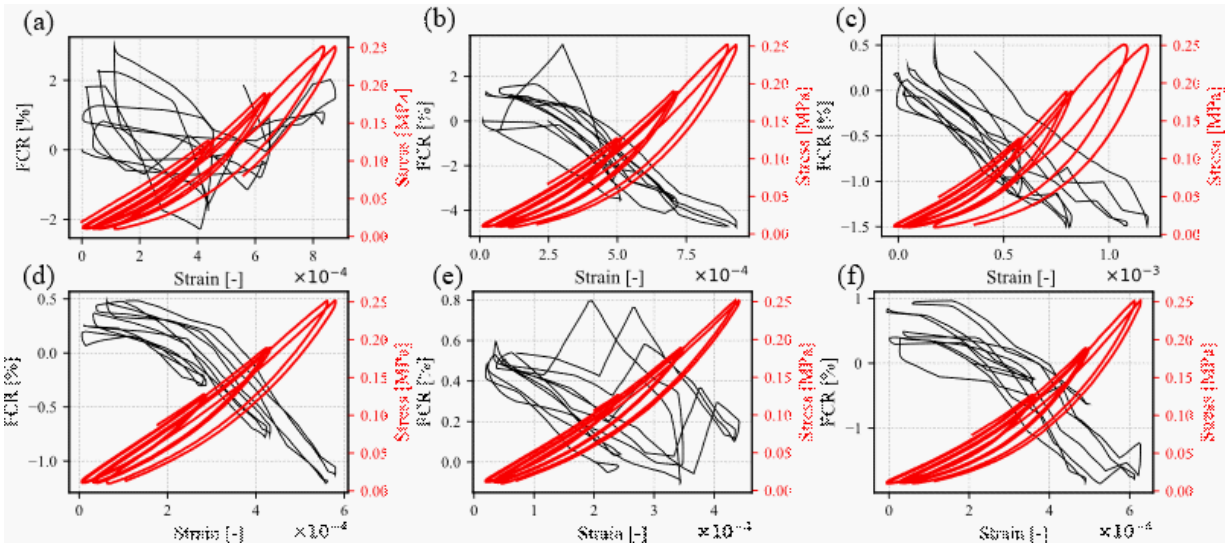

Figure 9 – Fractional change in electrical resistance (FCR) as a function of strain for lime mortars under cyclic compressive loading: (a) REF, (b) CNT 0.20 wt.%, (c) CNT 0.40 wt.%, (d) CMF 0.05 wt.%, (e) CMF 0.10 wt.%, and (f) CMF 0.20 wt.%.

4. Conclusion

The incorporation of CNTs and CMFs altered the fresh-state, mechanical, electrical, and electromechanical behavior of lime mortars, confirming the potential of these additions to develop self-sensing materials. The results showed that the performance of the mixtures did not evolve monotonically with increasing filler content, indicating the existence of optimal formulations that balance dispersion, matrix integrity, and conductive network configuration. Among the mixtures containing CNTs, the 0.20 wt.% content exhibited the best overall performance, combining increased mechanical strength, reduced electrical resistance, and greater electromechanical sensitivity. Among the mixtures containing CMF, the 0.05 wt.% content showed the best mechanical performance, while 0.20 wt.% exhibited the best electromechanical response. From an electrical perspective, CMFs were more effective at reducing the matrix's overall electrical resistance.

In general, mortars containing conductive additives have shown promise for their enhanced mechanical and sensing performance. This result is particularly relevant for retrofitting applications on existing structures, in which the objective is to combine additional functionality with compatibility with the original matrix to be restored. As a future perspective, studies will focus on evaluating the evolution of these properties over time, particularly relevant for verifying the stability of the mechanical, electrical, and electromechanical behavior of the developed formulations. Furthermore, complementary microstructural analyses may contribute to a deeper understanding of how these inclusions influence the matrix's internal structure and performance. Such advances may consolidate the development of lime mortars with potential application as sensing materials for monitoring historical heritage structures.

Abstract: Historic constructions constitute an architectural and cultural heritage of inestimable value, reflecting cultural and economic aspects that are essential to the history of a society. The preservation of historic monuments depends primarily on knowledge of their construction techniques; however, this task proves to be a major challenge, as most of these monuments exhibit complex and poorly documented construction methods. Unlike modern constructions, whose composition, geometry, and behavior are well known, historic buildings are composed of thick masonry with heterogeneous internal material distribution and a wide variety of techniques, configurations, and construction typologies. In this context, deepening the understanding of these structures becomes essential through the development of technical records and documentation that allow for an accurate characterization of their construction features. Accordingly, the main objective of this study is the application of Ground-Penetrating Radar (GPR) for the non-destructive investigation of the internal structure of the masonry of the Church of Almofala, located in the municipality of Itarema, Ceará, Brazil. GPR surveys were carried out on internal masonry elements of the building, aiming to identify construction patterns, interfaces, voids, moisture presence, and internal anomalies. The adopted methodology was structured into four main stages: (i) characterization of the building, (ii) GPR data acquisition (iii) signal processing and (iv) interpretation and analysis of the results. The results demonstrate the effectiveness of GPR in detecting internal interfaces and characterizing construction heterogeneities, highlighting its potential as a supporting tool for diagnostic, rehabilitation, and preservation actions of built cultural heritage.

Keywords: Non-destructive testing; GPR; Historic heritage.

1. Introduction

Ground-Penetrating Radar (GPR) is a non-destructive geophysical technique based on the propagation of electromagnetic waves in natural media, such as geological formations, and artificial media, such as masonry and concrete. The method enables the identification of contrasts between materials with different dielectric properties through the analysis of reflected signals. The system operates by means of transmitting antennas, responsible for emitting electromagnetic pulses, and receiving antennas, which record the signals reflected by internal elements of the structure (Annan, 2003; Alvarado et al., 2025). The signal is generated at the boundary between two or more materials and is reflected when the electromagnetic properties of the materials change. Thus, the radar is capable of detecting materials as long as there is a contrast in the electromagnetic properties between the investigated media. (Utsi, 2017).

GPR data acquisition is performed through the continuous movement of the equipment along linear profiles, enabling the sequential recording of reflected signals. After processing, these data are converted into two- or three-dimensional images, known as radargrams or echograms, which represent the internal characteristics of the analyzed structure (Solla *et al.*, 2020; Alvarado et al., 2025; Grzyb et al., 2025).

Over the past decades, GPR has been widely applied in several fields, including archaeology, glaciology, geology, civil engineering, and, more recently, in the conservation of historic heritage (Solla, 2024; Balasubramani, 2025; Brandes et al., 2025; Hatem et al., 2025). Its increasing use in this field is associated with its ability to provide rapid and detailed information about the interior of structures, often inaccessible through conventional methods. Unlike other testing techniques that require longer processing and interpretation times, GPR provides near-immediate results, making it advantageous for preliminary diagnostics and field inspections.

Recent studies highlight a wide range of applications in historic heritage, among which the following stand out: the characterization of masonry, enabling the analysis of composition, thickness, and arrangement of construction layers (Cruz et al., 2024; Grzyb et al., 2025), the location and identification of ancient foundations, often absent from historical records (García-Nieto *et al.*, 2024; Parnow et al., 2024), the detection of corrosion in metallic reinforcements ((Solla, 2024)); the identification of voids and hidden cavities within walls (Cruz et al., 2024), the distinction of construction materials and overlapping layers within the masonry (Alvarado et al., 2025), and the assessment of the structural condition, including the presence of cracks, deterioration, and moisture (Perez-Gracia, Solla and Fontul, 2022; Elkarmoty et al., 2024).

The application of GPR in historic masonry presents high potential, considering that these structures are characterized by significant heterogeneity resulting from the use of different materials and multiple construction phases. Pioneering studies, such as that of Binda (1998), demonstrated the effectiveness of the method in detecting voids, inclusions, and defects, as well as in assessing wall conditions and identifying moisture and internal layers (Binda et al., 1998).

Historic masonry is composed of a combination of different materials, mainly stone, brick, and blocks. It is also possible to identify the presence of natural components such as lime, earth, and, in some cases, residues of materials available at the construction site (De Almeida, 2013; Carlos and Domingues, 2017). These structures may be bonded with mortar, being referred to as mortared masonry, or, in many cases, simply assembled without binders, characterizing dry-joint masonry (ICOMOS, 2006; Carlos and Domingues, 2017). In addition, they exhibit significant variability in thickness and internal configurations, and may consist of single or multiple layers depending on the construction typology and structural function (Rosa, 2013; Jorne et al., 2015).

This diversity is related to the way technical knowledge was transmitted. According to Mateus (2002), construction techniques were disseminated through model buildings used as references and later adapted to local conditions. This process contributed to the formation of structures with high internal variability and a lack of construction standardization, characteristics that increase the difficulty of their investigation (Mateus, 2002).

Given this complexity, the use of non-destructive techniques becomes essential for the characterization of these structures. However, the interpretation of GPR radargrams still represents a significant challenge, as it depends directly on the experience of the operator and interpreter and is influenced by factors such as the properties of the investigated medium, acquisition parameters, the equipment used, and data processing conditions (Fernandes, 2006; Martini, 2019; Bevan. B, 2020)

Despite the advances observed in the application of GPR in historic masonry, there are still limitations related to signal interpretation in highly heterogeneous media, especially in buildings with poorly documented construction techniques. The complexity of radargrams, combined with material variability, makes the accurate identification of interfaces and internal anomalies difficult, highlighting the need for applied studies aimed at improving interpretative criteria.

In this context, the Church of Almofala, located in the municipality of Itarema, Ceará, Brazil, stands out as an important example of historic heritage, characterized by traditional masonry construction techniques, making it a relevant object for GPR investigation. Therefore, the present study aims to apply the GPR method to investigate the masonry of the Church of Almofala, seeking to identify construction patterns and

possible internal anomalies, such as voids and moisture, thereby contributing to non-destructive diagnostics and the preservation of built cultural heritage.

2. Methodology

The study began with the delimitation of the investigation area, defined based on the selection of the Church of Almofala, a building of significant historical and religious value to the region. Subsequently, GPR surveys were carried out on the masonry of the church, aiming to identify construction interfaces, the presence of hidden elements, cracks or debonding between layers, and moisture.

After the data acquisition stage, signal processing was performed, including the application of filters and the definition of parameters compatible with the characteristics of the investigated medium. Finally, the analysis of the obtained responses was conducted based on the interpretation of reflection patterns observed in the radargrams. The methodological process was carried out as presented in Figure 1.

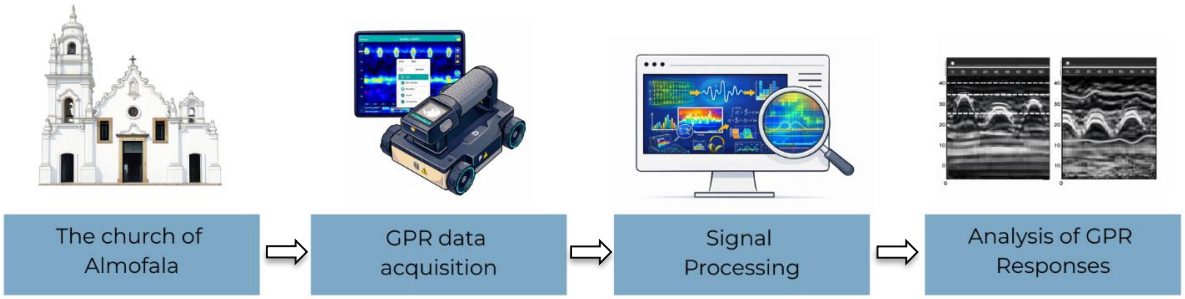

Figure 1: Stages of the methodological process.

2.1 The church of Almofala

The Church of Immaculate Conception, popularly known as the Church of Almofala, is located in the district of Almofala, in the municipality of Itarema, on the coast of Ceará. The church is listed by the National Institute of Historic and Artistic Heritage (IPHAN) under registration number 652-T-62 and is recognized as an important cultural and historical landmark of the region. (Carvalho *et al.*, 2013).

he construction of the church dates back to the early 18th century, having been built between 1712 and 1758, replacing an earlier chapel made of wattle and daub and thatch. The church is composed of brick and stone masonry, with walls approximately 77 cm thick. The materials used include large bricks, weighing around 5 kg, lime- and clay-based mortar, as well as the incorporation of natural elements such as seashells from the coast. The original structure also made use of wood, such as Brazilian cedar, used in elements like the roof and frames, which were later replaced due to degradation over time.

(Carvalho *et al.*, 2013; Luz, Silveira and Soeiro, 2021).

One of the most remarkable aspects of the church's history refers to its burial by a migrating sand dune, which began around 1897 as a result of changes in the region's wind patterns. The building remained covered by sand for approximately four decades, being progressively uncovered from the 1930s and completely excavated around 1943. This event contributed to the deterioration of several construction elements, especially those more susceptible to moisture and the weight of the sand overburden, such as the roof and wooden componentes (IPHAN, 1980; Carvalho *et al.*, 2013).

Throughout the 20th century and the early 21st century, the church underwent several restoration and maintenance interventions. The first actions took place between the 1940s and 1950s and were carried out by the local community without adequate technical rigor.

Subsequently, more structured interventions were conducted by preservation agencies, such as those promoted by SPHAN/Pró-Memória in the 1980s, which included the restoration of the roof, plaster, frames,

and architectural elements. Other relevant interventions occurred in 1997, focusing on the recovery of structural elements, and in 2005, aimed at preventive maintenance, especially in the treatment of infiltration and efflorescence (Carvalho *et al.*, 2013).

Currently, the church is in regular use for religious activities and is in good overall condition. However, it presents pathological manifestations mainly associated with environmental agents, such as marine aerosol (salt spray), moisture, and the natural aging of materials.

Among the main observed issues are the presence of infiltration, salt efflorescence, degradation of wooden elements, peeling of coatings, and plaster detachment. Additionally, inappropriate interventions carried out over time, involving the use of materials incompatible with the original construction, have contributed to the emergence of new anomalies (Carvalho *et al.*, 2013; Luz, Silveira and Soeiro, 2021).

In this context, the Church of Almofala represents a relevant case study for the application of non-destructive techniques, such as GPR, contributing to the investigation of construction characteristics in heterogeneous media and to the understanding of wave reflection behavior in complex built environments with the presence of anomalies.

Figure 2: Church of Almofala, Itarema, Ceará, Brazil: (a) Re-emergence of the church after the removal of the sand volume (Carvalho, 2013); (b) External view of the church in its current state; (c) Internal view of the church in its current state.

2.2 GPR data acquisition

The GPR equipment used in the tests was the Proceq GP8000 model, characterized as a handheld, wireless, and lightweight device, suitable for investigations on both vertical and horizontal surfaces. The equipment operates with a central frequency antenna of 2000 MHz, which provides more detailed images but with reduced penetration depth, making it appropriate for the study of shallow structures such as masonry, concrete, and architectural elements (Elkarmoty et al., 2024; Jasieńko, Raszczuk and Frąckiewicz, 2024).

The regions selected for the study encompassed masonry areas defined based on a preliminary inspection of the building, prioritizing locations that exhibited visible pathological manifestations, such as cracks and moisture presence, as well as zones of structural interest and construction uncertainty.

GPR data acquisition was performed by moving the antenna along the surface of the masonry, following previously defined linear and continuous trajectories, with lengths varying according to the extent required

or each investigated area. In total, four acquisitions were carried out, distributed across different points of the church (Figure 3).

Subsequently, the data were processed using the Proceq GPR application, with the application of filters and the definition of parameters compatible with the analyzed material.

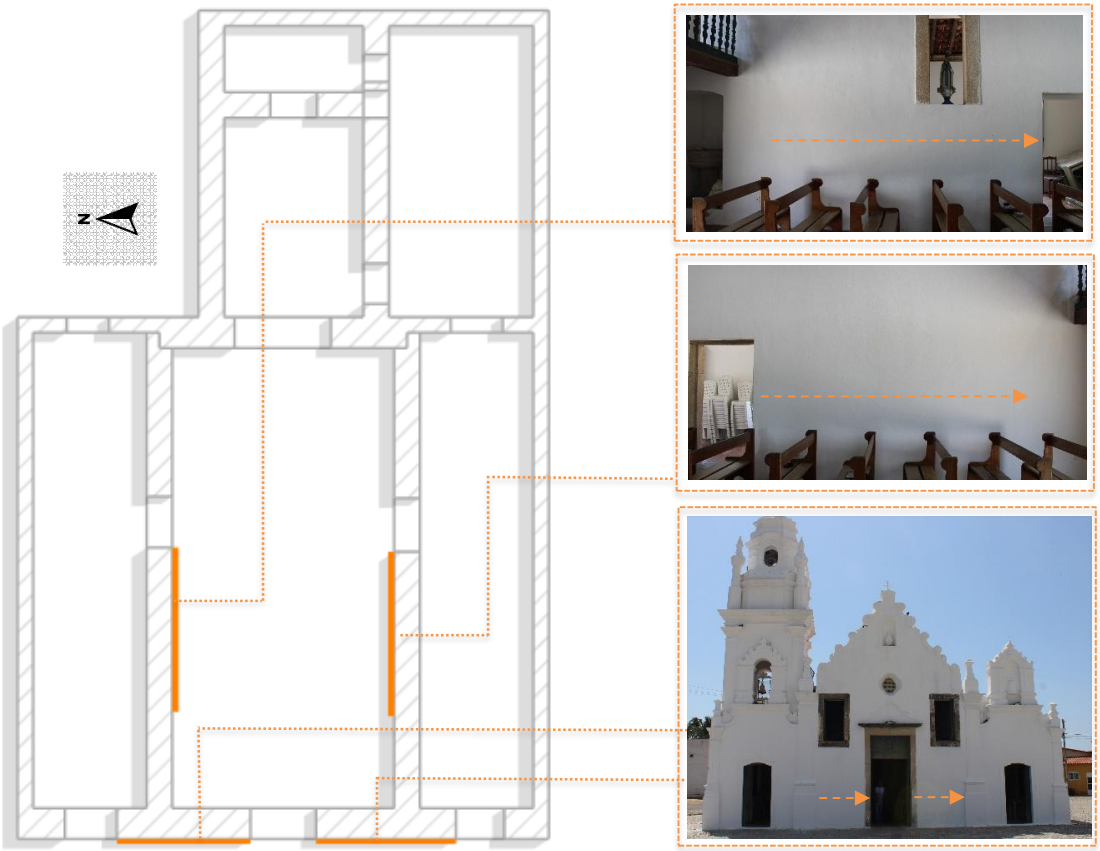

Figura 3: Data acquisition locations

2.3 Signal Processing

Data processing was carried out using the GPR's own application, which includes the main parameters for analyzing the results. The primary objective of this stage is to improve the quality of the acquired signal to enhance the interpretation of reflections, avoiding distortions or the loss of relevant targets. Figure 3 illustrates the difference between a raw radargram and the same radargram after processing. Processing techniques vary according to the equipment, and there are no fixed rules for parameter selection; these are defined based on the operator's experience and the level of detection required (Utsi, 2017).

First, the dielectric constant of the investigated medium was defined. According to Carvalho, the church is mainly composed of clay-based bricks, with inclusions of mortar and regional elements such as seashells. In this context, clayey materials exhibit a wide range of dielectric constant values, which may vary between 8 and 40 for moist clays, while under dry conditions these values typically range between 2 and 5 (Reynolds, 2011). In heterogeneous masonry, defining this parameter becomes even more challenging, and the adoption of representative average values is common. Thus, for GPR analysis purposes, a weighted average can be adopted, considering the volumetric contribution of the different constituent materials, such as

bricks, mortar, and possible infill materials, resulting in an average value of approximately 7.0 for the overall structure (Qian *et al.*, 2026).

For the visualization of radargrams, a grayscale color scale was adopted, as it provides better perception of signal amplitude variations and enhances the identification of reflection continuity, even in regions where signal intensity is reduced. Although chromatic scales may be visually more appealing, they can lead to overinterpretation of the data or make it difficult to identify low-amplitude targets. In this sense, as discussed by Erik Utsi, the grayscale scale is a more appropriate alternative for analysis, allowing for a more accurate and consistent representation of the patterns present in radargrams (Utsi, 2017).

Other processing procedures were also applied to improve the quality of the radargrams and assist in data interpretation. Among these, noise cancellation stands out, used to reduce interference and improve the signal-to-noise ratio, and background removal, applied to eliminate reflections associated with the homogeneous medium and highlight internal discontinuities. Additionally, gain adjustments were applied, including linear gain and time gain compensation (TGC), aiming to compensate for signal attenuation with depth. The definition of the time window allowed the establishment of the investigation limit, while A-scan analysis was used to support the interpretation of individual signals. The adopted spatial sampling rate directly influenced the resolution of the obtained data, and a repetition rate of 1 scan/cm provided adequate spatial resolution for identifying variations along the profiles. Furthermore, the adoption of a 1:1 aspect ratio ensured proper geometric representation of the radargrams, preventing distortions in the interpretation of features (Utsi, 2017). The adopted processing parameters are presented in Table 1, and the comparison between the raw radargram and the processed radargram can be observed in Figure 4.

Filtering	**2000MHz**
Dielectirc constant (εr)	7
Noise Cancellation	Activated
Background Removal	6 ns
Linear Gain	16-20 dB
TGC (Time Gain Compensation)	3-4 dB/ns
Time Window	16 ns
Repetition Rate	1 scan/cm
Viewing scale	Grayscale
Aspect Ratio	1:1

Table 1: GPR processing parameters.

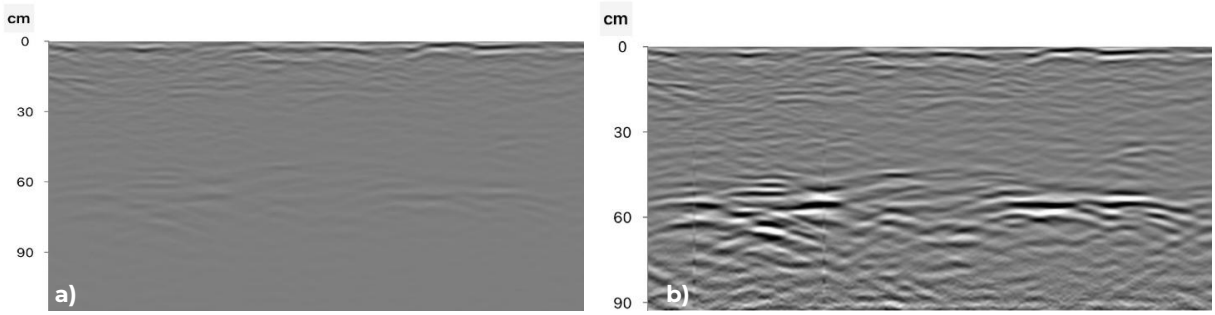

Figure 4: Difference in radargram processing: (a) Raw radargram; (b) Processed radargram.

2.4 Analysis of GPR Responses

The interpretation of GPR data in historic masonry presents inherent limitations due to the heterogeneity of the medium, which results in complex and non-uniform dielectric contrasts. This condition may lead to multiple reflections, signal scattering, and variable attenuation, contributing to ambiguity in the identification of internal features.

The analysis of GPR responses was structured based on interpretative criteria applied to radargrams, aiming to identify internal features of the masonry through the evaluation of electromagnetic signal reflection patterns. For this purpose, parameters such as continuity, amplitude, and geometry of the reflections were considered.

Initially, continuous (linear) reflection patterns were used to identify possible interfaces between materials, bedding joints, and extensive discontinuities, such as cracks or fractures. It is important to note that GPR does not directly detect the opening of these discontinuities, but rather the variations in electromagnetic properties associated with them, such as the presence of air, moisture, or changes in material composition.

(Fernandes, 2006; Utsi, 2017).

Subsequently, responses with hyperbolic geometry were associated with the presence of point targets or small-sized features, such as voids, inclusions, or localized discontinuities. The occurrence of multiple overlapping hyperbolas was interpreted as an indication of heterogeneous or degraded media, possibly related to intense cracking, internal voids, delamination, or fragmented materials (Fernandes, 2006; Utsi, 2017)

In the specific case of air-filled voids, these tend to exhibit high reflection coefficients, resulting in high-amplitude signals. However, in voids with irregular or asymmetric geometry, increased signal scattering may occur, reducing the accuracy in defining their boundaries (Qian *et al.*, 2026).

Additionally, regions with significant signal attenuation were analyzed as possible indicators of moisture presence. Under high moisture conditions, the energy of the electromagnetic signal may dissipate, resulting in radargrams with a low presence of reflections, characterizing a highly moist medium. On the other hand, the interface between dry and moist regions generates high-amplitude reflections (Perez-Gracia *et al.*, 2021).

3. Results

3.1 Analysis and Interpretation of GPR Responses

The analysis of the radargrams allowed the identification of different reflections within the masonry, mainly interfaces between construction layers, voids, and moisture. The obtained radargrams reveal distinct reflection patterns directly associated with the internal heterogeneity of the investigated masonry. In general, the presence of well-defined interfaces, homogeneous zones, regions with strong signal attenuation, and areas with high structural complexity can be observed.

The blue arrows indicate the superficial layer, characterized by continuous linear reflections, interpreted as the interface between the external plaster and the beginning of the brick masonry. This type of response is typical of planar boundaries between materials with different dielectric properties, highlighting the transition between construction layers.

Similarly, the white rectangles, highlighted in Figures 4a and 4b, show continuous sub-horizontal reflectors associated with internal interfaces within the masonry. These features may be related to the arrangement of bricks and bedding joints, reflecting variations in material composition and possible distinct construction phases.

The red arrows indicate high-amplitude reflections associated with more pronounced dielectric contrasts within the medium. These responses are typically related to the presence of air-filled voids or localized discontinuities, as air presents a high contrast relative to the surrounding materials, resulting in stronger

reflections. Such features are particularly evident in Figure 4a and may indicate internal detachment or zones with loss of cohesion.

The light blue arrows, observed in Figure 4c, are interpreted as transitions between regions with different moisture contents, such as the interface between dry zones and areas with higher water presence. As discussed by Utsi (2017), variations in moisture content significantly influence the electromagnetic response due to the increase in dielectric permittivity and electrical conductivity, resulting in amplitude contrasts and signal distortions. Alternatively, these responses may also be associated with heterogeneous regions filled with different materials.

The orange rectangles highlight areas with low reflectivity or absence of reflections, characterized by a "cleaner" appearance in the radargram. This behavior is consistent with the attenuation of the electromagnetic signal, generally associated with the presence of moisture, which promotes the dissipation of signal energy and reduces the visibility of internal interfaces. This phenomenon makes interpretation more difficult and may mask relevant features.

Finally, the region highlighted in green presents a highly heterogeneous pattern, characterized by multiple overlapping reflections, irregular geometries, and significant amplitude variation. This behavior indicates a complex internal medium, possibly associated with degradation processes, the presence of voids, material fragmentation, or irregular infill. This type of response is related to signal scattering, typical of non-homogeneous media and frequently observed in historic masonry.

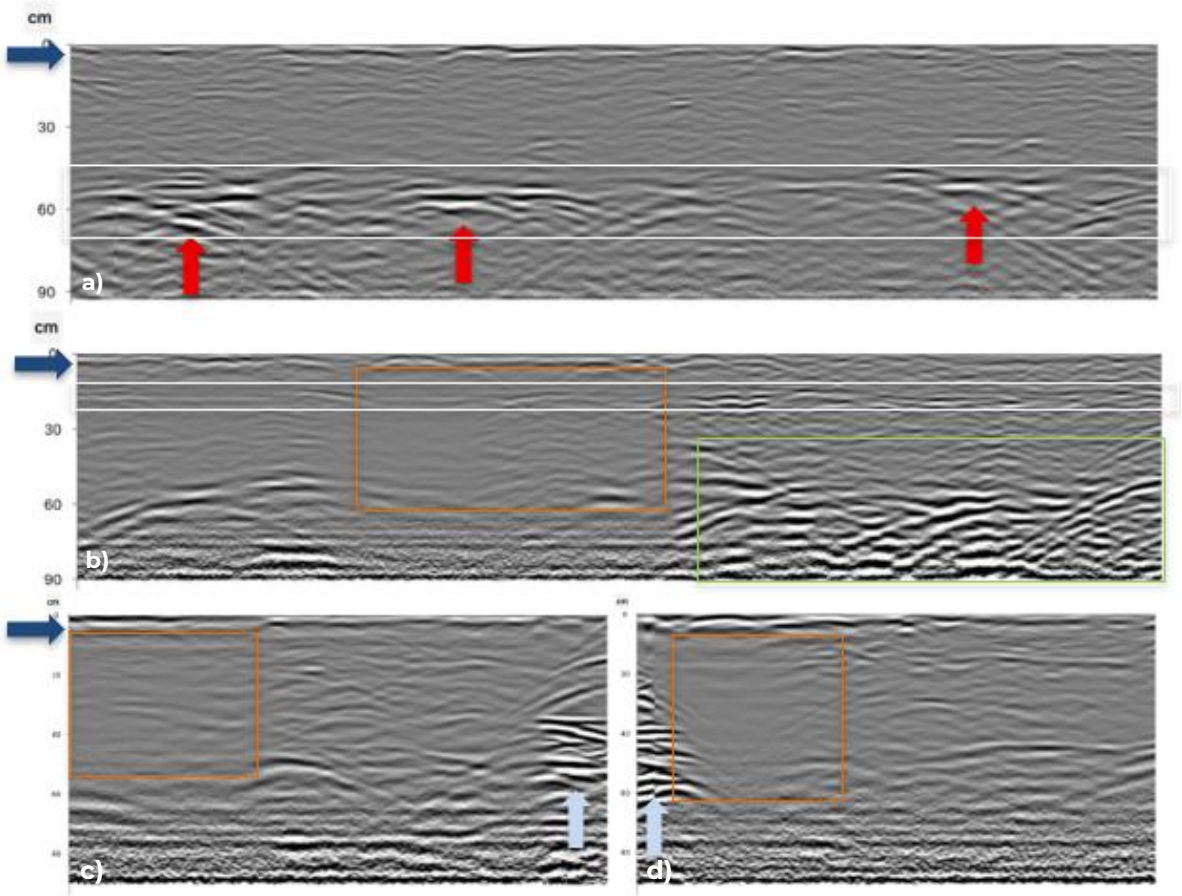

Figure 5: Radargrams obtained in the investigated masonry: (a) Presence of interfaces between layers and strong reflections indicative of voids; (b) Presence of interfaces between layers and regions of signal attenuation indicative of moisture, along with strong reflections indicating high heterogeneity; c) and d) Presence of interfaces between layers, signal attenuation possibly indicative of moisture, and strong reflections demonstrating heterogeneity.

4. Conclusion

Based on the obtained results, the following conclusions can be highlighted:

· The application of GPR proved to be effective in identifying internal features in historic masonry, contributing to the non-destructive analysis of these structures;

· The careful definition of processing parameters was essential for improving radargram quality and increasing the reliability of interpretations;

· The use of filters, such as noise removal, background removal, and gain compensation, made it possible to highlight relevant reflection patterns without compromising data integrity;

· The appropriate selection of the dielectric constant, combined with the use of a grayscale scale, facilitated the identification of signal continuity and the distinction between different internal features;

· The interpretation of radargrams enabled the identification of interfaces between construction layers, regions with possible voids, zones of attenuation associated with moisture presence, and areas with high internal heterogeneity;

· The obtained results reinforce the potential of GPR as an efficient tool for investigating historic masonry, even considering the limitations imposed by the heterogeneous nature of these materials;

· The interpretation of GPR data remains dependent on the operator's experience and prior knowledge of signal behavior in heterogeneous media.

Therefore, the application of the method requires rigorous analysis and interpretation criteria in order to minimize ambiguities and ensure greater reliability of the results.

Abstract: The conservation of built historical heritage requires strategies that go beyond the preservation of memory and collective identity, incorporating technical actions focused on maintenance to ensure the long-term integrity of buildings. In this context, the use of technologies for the maintenance of built heritage has been widely discussed within the scientific community and has become a fundamental strategy for the conservation of these assets. The use of drones for surveying pathological manifestations in historic buildings has become increasingly common and contributes to the development of more accurate diagnoses. With the aim of contributing to the preservation and documentation of historic buildings, this paper analyzed the pathological manifestations identified in one of the earliest residential condominium complexes in Fortaleza/CE, the Dona Bela Building, a residential complex composed of three blocks. Based on the photogrammetric survey, on-site measurements, and photographic data acquisition, a set of detailed damage maps of the apartments and facades was produced, as well as a technical report on the identified pathologies. These outputs contribute to the strengthening of maintenance and management strategies for historical heritage.

Keywords: Damage mapping; Drone surveying; Historic Buildings; Maintenance strategies; Pathological manifestations.

1. Introduction

The first notion of urban historical heritage emerged in the 18th century and became consolidated through the accelerated modernization processes of major European cities, when preservation gained prominence and came to be recognized as an asset of irreplaceable value for society, whose loss is considered irreparable (Choay, 2011). Since then, historical heritage has played a crucial role in understanding the past, contributing to the cultural identity and collective memories of societies. However, these assets are constantly exposed to environmental changes, natural hazards, and other factors, leading to their gradual deterioration over time. (Hajirasouli and Banihashemi, 2020)

In the contemporary context, the documentation of historic buildings face frequent challenges, as records are often incomplete, fragmented between interventions, or even nonexistent, which compromises their long-term preservation (Godinho *et al.,* 2020). In this scenario, documentation becomes essential not only to preserve building information over time but also to support decision-making and maintenance processes, highlighting the importance of incorporating recently available technologies. *(*Rubens *et al.,* 2022*)* Damage mapping stands out as a strategic tool in this process, as it enables not only systematic recording but also the classification of pathological manifestations, supporting the identification of the causes of alteration and deterioration of architectural surfaces (Scandurra and Luggo, 2023).

With the progressive aging of buildings, structures undergo changes over time due to the interaction between the built environment and external conditions, resulting in a gradual reduction of their service life (De Moura Junior *et al.,* 2022). Pathological manifestations such as cracks, infiltrations and oxidations commonly found in historical buildings are further aggravated by environmental and climatic conditions, while in older constructions, structural problems caused by material degradation are among the main

causes. The identification and analysis of these pathologies through technical reports and damage maps are essential steps in understanding the conservation state of building, and should be conducted through survey of existing damages (Xavier *et al.,* 2022). However, traditional inspection techniques are based on in situ measurements, which may present limitations in terms of spatial accessibility, operator safety, and the level of precision and detail obtained, especially in buildings under continuous use.

In this context, advances in digital technologies have enabled greater accuracy in the diagnostic documentation of built heritage through in situ surveys.. Murphy *et al.,* (2009) define Historic Building Information Modelling (HBIM) as a methodology for the development of parametric models based on Building Information Modelling (BIM) for historical buildings, incorporating historical data and information captured through laser scanning and photogrammetry. Currently, laser scanning and photogrammetry are considered highly accurate and non-invasive methods for acquiring geometric data in historical buildings. (Aricò *et al.,* 2024). The integration of these methods allows for the generation of point clouds derived from on-site data acquisition, a process known as Scan-to-BIM (Brumana *et al.,* 2019). The use of these techniques, combined with Unmanned Aerial Vehicle (UAV), which have become accessible tools for heritage data acquisition, has proven advantageous in improving surveys, particularly for capturing hard-to-reach areas such as tall buildings, roofs and upper facades (Sun *et al.,* 2015).

The combined use of photogrammetry, laser scanning and UAVs constitutes a technological approach capable of enhancing the development of accurate and efficient damage maps, enabling the analysis, classification and identification of pathologies with greater rigor. In parallel, thematic mapping within HBIM models has been widely discussed in recent years. While some researchers focus on geometric representation of damage through ultra-thin layers overlaid onto model elements, others encode such information as parameters associated with each component of the model. Additionally, the use of standardized hatching to represent different types of deterioration has become an effective strategy for identifying pathologies with greater scientific rigor, promoting the adoption of internationally shared terminology and contributing to the standardization of diagnostic processes (Delpozzo *et al.,* 2022).

Thus, this study aims to analyze the pathological manifestations identified in the Dona Bela Residential Complex, built in the 1950s and one of the first multifamily residential buildings in the city of Fortaleza, Ceará, Brazil. The selection of this case study is justified by its historical relevance in the process of urban verticalization, as well as by its current condition of continuous use, highlighting the real limitations associated with conducting inspections in inhabited historical buildings. Through the integration of UAVs surveys, photogrammetry, in situ measurements, and photographic records, it was possible to develop a technical report of the identified pathologies, as well as thematic damage maps of both the building facades and floor plans. As a scientific contribution, this study proposes an integrated technological approach for damage mapping in inhabited historical buildings under conditions of restricted access. In this sense, the research reinforces the potential of digital technologies as fundamental tools for the documentation and management of historic buildings in continuous use.

2. Case Study

The Dona Bela Residential Complex, located on Coronel Ferraz Street in the city of Fortaleza, state of Ceará, constitutes an important architectural landmark in the context of vertical multifamily residential use. During this period, a New Urban Code for the municipality of Fortaleza (1952) was established, regulating the so-called “apartment houses”:

Art. 339° – When multiple dwellings are grouped within the same building, sharing a common main entrance connected to all units and a properly installed concierge, this configuration shall be defined as an apartment house. (Prefeitura de Fortaleza, 1952)

According to Cavalcante (2015), apartment buildings began to be constructed in residential areas in the second half of the 1950s, following the city’s urban expansion towards the Centro-Aldeota axis, also known as the Outeiro district, where the case study of this research is located. In a context marked by verticalization and the predominance of mixed-use buildings, with emphasis on commercial and institutional activities, Dona Bela stands out as the first apartment complex designed exclusively for residential use built in the 1950s.

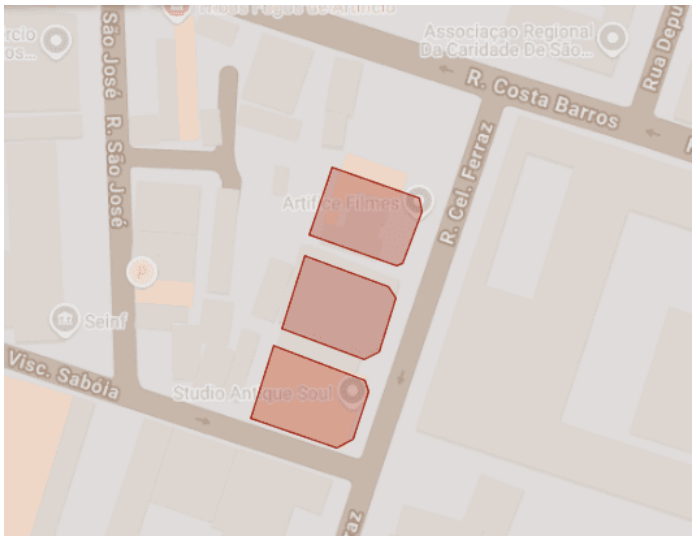

Figure 1 – Dona Bela urban complex location.

Constructed in the second half of the 1950s, the Dona Bela Building (Figure 2) features a reinforced concrete structure and consists of three apartment blocks (A, B and C), each comprising three floors with two units per floor, totaling 18 units in the complex. Cavalcante (2015) states that although the authorship of the projects is unknown, the real estate company responsible for the development, Imobiliária Pedro Philomeno, presents aesthetic similarities with other buildings, such as the São Pedro Building (Figure 3), which was demolished in 2024, suggesting the possibility of a common designer across different projects.

Figure 2 – Dona Bela Building.

Figure 3 – São Pedro Building.

Each residential unit includes four bedrooms, one social bathroom, a kitchen with dining area, living and dining rooms, as well as a service area and bathroom (Figure 5). Vertical circulation is organized through two staircases: one for service and another for social access. (Cavalcante and Paiva, 2019)

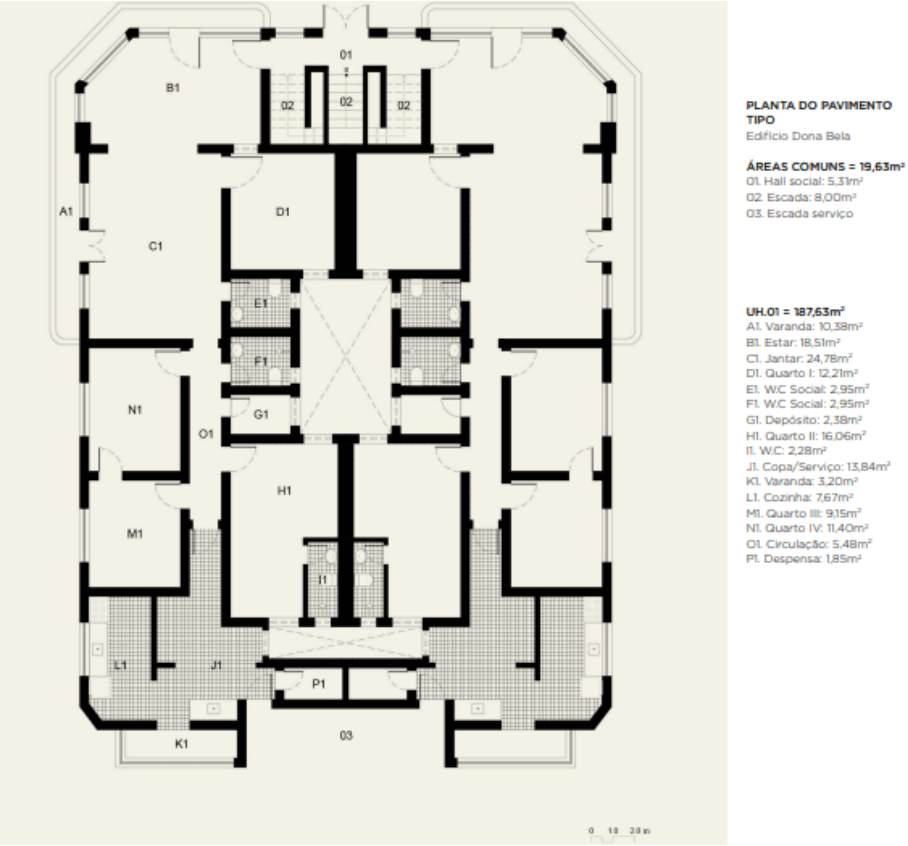

Figure 4 – Typical floor plan of the Dona Bela Building designed by Marcia Cavalcante

The complex stands out for reflecting architectural features associated with Mediterranean-influenced modernism (Secultfor, 2015), characterized by straight lines and parapets, slabs resembling canopies, rounded balconies, and monochromatic finishes, predominantly in white tones, with wooden louvered window frames and facade ornaments (Figure 5).

Figure 5 – Dona Bela building facades.

Due to its importance not only for Ceara's modernist architecture but also as one of the few remaining inhabited examples of early multifamily residential buildings, the Dona Bela Complex was listed as a protected heritage site in 2015 by the Secretariat of Culture of Fortaleza. This designation was motivated by its pioneering architectural production in reinforced concrete, particularly associated with developments

by entrepreneur Pedro Philomeno Gomes. Furthermore, the complex is located near the first protected urban architectural ensemble in the city, reinforcing its historical significance in the context of Fortaleza's urban development (Secultfor, 2015).

Currently, the Dona Bela Complex remains inhabited, although its occupancy profile has changed over time. Unlike its original residential population, the complex now accommodates residents engaged in cultural and creative economy activities, such as artists, music producers, filmmakers, and young adults interested in the reoccupation and revitalization of Fortaleza's downtown area. Some residents have transformed their units into collaborative and cultural spaces which, especially on weekends, activate Coronel Ferraz Street and have become symbols of resistance against the urban decline that has affected the neighborhood in recent decades.

However, these new uses and forms of occupation have led to transformations within the residential units, including the construction of independent annexes on the rooftops of each block and localized interventions carried out by residents, such as the subdivision of existing units to accommodate additional occupants. These actions, combined with the aging of construction materials, exposure to regional climatic conditions, and the lack of proper maintenance, contribute to the progression of pathological manifestations within the Dona Bela Complex.

In this context, the Municipality of Fortaleza launched in 2025 the Call for Proposals to Promote the Cultural Heritage of the City of Fortaleza, through which 16 architectural assets were selected to undergo technical assessments conducted by architects, engineers and specialized professionals to evaluate their current condition. The Dona Bela Complex was among the selected properties.

Given this scenario, an in situ survey and a technical report on pathological manifestations were carried out with the aim of documenting, identifying and mapping the damages present in the residential complex. This process sought to understand the current state of conservation of the building and to support strategies for maintenance and preservation of the existing heritage.

3. Methodology

This research adopts a case study approach focused on the diagnosis of pathological manifestations supported by innovative technologies to enhance the maintenance and management of a historic residential building. The process was divided into five stages (Figure 6) and combined digital surveying technologies, in situ inspections for data acquisition, and the development of a technical report for the identification of pathologies through damage mapping.

It is important to emphasize that the methodology was adapted due to the building's condition of continuous use, which imposes limitations on access and data acquisition in certain residential units. Therefore, complementary strategies were implemented to ensure comprehensive data collection.

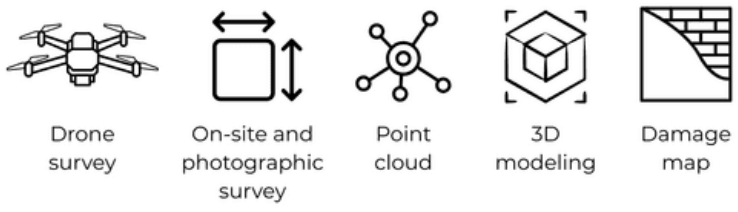

Figure 6 – Methodological workflow

3.1 Drone Survey

An Unmanned Aerial Vehicle (UAV), mode DJI Mavic 3T Thermal, was used to capture high resolution images of facades and upper areas of the building complex that were not accessible through conventional inspection methods (Figure 7). The aerial survey enabled precise documentation of upper areas while minimizing physical intervention, Additionally, thermographic data were acquired using the UAV's thermal camera (Figure 8).

However, some limitations were identified during the process, particularly related to the presence of exposed electrical wiring and surrounding vegetation, resulting from the continuous use of the building. These factors affected image quality, especially at ground and first-floor levels. As a result, complementary in situ photographic records were required to support visual data acquisition.

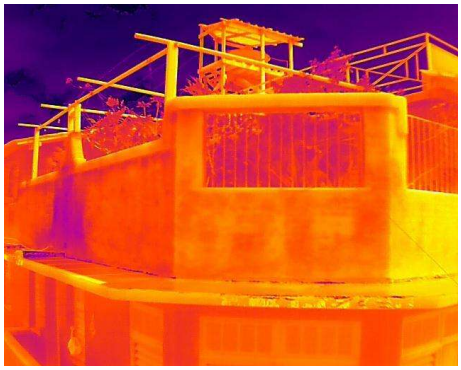

Figure 7 – Image captured by UAV. **Figure 8** – Thermography by a UAV's thermal camera.

3.1.1 On-site and photographic survey

For the in situ survey, both digital laser measuring devices and steel measuring tapes were used to obtain dimensional data for each apartment. Photographic records were also collected for all units where access was granted, documenting not only deviations from the original layout but also pathological manifestations relevant for future maintenance.

The acquisition of photographic data from both internal and external areas enabled systematic documentation of the current condition of the buildings, as well as the modifications carried out over time (Figure 09 and 10).

Figure 9 Staircase built by residents. **Figure 10** – Exposed Rebar.

3.1.2 Point Cloud

Based on the data obtained from UAV and in situ surveys, a point cloud of the Dona Bela building complex was generated (Figure 11). This dataset served as the basis for the development of the three-dimensional model and for the identification of pathological manifestations. This approach aligns with recent HBIM implementation strategies, which integrate multiple data acquisition techniques to support heritage conservation processes (Vieira *et al.,* 2023).

It was observed that the quality of the point cloud varied throughout the building. Higher accuracy was achieved in upper areas, such as the roof and second floor, where external interferences, such as electrical wiring and vegetation, were absent. In contrast, ground and first-floor levels presented lower data quality due to these obstructions, which limited visibility and data capture.

Despite these constraints, the point cloud enabled the identification of several facade pathologies and supported the development of the building's 3D model (Figure 12).

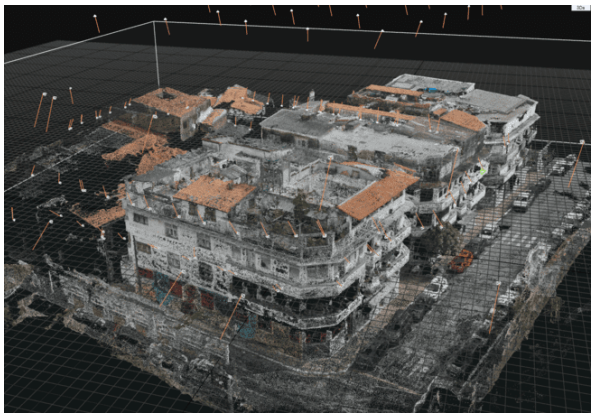

Figure 11 Dona Bela point cloud.

Figure 12 Pathologies detected on the facade.

3.1.3 3D modelling

Based on the collected data, an information model was developed using BIM software (Figure 13). The Dona Bela complex was modeled on Revit®, and subsequently exported to the Industry Foundation Classes (IFC) format to allow interoperability with other platforms and collaborative data enrichment among the research team.

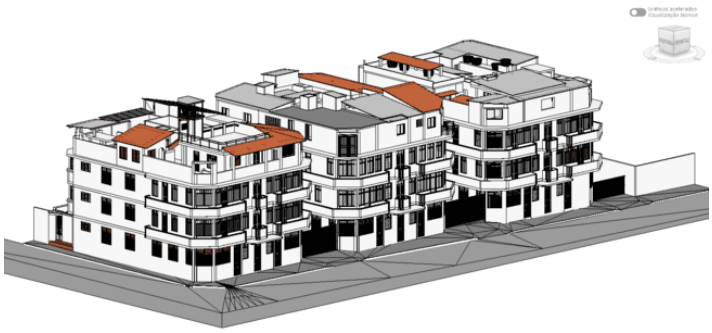

Figure 13 Dona Bela 3D modelling

The BIM model supported the development of damage maps for both facades and floor plans, which were incorporated into the technical pathology report.

3.1.4 Damage map

A technical report of pathological manifestation was developed, integrating all documented processes, in situ photographic records, and the categorization of pathologies by type, building, block, and apartment unit. The identification and classification of pathological manifestations were guided by established criteria from construction pathology studies.

Images captured by the UAV served as the basis for identifying and recording the detected pathologies. Additionally, the BIM model created in Revit enabled the creation of damage maps for both the facades and the floor plans of the Dona Bela Complex.

Pathological manifestations were modeled in the BIM environment using generic model families. During this process, challenges were encountered regarding the geometric representation of pathologies, particularly in defining their shapes and in cases where multiple pathologies overlapped within the same area. For larger and continuous pathologies, linear demarcations were adopted to represent their spatial propagation across extended surfaces.

Following the modeling process, specific parameters were assigned to each pathology, including location data such as building name, block, facade or internal view, and floor level. In addition, visual coding

strategies, such as color differentiation and graphical markings, were applied to enhance identification and to ensure consistency with the damage mapping system.

Furthermore, an image parameter was implemented to associate photographic records with each modeled pathology, enabling the integration of visual documentation and facilitating the identification and classification of pathological manifestations within the BIM environment.

4. Results and Discussion

The results of this study are focused on the identification of pathological manifestations affecting both facades and internal environments of the residential units within the Dona Bela Complex. The main damages identified include coating detachment, cracks, infiltration, loss of elements, moisture-related deterioration, oxidation, and surface soiling, indicating different stages of degradation over time, combined with material aging and exposure to environmental conditions. These findings reinforce the need for a systematic maintenance plan for the historic building.

The development of the technical pathology report enabled the visualization of damages in each residential unit by block, as well as the categorization of pathologies and the corresponding damage maps. This structured systematization supports both documentation and future decision-making processes related to maintenance and management.

The categorization of pathologies was carried out using an alphanumeric coding system designed to ensure traceability and systematic data organization, contributing to the informational enrichment of the damage maps. The identification was structured by block, location (internal or external), and floor level. For example, in Block C, facade images were labeled with the code CF followed by a numerical identifier (Figure 14), while ground-floor units were labeled with codes beginning with C followed by numbering (Figure 15). For instance, C101 refers to Block C, ground floor, unit 1. This standardization enabled the structured organization of photographic records and identified pathologies, facilitating analysis and comparison across different areas of the building.

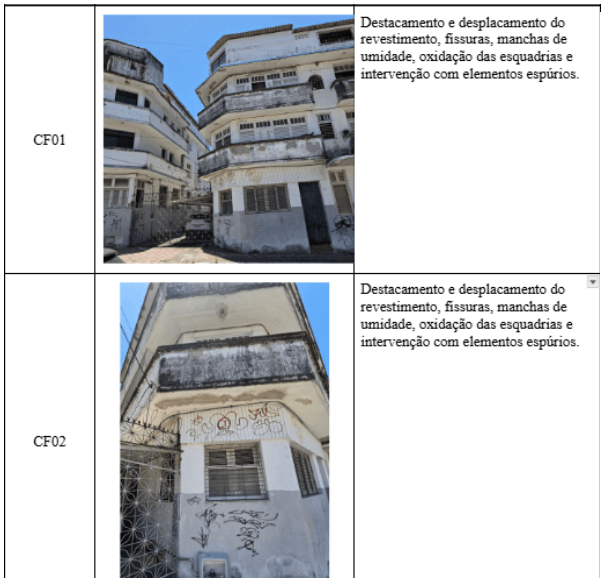

Figure 14 Categorization of block C facades.

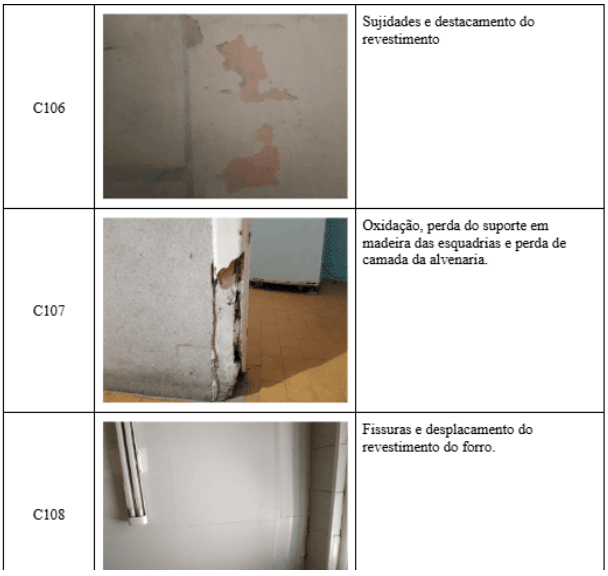

Figure 15 Categorization ground floor block C.

Based on this categorization, damage maps were developed for both facades (Figure 16) and residential units in floor plan representation (Figure 17). These maps enabled a systematic visualization of the spatial distribution of pathologies, as well as the identification of damage concentration in specific areas, particularly those exposed to weather conditions and water accumulation, such as the building facades.

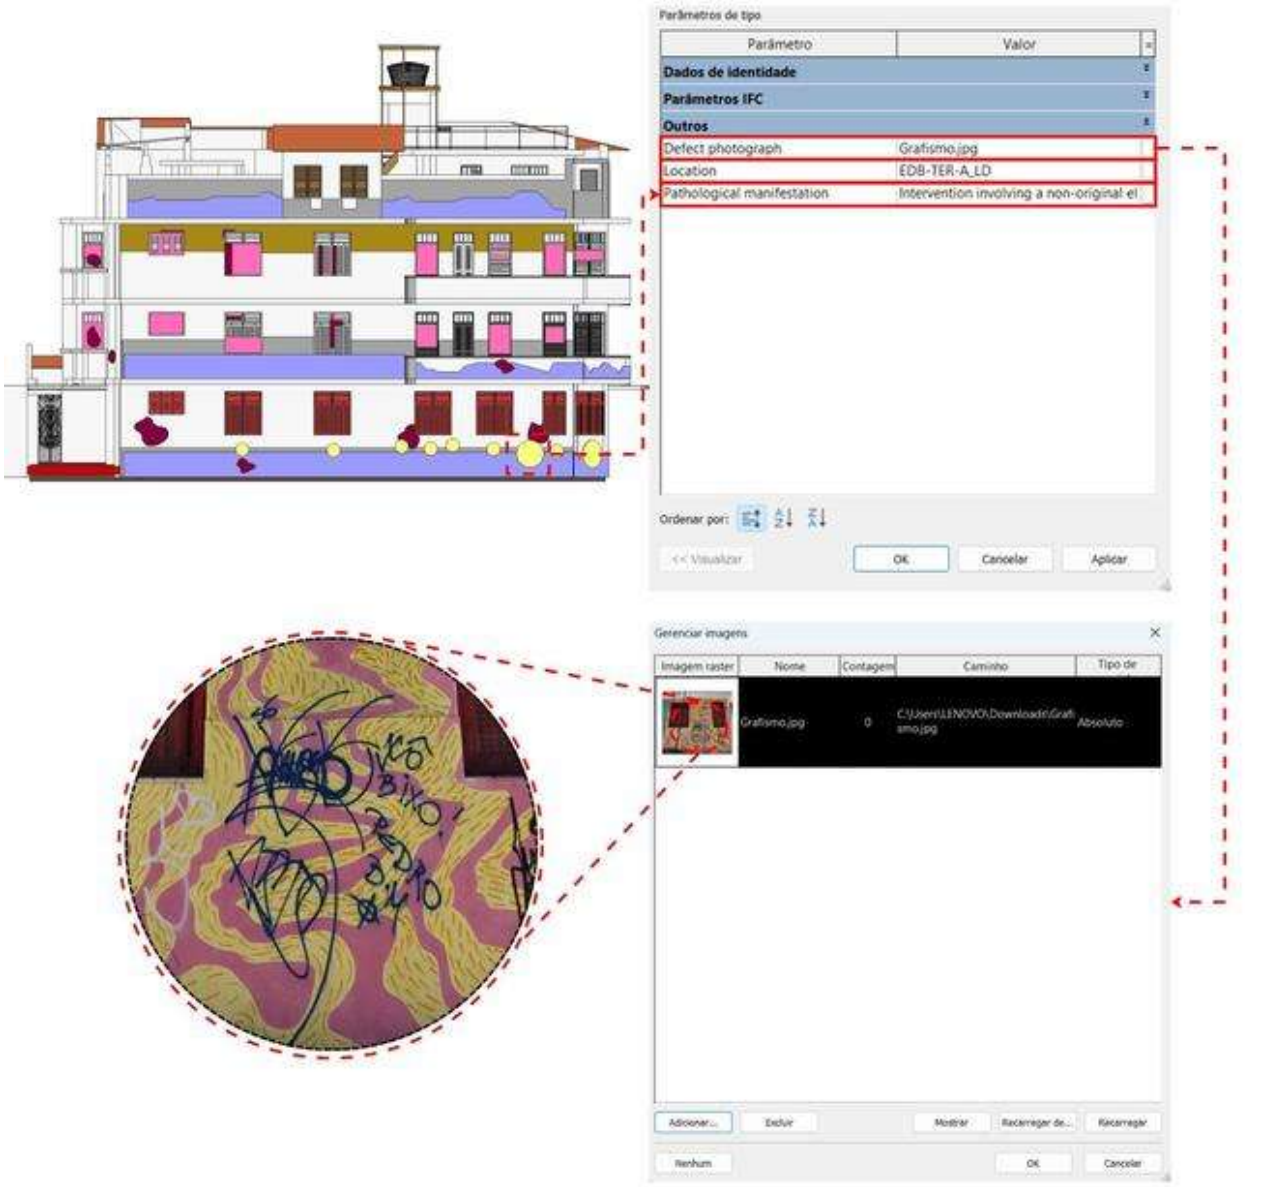

Figure 16 Damage map Block A facade.

Figure 17 Damage map housing unit

The analysis of internal environments revealed significant modifications to the original layout due to interventions carried out by residents, These changes include the creation or removal of spaces within each unit, reflecting spatial adaptations to contemporary needs. Additionally, a greater variability of pathological manifestations was observed, indicating the combined influence of the lack of systematic maintenance and interventions performed without proper technical supervision over time.

The results demonstrated a predominance of pathologies related to humidity. Among the manifestations identified, 19.8% correspond to infiltration stains, 19.1% to coating detachment, 13.5% to cracks, 11.5% to coating flaking, 7.6% to dirt, while other pathologies such as yellowing, oxidation, and loss of elements accounted for lower percentages.

On the facades, for example, the most recurrent pathological manifestations were coating detachment, cracks, surface soiling, and oxidation process. These areas exhibited a higher concentration of pathologies when compared to the internal environments, a condition associated with continuous exposure to solar radiation, rainfall, and humidity variations. These results corroborate studies that relate climatic exposure to the aging and progressive degradation of historical buildings. (Xavier et al., 2022)

Furthermore, the analysis indicated significant differences in the concentration of pathologies among the blocks of the complex. Block C, for instance, presented fewer internal modifications when compared to the others blocks, preserving the original spatial configuration of the floor plan in several residential units and exhibiting a lower incidence of interventions carried out by residents. In contrast, substantial alterations were observed in the roof areas of all three blocks over time. Originally intended for laundry and service functions, these spaces have gradually been adapted to accommodate new uses and annexes constructed by residents. Such interventions not only altered the original spatial typology but also directly influenced the conservation conditions of the building, particularly due to the overlap of constructions materials, successive architectural adaptations, and the lack of adequate technical supervision throughout the years.

The condition of continuous use of the building, combined with ongoing modifications, proved to be a determining factor in the heterogeneous distribution of pathologies. Furthermore, restricted access to certain units limited data collection, highlighting a common challenge in studies involving inhabited historical buildings. This condition reinforces the need for integrating multiple survey techniques, as adopted in this study, as well as flexible methodologies capable of addressing operational constraints and ensuring reliable data acquisition in contexts of continuous occupation.

5. Conclusion

Through the integration of technologies applied to data acquisition for assessing the current state of conservation of Dona Bela Complex, it was possible to identify and analyze the various pathological manifestations present in the building. Based on these data, an updated technical diagnosis was developed, supported by the production of damage maps to assist decision-making processes, enabling a more comprehensive understanding of the current conditions of the complex.

Furthermore, the results revealed that pathological manifestations are heterogeneously distributed across both residential units and facades, being directly associated with material exposure to environmental factors, as well as the lack of systematic maintenance and the absence of technical supervision over interventions carried out over time.

The integrated use of UAV systems, photogrammetry, point cloud generation, and three-dimensional modelling proved to be effective for the documentation and diagnosis of the identified pathologies. Even within a context marked by visual and spatial constraints, the combination of these tools enabled the acquisition of accurate findings to reinforce the potential of damage mapping and systematic data organization as key tools to support decision–making in maintenance and conservation processes.

Overall, this study highlights the importance of integrating these technologies, as well as the need for developing protocols that enable continuous monitoring of conservation conditions in inhabited historic buildings. In this sense, the integration of digital technologies and technical diagnosis represents a promising approach for the conservation and preservation of built historical heritage.

Abstract: The use of digitization technologies has become a highly valuable tool in the documentation of built heritage. Equipment such as drones and laser scanners enables more accurate building mapping, facilitating the creation of HBIM (Heritage/Historic Building Information Modeling) models. This paper aims to detail the 3D modeling process for the Dona Bela building, a modernist structure of historical significance in the city of Fortaleza, Brazil. For this process, digital surveys were conducted using photogrammetry and thermography with drones, as well as traditional surveying methods. As a result, a point-cloud-based 3D model was generated that presents in detail the characteristic elements of the façades, as well as their pathologies. Thus, the effectiveness of these technologies in the documentation and preservation of built heritage is evident.

Keywords: Point-cloud, HBIM, Digital documentation, Digitization, Built heritage.

1. Introduction

Historical heritage is fundamental to the culture and identity of a people. For both tangible and intangible heritage, the documentation of the asset is essential, as it is through such documentation that we comprehend the history and relevance of the heritage, and enable actions for its preservation and protection (Cardellicchio et al., 2024). However, we emphasize here the importance of documenting built heritage, which encompasses construction methods, structural and architectural elements, and condition assessment reports, among other aspects. Evidently, the process of acquiring and preparing this documentation requires a high degree of precision and data processing (Ribeiro et al., 2025). In the case of in loco data acquisition, such as the technical surveying of the building or the preparation of a report on its state of conservation, the acquisition process becomes a challenge. The methodology of acquisition using tape measures, sketches, and photographs, although still common, entails inaccuracies and is more time-consuming. In cases involving the detailing of façades, balconies, and roofs, access is often unfeasible, and it also poses risks to the professional in charge, especially when dealing with historical buildings, which frequently exhibit an advanced state of deterioration (Fidelis et al., 2024).

Given this fact, the use of digitization equipment, such as laser scanners and photogrammetry, greatly assists the data acquisition process, serving as an efficient and safe alternative with greater informational richness. Through these technologies, it is possible to produce three-dimensional models with a high degree of fidelity (Rubens et al., 2023) that, in addition to serving as heritage documentation (Merzhiievska et al., 2026), also allow for the management and maintenance of the building (Aroquipa et al., 2025), as well as serving as an instrument for heritage education, whether through its use in educational institutions or by making digital models available on the internet, enabling access to both researchers and the general public worldwide (Kilis et al., 2025).

It is important to emphasize that when it comes to the digitization of built heritage, the management of this data constitutes a multidisciplinary field that requires the participation of specialists from the areas of architecture, engineering, conservation and restoration, computer science, and many others (Vieira et al.,

2023). Furthermore, for a multidisciplinary team to manage this quantity of data throughout the entire life cycle of the heritage asset, the use of an integrated information system that allows for interoperability between all its agents is necessary (Allegra et al., 2020; Apollonio et al., 2019). Information modeling software acts in this space by providing the necessary instrumental and methodological subsidies for this demand (Dionizio and Dezen-Kempter, 2025).

First introduced by Murphy et al. (2013), Heritage/Historic Building Information Modelling (HBIM) consists of an approach for constructing parametric models in a BIM (Building Information Modelling) environment for existing buildings, based on historical data and captures via photogrammetry and laser scanning. Since then, much has been contributed to the field, whether in the proposal of protocols (Ribeiro et al., 2025), in the definition of methodologies (Rubens et al., 2023), or in the digitization of buildings of historical relevance (Fidelis et al., 2023), which has facilitated the establishment of the HBIM approach as a current practice in the documentation, preservation, management, and accessibility of built heritage.

Based on this, the objective of this paper is to present the high-resolution aerial photogrammetry and thermography acquisition process for the production of a three-dimensional model of the Dona Bela building, a historical construction located in the center of Fortaleza-CE. With the use of a drone and the RealityScan® tool, the captured images were converted into a three-dimensional model and a point cloud of the building.

2. Dona Bela Building — historical and architectural details

Erected in the second half of the 1950s, the Dona Bela building is the first in the city of Fortaleza intended exclusively for residential purposes (Cavalcante, 2021). Located at Rua Coronel Ferraz, nos. 26-76, in the *Centro* neighborhood, it features rounded-corner balconies that surround its façades and extend over the sidewalks in composition with its generally straight corners. Such characteristics, combined with marquee-type slabs, monochromatic finishes, and wooden shutter frames, evidence the stylistic appreciation of the developments by Imobiliária Pedro Philomeno, responsible not only for the Dona Bela Building but for other emblematic architectural projects in Fortaleza: the Lord Hotel (1956), also located in the city center, and the Iracema Plaza Hotel (1951), commonly known as the Edifício São Pedro, which achieved the distinction of being the first luxury hotel built on the Fortaleza coastline (Gomes, 1988). All three developments present architectural characteristics of a clear modernist tendency — something considered innovative at the time, the style of which only officially began in the capital in the late 1950s[1].

Designed as 3 apartment blocks, each with 3 floors, with 2 apartments per floor, totaling 18 apartment units[2], the building — which can be seen in Figure 1 — had its provisional heritage listing opened on June 30, 2016 (Secultfor, 2016). According to the technical opinion issued on November 18, 2015, the architectural relevance of the Dona Bela building and its sister buildings "represents visionary attitudes in the city" (Secultfor, 2015). Beyond the architectural level, the building also plays an important role in the city's cultural identity, as it hosts various cultural projects, such as *Casa Sônica*—a space dedicated to musical realization and a laboratory for sound performances (Secult, 2025)—and the *Salão das Ilusões*, which has inhabited the space for 16 years and is an important catalyst for cultural projects in the areas of visual arts, fashion, music, scenography, and gastronomy (O Povo, 2018). Such historical relevance reinforces the importance of its preservation, both physically and documentally.

[1] It is only in the late 1950s that the first moment of modern architecture in Fortaleza emerges, when newly graduated architects from Ceará, such as José Liberal de Castro, José Neuson Braga, Ivan Brito, and others, return to the capital and bring debates about the trend practiced in Rio and Recife (Paiva and Diógenes, 2017).

[2] Over the years, the morphology and use of the spaces have been altered, so that, currently, the upper floor, originally intended for laundry rooms, has been re-adapted to accommodate new apartment units, just as some lower apartments have undergone reconfigurations.

Figure 1 – Dona Bela Building. Source: Authors, 2025.

Today, ten years after the issuance of the provisional heritage listing, the building still remains without definitive listing, suffering from a process of progressive deterioration and undergoing small renovations exclusively at the initiative of the tenants, which reinforces the importance of urgent heritage safeguarding actions.

Given this, due to the *Edital de Fomento ao Patrimônio Cultural Edificado*, carried out by the *Secretaria Municipal da Cultura de Fortaleza* (Secultfor), with funding from the *Política Nacional Aldir Blanc de Fomento à Cultura* (PNAB), a new survey of the building was carried out to prepare a technical report on the current state of conservation of the building, for the purpose of forwarding to the definitive heritage listing registration of the building. The present work is part of the actions of this project.

3. Materials and methods

The digitization process of the Dona Bela building follows the HBIM protocol (Figure 2) and ranges from the gathering of technical documentation and historical information of the building to the equipment and tools to be used and the level of detail necessary for the documentation (Rubens et al., 2023). This complete protocol is divided into four stages: planning, acquisition, processing, and BIM modeling. Since the scope of the present work was to collect data on the pathologies of the roof and upper floors, as well as to produce a low-density point cloud, only for the purposes of complementation and compatibility with the technical survey of the internal areas of the building, this work will be limited to the first three stages of the protocol, which will result in the construction of the building's point cloud.

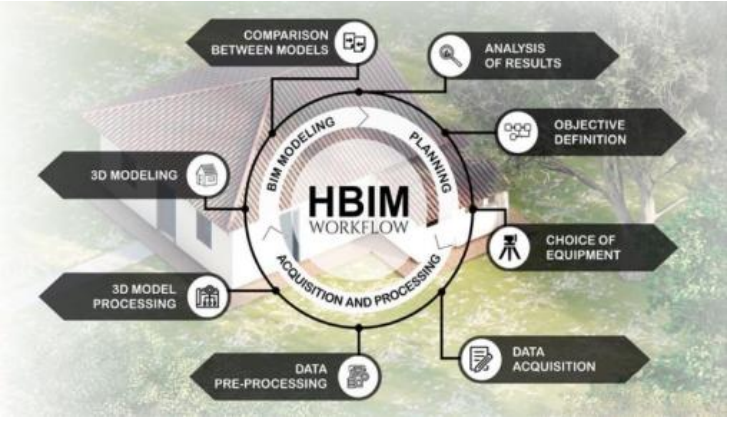

Figure 2 – HBIM procedural workflow. Source: Rubens *et al.*, 2023.

3.1 Planning

Before starting the building data acquisition, it is necessary to conduct a preliminary study based on the construction's historical and archival documentation. This stage is fundamental for us to know the past of the building and understand its present state (Bruno and Roncella, 2018). Consequently, it is necessary to establish some definitions: what is the objective of the model and what are the acquisition equipment. These prior definitions are important because the product to be generated and the equipment to be used must be aligned with the purpose of the model. Along with this, it is also necessary to define the mode of acquisition, the level of precision, and the form of data storage. For the case of the Dona Bela building survey, documentary research was carried out in the literature, newspaper reports, and official documents that present information regarding the history of the building, original plans, and construction methods, in addition to reports from tenants about changes made over the years. Such information was valuable for us to have a general scope of the construction and thereby guide our approach regarding our objective.

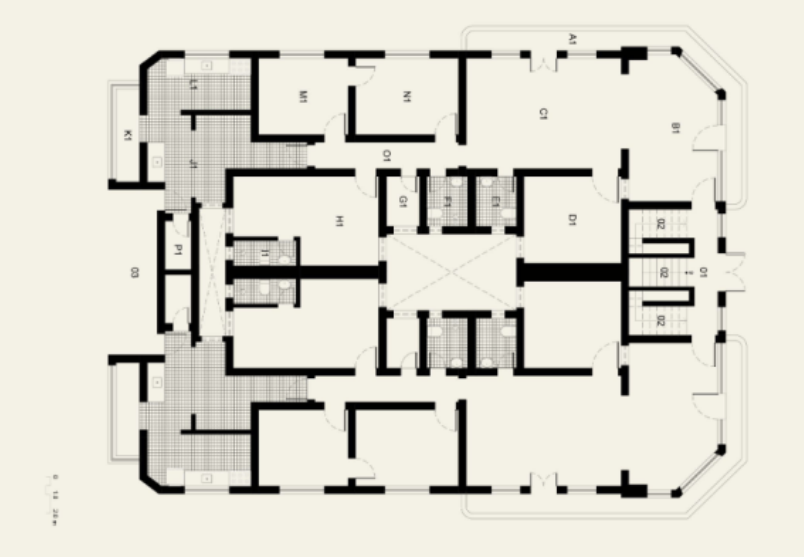

Figure 2 – Typical floor plan. Source: Cavalcante, 2021.

3.2 Data acquisition and processing

Following the planning stage, the data acquisition and processing phase begins. This moment is subdivided into three instances: capture, pre-processing, and point cloud processing. In the capture phase, it is necessary to analyze the building's surroundings and identify which elements may cause visual obstruction to the equipment. Conditions such as the weather, vegetation, and public utility wiring can compromise or even make the capture unfeasible. In the survey in question, the presence of vegetation and public utility wiring on the building's front façade was observed, which compromised captures at the first and second-floor levels, conditioning the flight to favor top and upper-floor captures. It is important to emphasize that, as it is a public area and a residential building owned by third parties, it is necessary to request flight permission. As this survey comprises an action that integrates a public notice, such requests, both from the city government and the tenants, were already granted in advance.

The equipment used was a DJI Mavic 3T Thermal drone model (Figure 3), which performed an overflight over the roof and in front of the façades of the 3 apartment blocks.

Figure 3 – DJI Mavic 3T Thermal. Source: Authors, 2025

Equipped with three high-resolution cameras—a 48MP wide lens with 1/2-inch CMOS, a 12MP telephoto lens with 1/2-inch CMOS and hybrid zoom capacity of up to 56x, and a thermal lens that provides data on point and area temperature, high-temperature alerts, color palettes, and isotherms. 204 images of 4000 x 3000 pixels (Figure 4) and 204 thermal images of 640 x 512 pixels (Figure 5) were captured, with a 2-second interval between each capture. This interval between captures is important to ensure corresponding texture and volumetric elements between images, enabling overlap, a factor necessary for producing a detailed 3D model of the building. Only one day was necessary for the acquisition of the aerial photogrammetry of the building.

Figure 4 – Façade and rooftop of Dona Bela building captured with DJI Mavic 3T high res lens. Source: Authors, 2025.

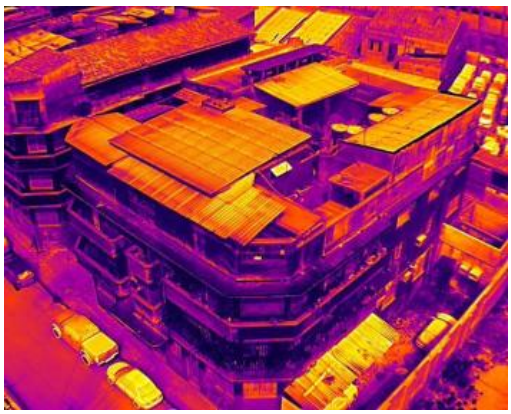

Figure 5 – Façade and rooftop of Dona Bela building captured with DJI Mavic 3T termal lens. Source: Authors, 2025.

The pre-processing phase consists of the preparation of the three-dimensional model. The software used was RealityScan®, which allows aligning and converting the photogrammetry of the building into a 3D model mesh (Figure 6) and a point cloud (Figure 7). The intent of this 3D model is to document the pathologies of the roof and façades of the building, as well as those of its architectural elements, while the point cloud provides the volumetric data of the building.

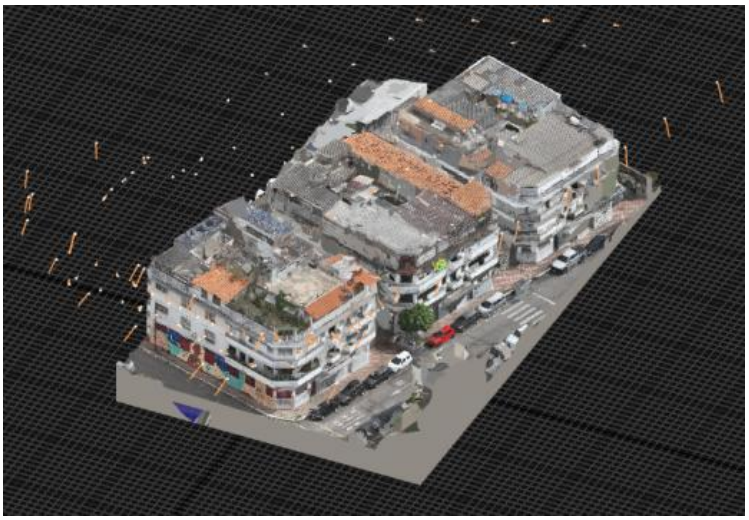

Figure 6 – 3D Model of Dona Bela building on RealityScan®. Source: Authors, 2025.

Figure 7 – Point cloud-based model on RealityScan®. Source: Authors, 2025.

4. Results and discussions

The photogrammetry performed with the drone allowed for the generation of a three-dimensional model of the building with practicality, efficiency, and safety, making it possible to represent both the architectural elements and the pathologies present on the façades and roof, both with a high level of detail, which is impractical through traditional survey techniques. The details of the façade and the pathologies can be observed in Figure 8.

Figure 8 – Façade details and pathologies on 3D model. Source: Authors, 2025.

The aerial thermography captured allowed us to analyze the heat distribution in the building. When this type of mapping is performed, the temperature difference can be visualized in the images, allowing for the identification of infiltrations without the use of invasive methods, an intervention not recommended in historical buildings (Cruz et al., 2024). Such analysis enables the immediate conclusion of some causes of pathologies. For example, in Figure 9, we can identify the region of lower temperature (in violet), which indicates the occurrence of infiltration as the cause of the pathology, as indicated in Figure 10.

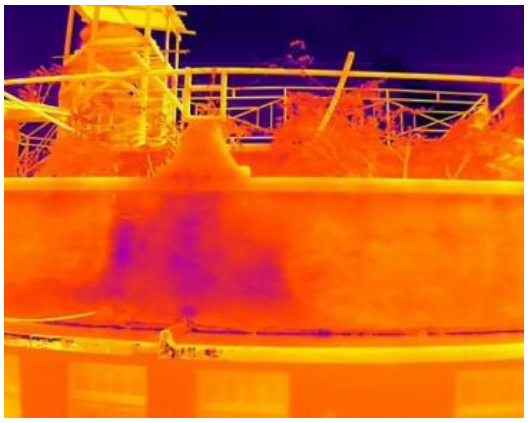

Figure 9 – Humidity detected with thermal camera. Source: Authors, 2025.

Figure 10 – Pathology related to detected humidity. Source: Authors, 2025.

The level of detail obtained with the 3D model allowed for the construction of a point cloud with 536,725 points. An analysis carried out in the RealityScan® software showed that the quality level of the top captures was superior compared to the captures perpendicular to the ground, especially of the façades at the first and second-floor levels, which corroborates the flight plan carried out by the drone. However, the quality level obtained meets the expectations of the work, since the model complements the data collected by the traditional survey method. The result of the analysis can be seen in Figures 11 and 12.

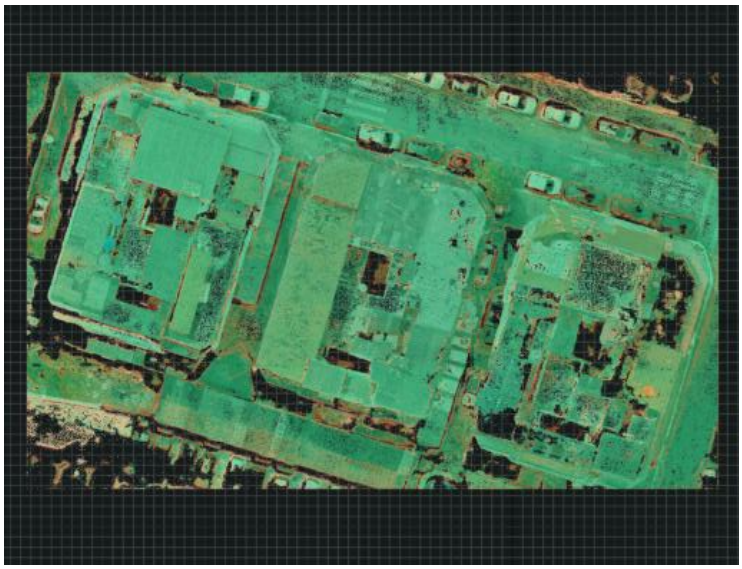

Figure 11 – Mesh quality analysis of top view captures. Source: Authors, 2025.

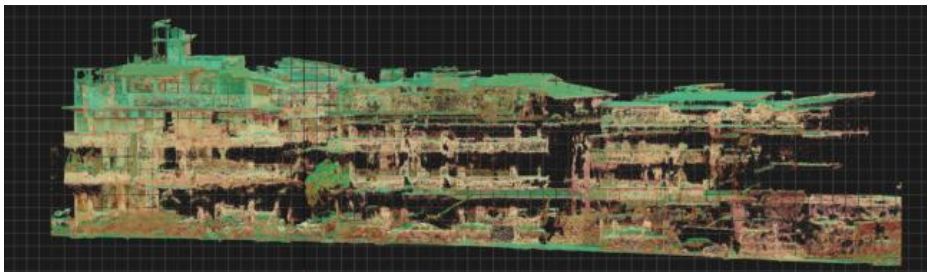

Figure 12 – Mesh quality analysis of side view captures. Source: Authors, 2025.

All data collected in this survey, especially the model built through aerial photogrammetry, are vital for the creation of an HBIM model of the building. Such data allow for the construction of parametric families and the mapping of the building's structural and pathological elements, which enables not only the updating of heritage documentation but also its preservation and management and re-adequation actions of the property in more efficient and precise ways.

5. Conclusions

Through the study conducted on the Dona Bela Building, it was verified that the use of aerial photogrammetry and thermography proved to be an efficient and promising method for surveying built heritage. Therefore, it can be concluded that:

- Aerial photogrammetry provided dimensional, aesthetic, and pathological manifestation information necessary for the construction of an adequate 3D model of the building, serving as both a source of geometric data and documentation of the built heritage;
- Thermography provided conclusive data on the heat distribution in the building, enabling a quick and efficient diagnosis of pathologies associated with humidity, without the need for invasive interventions in the structure, ensuring its integrity.
- The point-cloud-based model reached the expected quality level, providing reliable geometric data for the preparation of a BIM model.
- The study showed that the use of digitization technologies is a good ally for mapping pathologies and technical surveying of historical buildings, providing precise data efficiently and safely.
- Situations in which it is not possible to carry out a complete flight plan around the building, due to visual obstructions, impose the use of complementary capture techniques to improve the level of

detail of the model, which can be terrestrial photogrammetry or laser scanner survey. Such approaches need to be evaluated during the planning stage.

Abstract: Currently, the digitalization of architectural heritage through photogrammetry and 3D scanning has established itself as a fundamental strategy for preservation and documentation, with the point cloud of buildings as its central product. Although frequently used as a reference for Building Information Modeling (BIM), point clouds also possess aesthetic and informative potential, allowing them to be manipulated as visual material in immersive exhibitions focused on heritage education. In this sense, this work systematizes production techniques and design decisions for an immersive experience based on point clouds within a museum context. The research reports on the development of the exhibition “Do Ponto ao Patrimônio” (From Point to Heritage), presented at the Museum of Image and Sound of Ceará (MIS-CE) in an immersive environment known as “Tear da Experiência” (Experience Loom), as part of the Chief Scientist Program for Culture of Ceará, held in 2024 in a room equipped with a Computer Assisted Virtual Environment (CAVE) system. The main objective is to evaluate the effectiveness of this immersive approach in fostering heritage awareness. The methodology involved an empirical assessment with 14 visitors, triangulating semi-structured interviews with Likert-scale questionnaires. Point clouds were processed and stylized in Blender, with an emphasis on procedures via Geometry Nodes for composing camera movements, density and opacity variations, dissolution and distortion effects, and the construction of visual rhythms consistent with the narrative. Results indicate that the immersive experience acts as a mediator of memory, facilitating affective engagement and critical awareness regarding heritage loss, particularly in the case of the demolished São Pedro Building. Finally, the set of language and performance strategies that sustained the readability and artistic character of the CAVE experience are discussed, pointing out limitations and recommendations for future exhibition designs involving point clouds.

1. Introduction

As cities expand, the conflict between urban growth and the preservation of cultural heritage becomes a complex management challenge. Policies fail to protect architectural heritage and its historic buildings from wars, uncontrolled tourism, and unregulated urbanization (UNESCO, WHC. World Heritage in Danger, 2021), a scenario that often results in demolitions and the disfigurement of monuments, especially in the southern hemisphere. In this context, the adoption of participatory approaches — which recognize the local community as a central agent in protection policies — becomes essential. Engaging and raising public awareness through formal and non-formal educational experiences (FRULLO; Mattone, 2024) can serve as a tool to strengthen the sense of belonging and the urgency regarding the preservation of built heritage.

The use of museums as spaces that promote heritage education is widely advocated by Van Boxtel, Grever, and Klein (2016), since these institutions offer objects and narratives capable of connecting the public to their own history. Recently, the digitization of architectural heritage through photogrammetry and 3D laser

scanning has become a fundamental strategy for preservation and technical documentation (Penjor et al., 2024). The main product of this process is the "point cloud": a dense set of three-dimensional coordinates that captures the geometry and appearance of a structure with high precision.

Although point clouds are often used only as a reference for modeling in Heritage Building Information Modeling (HBIM), they have an intrinsic aesthetic and informative potential, and can be manipulated as primary visual material in immersive exhibitions, functioning as an alternative to involve technological advances and heritage education in the same context. Gabellone (2023) presents the Virtual Neapolis project, which aims to promote heritage sites and the history of the city of Naples through a Virtual Reality (VR) experience. To build the tour, tools such as photogrammetry (which can generate a point cloud and a mesh), 3D modeling, virtual restoration, among others, were used.

In this sense, this work aims to present the production techniques and design decisions involved in the development of an immersive experience based on point clouds. The article reports on the development of the exhibition "From Point to Heritage," presented at the Museum of Image and Sound of Ceará (MIS-CE) in 2024. To explore the exhibition as a tool for public awareness, this study conducted an empirical evaluation with 14 participants. The methodology adopted a mixed-methods approach, triangulating semi-structured interviews with a Likert-scale questionnaire. This phase indicates how immersion influences public perception of heritage and willingness to engage in preservation.

From a scientific point of view, the article contributes in four fronts: (1) it systematizes a workflow for transposing point clouds into immersive audiovisual narratives; (2) it discusses point clouds not only as a technical support for modeling, but also as a visual, aesthetic, and educational language; (3) it proposes an interpretation of the experience based on the relationships between heritage mediation, narrative, and attention; and (4) it indicates empirical insights regarding the potential of immersive technologies in promoting heritage awareness.

2. Theoretical Framework: The Aesthetics of Point Clouds and Heritage Education

Three-dimensional documentation through laser scanning and photogrammetry is often reduced to its metric utility in engineering and architecture, traditionally being used as a basis for digital modeling in the Scan-to-BIM and HBIM workflows. In this field, the point cloud serves as a support for geometric recording, documentation, analysis, and modeling of historical buildings, although important challenges persist regarding interoperability, process automation, and the translation of complex geometries, deformations, and irregularities of the built heritage into consistent parametric models (Vieira et al., 2023; Cotella, 2023; Penjor et al., 2024).

However, beyond this technical use, the point cloud can also be understood as an expressive medium, endowed with aesthetic, narrative, and educational potential. Recent studies show that its discontinuous, translucent, and spectral visuality can be explored as its own visual language, both in artistic practices and in immersive applications aimed at heritage mediation. In this sense, the point cloud ceases to operate merely as an intermediate step in modeling and begins to be used directly as a rendering asset, interactive storytelling, and museum experience, favoring sensitive ways of approaching landscapes, buildings, and processes of historical transformation (Gabellone, 2023; Ivsic, McCormack, and Dziekan, 2023; Lei, Fiorillo, and Fassi, 2024; de Kleijn et al., 2024).

In the debate on motivation and learning in museums, Csikszentmihalyi and Hermanson (1995) offer a central contribution to this research by understanding the museum experience not as a simple transmission of information, but as an expanded form of learning, involving cognitive, sensory, and emotional dimensions. Starting from the idea that attention is a scarce and contested resource, the authors argue that the visitor's experience depends on the environment's ability to mobilize curiosity, interest, and engagement through qualities such as novelty, surprise, complexity, and ambiguity. These elements function as stimuli capable of attracting and sustaining the subject's psychic energy, favoring exploratory behaviors and paving the way for states of intrinsic motivation. In this context, the concept of flow becomes especially relevant, as it designates a condition of deeper engagement, in which there is a balance between the challenges proposed by the experience and the visitor's willingness to face them.

This understanding directly dialogues with the perspective adopted in this research and with the **Experience Loom** model, developed by Ricca (2023), in which design is conceived from the articulation between different attentional layers and their transitions. In the thesis, the author proposes the so-called attention-based design as a means of structuring experiences capable of guiding the subject from more peripheral and automatic levels to more focused and reflective levels, with everyday education as a horizon of mediation. From this perspective, the experience depends not only on the content presented, but on the way stimuli, rhythms, forms, and relationships of interest are organized over time, constituting a true narrative of attention. This formulation is particularly fruitful for the field of heritage education, as it allows us to understand the immersive experience as a mediation that not only informs about heritage, but also seeks to capture, guide, and sustain the public's engagement with its memory, its symbolic dimension, and its cultural permanence.

From this perspective, the visitor's brain is prompted to fill in the "gaps" between the bright points of the cloud, making a cognitive and perceptual effort that can favor states of greater engagement with the historical object. The point cloud then ceases to operate merely as a technical record and begins to function as a visual and narrative language, capable of articulating estrangement, curiosity, contemplation, and reflection. It is within this framework that the exhibition From Point to Heritage is situated, a work of the subproject "Technology and Innovation of the Cultural Heritage of Ceará," linked to the Chief Scientist of Culture Program. Conceived as an immersive audiovisual heritage education experience, the exhibition uses the deconstruction of the point cloud to guide the viewer on a journey among buildings that are part of the history of Ceará. The following details the methodological procedures and technical choices that enabled the transposition of the point cloud into the immersive environment.

3. Methodology

This work is characterized as applied research, with a qualitative approach, with exploratory and descriptive objectives, developed through a case study of the immersive exhibition From Point to Heritage (Gil, 2002; Creswell and Poth, 2018; Yin, 2018). The investigation systematizes the technical workflow and design decisions involved in transforming point clouds into an audiovisual exhibition narrative, encompassing the stages of data collection, processing, optimization, and animation.

In the field of design, the study approaches the Research through Design perspective, since the conception and materialization of the exhibition artifact also operate as a means of producing knowledge about processes, visual strategies, and heritage mediation (Frayling, 1994; Zimmerman, Forlizzi, and Evenson, 2007). From a practical point of view, the transformation of point clouds into a fluid exhibition narrative requires interaction between professionals from various fields: architecture, engineering, design, visual arts, and digital media systems. As analytical corpus, the script, storyboard, and decisions regarding capture, processing, deciphering, animation, and audiovisual editing of the exhibition were considered, understood as design evidence of the case study. The analysis focused on identifying how these technical and narrative decisions contributed to: (a) the visual legibility of the point clouds, (b) the construction of an immersive environment, and (c) heritage mediation through strategies of attention, contemplation, and reflection. Therefore, the workflow was divided into four phases, presented below.

3.1 Building Survey Process:

The digitization encompassed eight emblematic buildings of Ceará's heritage, with different typologies, construction materials, and states of conservation, namely the José de Alencar Theater, the Pinacoteca do Ceará, the MIS-CE, the School of Arts and Crafts, the São Pedro Building, the São Luiz Cinema-Theater, the Church of Our Lady of the Rosary of Black Men, and the Parish Church of Our Lady of the Rosary. Of the eight buildings mentioned above, the first six are located in Fortaleza/CE, while the last two are in the city of Aracati/CE. The survey adopted a hybrid approach so that the buildings could be scanned with the greatest possible coverage:

- **Terrestrial Laser Scanner (Leica BLK 360)**: Responsible for capturing external terrestrial and internal environments of the buildings, scanning the geometry through point clouds and the colors through panoramic photographs.

- **Aerial Photogrammetry (DJI Phantom 4)**: Used to record roofs, domes, and upper facades, completing the building's volumetry through a point cloud generated from digital photographs, the base files for performing photogrammetry.

In addition, some strategies were used to maximize information capture and reduce noise in the point clouds. One of the main strategies for a good survey is to have a well-defined planning phase, which is fundamental when considering the size of these buildings, which increases the number of captures required. By aligning schedules and agendas, it is possible to avoid rework by reducing the circulation of people and capture noise generated by sunlight (Vieira et al., 2023). However, even with good planning, some noise was still generated in the captures, such as people and objects, which were used as elements for the construction of the environment when interacting with the lights used in Blender.

3.2 Point Cloud Processing

After scanning the buildings, the data is extracted from the aforementioned tools and processed on computers. The laser scanner captures are processed in the Leica Cyclone Register 360 software, while the drone photographs undergo data analysis in the Reality Capture operating system, shown, respectively, in Figure 1 and Figure 2. After individual processing of the obtained data, CloudCompare is used to combine the two point clouds, resulting in the complete building represented by millions of points.

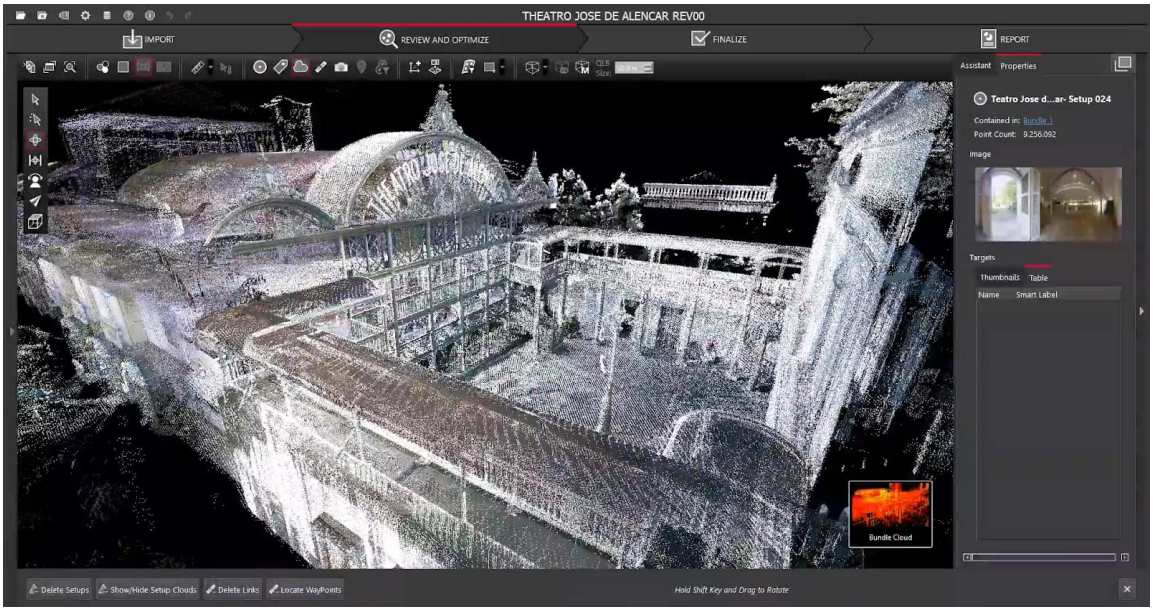

Figure 1 – Processing of the José de Alencar Theater in Leica Cyclone Register 360

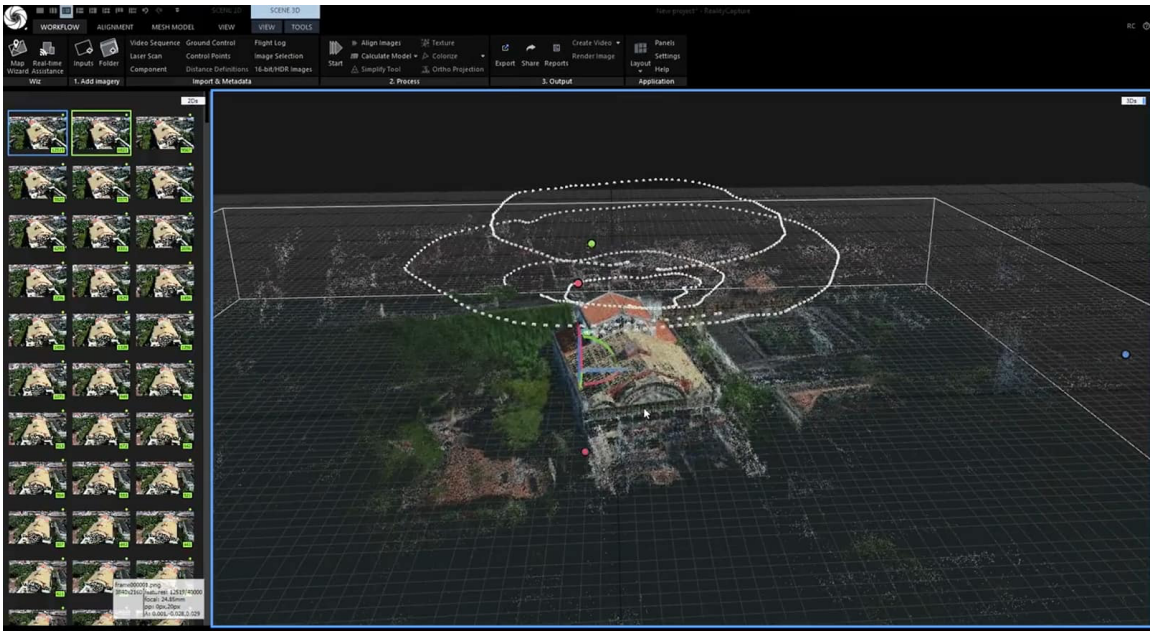

Figure 2 – Processing of the José de Alencar Theater in Reality Capture

3.3 Decimation and Optimization Strategies

To achieve the fluidity required for an immersive film, the original point clouds, containing billions of coordinates, needed to be drastically reduced while maintaining the legibility of the structural form. The Spatial Subsampling algorithm in the CloudCompare software was used. Unlike random decimation, which could destroy edges and fine architectural details, spatial subsampling ensures a constant minimum distance between points (e.g., 1 point every 5 millimeters), eliminating noise and unnecessary overlap, reducing the density to approximately 6 to 10 million points per cloud. However, in scenes with more than one point cloud, the ideal cloud density was between 1 and 3 million points, so the difference in density between clouds was used as a resource to generate contrast and highlight elements.

3.4 The Point Cloud Animation Process

To construct the immersive narrative, data from the eight digitized buildings were imported from CloudCompare into Blender software in PLY format. The structuring of the experience was based on a pre-defined script and storyboard, conceived as a contemplative and philosophical journey about the importance of historical heritage in consolidating the cultural identity of Fortaleza.

The technical configuration of the virtual environment consisted of implementing a rig of five synchronized cameras, whose proportions and fields of view replicate the projection surfaces (four walls and floor) of the immersive room at MIS-CE, which were named T1, T2, T3, T4, and T5. This setup step was important to ensure the absence of spatial distortions and to facilitate real-time visualization of the transitions between the point clouds.

With the point cloud in Blender and the camera setup ready, the camera movement to be performed is programmed, which uses angles and effects that make the film more dynamic, with the aim of providing new points of view of the heritage. Furthermore, light points are used in the recorded scenes to highlight volume and provide an atmosphere in the virtual space by simulating the real light points of buildings in the digital environment. To enhance cognitive engagement and the feeling of immersion, visual effects of fireflies and distortion were added to the point clouds. The noises that were kept in the point clouds interacted with the firefly, acquiring its brightness and color upon touch.

After rendering all the scenes, the videos were then compiled in the sequence established by the storyboard and edited in After Effects, which was responsible for adding subtitles and transitions. The finalization was

done by inserting an original soundtrack and diegetic sound effects, captured and mixed in the museum's audio laboratory and with tests in the immersive room as shown in Figure 3, consolidating the complete sensory experience.

Figure 3 – Sound production and video testing process.

4. Storytelling of the exhibition

4.1 Development in the immersive classroom

The immersive room at MIS-CE is composed of five synchronized projection surfaces (four perimeter walls and the floor). To achieve this, the vanishing points of the video had to be adjusted so that the spatial continuity of the buildings was not interrupted at the edges of the room. In addition, spatialized audio was used so that, when the visitor enters the projection, there is a collective and shared experience as shown in Figure 4.

Figure 4 – People's interaction with the exhibition.

4.2 Narrative Structure

More than organizing an exhibition sequence, the narrative structure of the show was conceived as a mediation strategy, in which decisions regarding form, rhythm, spatialization, and transition guide the visitor through different regimes of attention and symbolic engagement with the heritage. The immersive experience was structured in four main narrative acts. The first presents the point as the fundamental unit and starting point of the exhibition, demonstrating the genesis of form: how sets of points structure lines, which evolve into planes and grids until they consolidate the buildings (Figure 5). In the second act, the viewer is invited on a contemplative journey, in which the point clouds of the eight scanned buildings float in an ethereal space (Figure 6). This stage uses smooth camera movements and an atmospheric soundtrack,

allowing the public to appreciate the scale and typological diversity of Fortaleza's heritage without the distractions of the real urban environment.

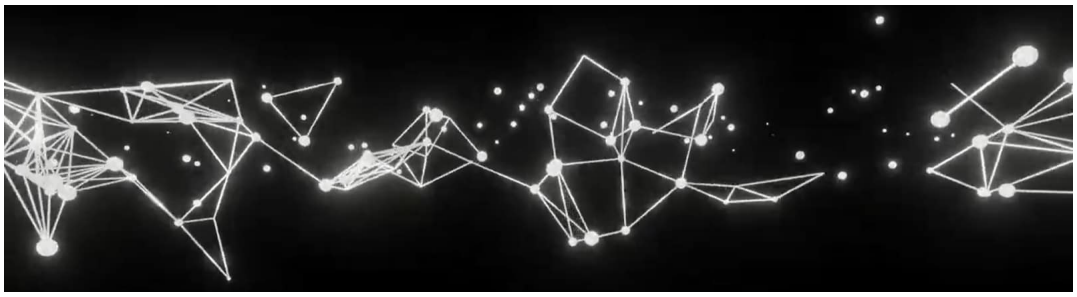

Figure 5 –The point as a representation of the beginning.

Figure 6 – Valley of the buildings.

In the third act, the narrative transitions from external visualization to the exploration of the interior of selected monuments, a journey made possible by the inherent transparency of the point cloud, which allows for a unique perception of internal spatiality (Figure 7) (FIgure 8). Finally, the narrative culminates in the São Pedro Building (Figure 9), the first building with more than 3 floors to be constructed on Iracema Beach and an icon of Ceará architecture (Government of the State of Ceará, 2023), which was demolished in 2024. In this segment, the point cloud takes on a critical documentary character. The visual transition uses distortion and fragmentation effects to symbolize the vulnerability of heritage in the face of urban neglect. By concluding the exhibition with a building that no longer physically exists but survives digitally, the narrative reinforces the urgency of preservation policies and the role of 3D documentation as a guardian of collective memory.

Figure 7 – Virtual tour of the José de Alencar Theater.

Figure 8 – Virtual tour of the Museum of Image and Sound of Ceará.

Figure 9 – Representation of the valley of buildings with the São Pedro building in the center.

The organization of these four acts suggests that the exhibition's storytelling is not limited to the sequential presentation of digitized buildings, but operates as a progressive construction of attention, engagement, and awareness. By starting from the abstraction of the point, moving towards the constitution of architectural forms, guiding the viewer through a contemplative journey among the buildings, and finally concentrating the experience on the São Pedro Building as the symbolic and critical apex of the narrative, the work structures different layers of discovery, permanence, and reflection. In this process, elements such as spatial continuity, sound ambience, smoothness or tension of camera movements, and fragmentation effects act as strategies of sensitive mediation, guiding the gaze and intensifying the relationship between visitor and heritage.

Thus, the narrative seeks not only to inform about the buildings represented, but to create conditions for a deeper engagement with their memory, approaching the notion of flow discussed by Csikszentmihalyi and Hermanson (1995) and which can be interpreted, in light of Ricca (2023), as a narrative of attention, in which the experience articulates initial capture, contemplative permanence and reflective deepening in immersive contexts of heritage awareness.

5. Results and Impact

To understand the impact of the exhibition on users, an empirical evaluation of the "From Point to Heritage" exhibition was conducted with 14 participants. The methodology was based on a mixed-methods approach, involving semi-structured interviews and a five-point Likert scale, structured into blocks of negative and positive aspects (Table 1 and 2).

The quantitative results suggest a positive reception of the immersive experience. In the block regarding negative aspects (Table 1), the majority of participants disagreed with the statements, suggesting that the exhibition was not perceived as repetitive or visually uncomfortable. Regarding positive aspects (Table 2), there was a strong consensus on the engaging character of the immersive room (12 out of 14 responses in

the maximum agreement category), which points to the effectiveness of the proposed decimation and animation workflow. Furthermore, there was a high level of motivation for physically (re)visiting the buildings (12 out of 14 responses in the maximum agreement category), indicating the technology's potential as a driver for heritage tourism and urban awareness.

Qualitatively, the analysis of the reports suggests that the exhibition acted as a memory mediator, allowing visitors to revisit affective experiences related to the presented spaces. The confrontation with the three-dimensional nature of the point clouds facilitated the immediate recognition of unique architectural elements — such as the patio of the Theatro José de Alencar or the auditorium of the Cine São Luiz — enabling visitors to access prior experiences. This mediation element was particularly notable in the case of the São Pedro Building; upon encountering the digital representation of a demolished monument, participants highlighted this moment throughout the interviews, with the term "São Pedro" being repeated 11 times across the 12 interviews. Thus, the exhibition may be understood as an important tool for raising awareness regarding heritage loss and the permanence of collective memory in the face of urban neglect.

Table 1 – Likert Scale: Negative Aspects

NEGATIVE ASPECTS					
SENTENCES	LINKERT SCALE (NUMBER OF RESPONSES)				
	1	2	3	4	5
The changes in angle and perspective during the experience caused me discomfort.	10	2	1	1	1
The scenes were too fast; I could not observe the buildings as I wished.	11	0	0	3	0
The soundtrack and sound effects did not seem connected to the visuals.	7	3	2	2	0
The sound distracted or overloaded my perception of the experience.	11	1	2	0	0
The experience is repetitive.	10	2	2	0	0

Table 2 – Likert Scale: Positive Aspects

POSITIVE ASPECTS

	1	2	3	4	5
The experience influenced my opinion on the preservation of the city's historical buildings.	0	1	1	5	7
I learned something new about the city's architectural heritage through the experience.	0	1	2	2	7
The experience motivated me to contribute to the preservation of architectural heritage.	0	0	4	7	8
The experience made me feel an emotional connection with the historical buildings presented.	0	1	1	5	7
I will talk about my experience of watching the exhibition with colleagues and family members.	0	0	0	7	7

I recognized all or most of the buildings represented.	1	1	1	7	3
I have previously read, heard, or watched materials or news about the built heritage of Ceará.	2	2	1	5	4
The immersive room provided an engaging experience.	0	0	0	2	12
After watching the experience, I am more interested in personally (re)visiting the presented buildings.	0	0	1	1	12

6. Conclusions

This work aimed to present the production techniques and design decisions involved in developing an immersive experience based on point clouds. From the exhibition "From Point to Heritage," it was possible to highlight that the digitization of heritage buildings has a potential that goes beyond the Scan-to-BIM workflow. By reinterpreting the point cloud, this work demonstrates the feasibility of using it as a means of public communication and heritage education, fundamental dimensions for the appreciation and preservation of heritage. The incorporation of these buildings into museum environments through immersive systems, such as the immersive room, expands the possibilities of bringing society and heritage closer together, by transforming the monument into a sensory and informative experience. This approach reinforces the role of museums in promoting a deeper historical understanding through engagement with heritage.

By visualizing the building through its points, transparencies, and overlays, the public is prompted to make a cognitive effort that, as suggested by Csikszentmihalyi and Hermanson (1995), can favor engagement conditions close to what they describe as flow, which can enhance intellectual and emotional engagement with the historical object. This strategy reinforces the idea that 3D surveying can generate products that transcend technical modeling, serving as a basis for narratives capable of democratizing access to heritage. Furthermore, community participation in non-formal educational experiences proves relevant for activating cultural protection policies and expanding the social reach of these actions. In this sense, technology allows buildings that are difficult to access, closed off, or have already materially disappeared to be visited virtually, making heritage knowledge more inclusive and accessible.

It is also possible to understand the narrative structure of the exhibition in light of the Loom of Experience, insofar as the immersive path organizes a progression between different attentional levels (Ricca, 2023). The initial impact of the point cloud visuality, the sound environment, and the spatialization of the content function as elements that capture and guide attention; then, the contemplative journey between forms, transparencies, and scales favors the permanence and deepening of the experience; finally, the arrival at the case of the São Pedro Building shifts the visitor to a more reflective layer, in which memory, loss, and the urgency of preservation are articulated in a critical way. In this sense, the exhibition not only presents information about the heritage but also constructs a narrative of attention, in which visual, sound, and spatial stimuli are organized to lead the public from an initial sensory perception to a deeper symbolic implication.

The case of the São Pedro Building powerfully exemplifies the urgency of this approach, consolidating 3D documentation as a safeguarding practice and also as a critical gesture of memory. Even in the face of physical demolition, its digital permanence in the museum acts as a historical record and as a manifestation against the loss of collective memory. In summary, this work demonstrates that digital technology, when articulated with educational processes in museums, can transform public perception of heritage and strengthen cultural identity through the recognition, awareness, and appreciation of historical structures.

Although this study is limited to a single case study, it presents not only the production methodology but also research findings regarding public reception. The collected data suggest the effectiveness of the proposed approach. Thus, this work not only validates the developed design workflow but also establishes technical parameters for future investigations and new applications of immersive technologies in heritage education.

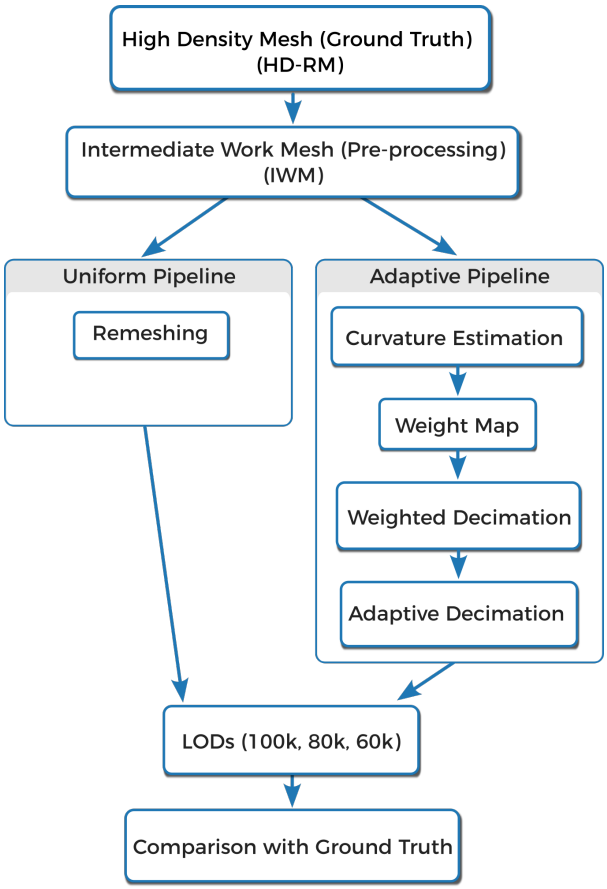
Abstract: The integration of complex 3D meshes into Heritage Building Information Modeling (HBIM) platforms is often limited by computational bottlenecks. This paper proposes and validates a workflow to quantitatively evaluate mesh optimization techniques using uniform and adaptive decimation. The methodology involves generating multiple Levels of Detail (LODs) in SideFX Houdini and then analyzing them in Python, with a focus on geometric accuracy and error distribution. The results demonstrate that adaptive decimation, although computationally more expensive, preserves critical details with greater fidelity and achieves a lower mean error. The protocol validates the adaptive approach as the superior strategy for optimizing digital assets in HBIM, offering a robust balance between efficiency and geometric fidelity.

Keywords: 3D mesh optimization; adaptive decimation; uniform decimation; geometric accuracy.

1. Introduction

The documentation and management of historic buildings constitute a central challenge for the preservation of cultural heritage. The Heritage Building Information Modeling (HBIM) approach has emerged as an advanced paradigm for this purpose, overcoming the limitations of traditional BIM in handling irregular geometries and the absence of original technical documentation. As noted by Noardo (2018), HBIM representations demand an exceptional level of detail and geometric accuracy to faithfully represent the as-is condition of the built heritage. In this context, three-dimensional reconstruction from point clouds has become a pillar of the HBIM workflow, providing the basis for accurate and information-rich digital models (Cotella 2023).

The acquisition of high-density point clouds is predominantly performed through photogrammetry and laser scanning (LiDAR). These technologies, frequently combined to optimize survey fidelity (Pepe et al. 2020; Pirotti et al. 2022), produce a massive set of points that requires processing to generate a continuous surface. The conversion of the point cloud into a polygonal mesh is a critical step, performed by surface reconstruction algorithms (Xu et al. 2021; Morel et al. 2018).



The result, however, is typically a very high-density mesh, whose data volume imposes severe computational bottlenecks, rendering its integration into HBIM platforms inefficient (Ismail et al. 2023). To overcome this limitation, optimization techniques such as mesh decimation are employed (Dunyach et al. 2013). Decimation strategies can be uniform or adaptive, preserving details based on curvature criteria (Wang et al. 2019). Although the literature describes these techniques in isolation, there is a gap in the systematic, comparative evaluation of their results in the context of HBIM. There is a lack of quantitative protocols to compare the impact of different decimation methods on the trade-off between geometric accuracy and polygonal density, especially when applied to complex elements such as architectural ornaments.

To address this gap, this study proposes and evaluates a methodological workflow for generating and optimizing 3D mesh models from point clouds for integration into HBIM platforms. The methodology comparatively investigates two polygonal decimation techniques implemented in the Houdini software: adaptive and uniform. The quantitative evaluation is performed through automated analyses, considering two main metrics: execution time and geometric accuracy. Therefore, the work aims to establish a protocol for optimizing digital assets in the context of built heritage documentation and to determine the advantages and limitations of each processing approach.

2. Methodology

This study employed an experimental workflow to comparatively evaluate two 3D mesh optimization strategies for HBIM applications. The methodology comprises six main stages: i) identifying the case study and input data; ii) specifying the hardware and software; iii) pre-processing and generating an intermediate working mesh; iv) generating three Levels of Detail (LODs) via uniform decimation; v) generating three LODs via curvature-based adaptive decimation; and vi) performing a quantitative comparative analysis of the results. The core processing workflow, from the input reference mesh to the final comparative analysis, is visually represented in Figure 1.

Figure 1 – Methodological workflow flowchart, from the input point cloud to the comparative analysis of the six generated LODs.

2.1 Object of Study and Input Data

The case study focuses on a pair of porcelain lion sculptures from Porto, Portugal, dating from the early 20th century. These pieces are distinctive architectural elements on the facade of the historic building that currently houses the Museum of Image and Sound of Ceará (MIS-CE), as illustrated in Figure 2. The high-

density polygonal meshes of both sculptures, generated via photogrammetry and comprising approximately 50 million polygons each, served as the 'ground truth' and primary data for the experiments.

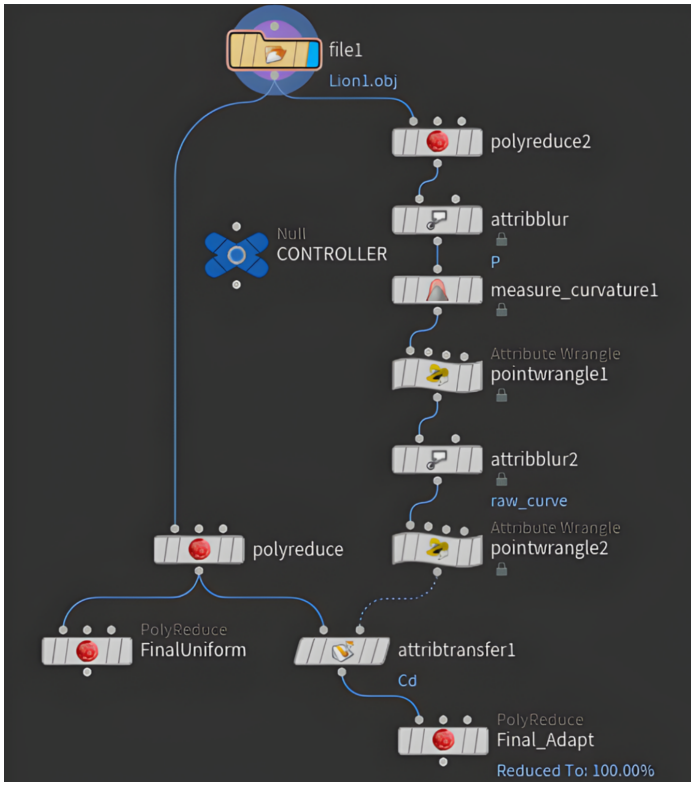
Figure 2 – Facade of MIS-CE, highlighting the lions (case study): (1) left and (2) right. Source: Adapted from MIS-CE (2024).

2.2 Hardware and Software Specifications

All experiments were conducted on a workstation with the following specifications: an Intel Core i5-12450H processor; 16 GB of RAM (DDR5, 4800 MHz); an NVIDIA GeForce RTX 2050 GPU (4 GB GDDR6); and the Windows 11 operating system. The following software and libraries were used: MeshLab (v. 2023.12) for normal computation and reference mesh generation; SideFX Houdini (v. 20.5.445) to implement the uniform and adaptive decimation workflows; and Python (v. 3.11.6) with the PyVista (v. 0.45.2) and VTK (v. 9.4.2) libraries for geometric distance computation, NumPy (v. 2.3.1) for numerical operations, Pandas (v. 2.3.0) for data manipulation, and Matplotlib (v. 3.10.3) / Seaborn (v. 0.13.2) for plot generation.

2.3 Reference Mesh Generation

The High-Density Reference Mesh (HD-RM), which served as the ground truth for the accuracy analyses, was generated using the MeshLab software. In this environment, the point cloud was initially processed with the Compute Normals for Point Sets function, setting the neighbors parameter to 20 to ensure a consistent vector orientation. Subsequently, with the normals computed, the surface was reconstructed using the Surface Reconstruction: Screened Poisson algorithm, where the octree depth was set to 11 to guarantee the capture of fine details. This process yielded a closed and geometrically faithful polygonal mesh, which was fundamental for the validation of the optimized models.



2.4 Intermediate Working Mesh Generation (IWM)

Due to the high density of the HD-RM, which imposed computational constraints, an Intermediate Working Mesh (IWM) was generated. The 50-million-polygon HD-RMs were imported into SideFX Houdini and subjected to an initial decimation using the PolyReduce node. The target was set to 35% of the original polygon count, resulting in more manageable IWMs. These IWMs served as the common starting point for the two subsequent optimization pipelines.

2.5 Optimization and Generation of Levels of Detail (LODs) in Houdini

Starting from the IWMs, two distinct workflows, detailed in Figure 3, were applied to generate three LODs for each method, with target polygon counts of 100,000, 80,000, and 60,000.

Figure 3 – The complete node graph of the workflow implemented in Houdini.

For the optimization, two distinct pipelines were applied. The first, uniform decimation, processed the Intermediate Working Mesh (IWM) with the Remesh node, aiming for a homogeneous topological reorganization. The polygon density was controlled by the "Element Sizing" parameter, which was iteratively adjusted to generate three distinct meshes for each sculpture, corresponding to the target LODs of 100,000, 80,000, and 60,000 polygons.

In contrast, the adaptive method implemented a selective decimation strategy to preserve geometric details. The process began with the creation of a weight map: the mesh was first smoothed with an AttribBlur node (15 iterations) to mitigate noise, and subsequently, the Measure Curvature node computed the curvature at each point. The resulting attribute was then processed with the AttribBlur and Attribute Wrangle nodes to generate the final map. Once created, this weight map was transferred to the IWM via the AttribTransfer node, and the mesh, now enriched with the attribute, was subjected to a final PolyReduce node. The operation of this final node was controlled by the map, forcing the algorithm to remove polygons from flat areas while preserving the topology in regions of high curvature. This procedure was repeated to generate the three corresponding LODs for each element.

2.6 Quantitative Analysis and Evaluation Metrics

To quantitatively assess the performance of each optimization method, the six generated Level of Detail (LOD) models were compared against the IWM. The analysis was conducted using a set of Python scripts, which implemented the following procedures.

Geometric deviation was computed using the PyVista (v. 0.45.2) library, which invokes the vtkImplicitPolyDataDistance function from the VTK (v. 9.4.2) toolkit. This method computed the signed Euclidean distance from each vertex of the optimized mesh to the closest point on the surface of the

reference mesh. From the resulting distance vector for each LOD, a set of statistical metrics was calculated in order to characterize the deviation. These include the Mean Absolute Error (MAE), defined as the average of the absolute distance values and indicating the overall mean deviation, and the Standard Deviation (σ), which measures the dispersion and variability of the signed errors. In addition, the Maximum Error was determined as the largest absolute deviation value found on any vertex of the mesh, while the 95th Percentile of Absolute Error represents the error value below which 95% of the vertices are found.

Additionally, an analysis was performed to compare the spatial concentration of inaccuracies. This procedure, executed at the face (polygon) level, followed these steps: 1) the mean absolute error was calculated for each face of a given LOD, defined as the average of the absolute errors of its constituent vertices; 2) an error threshold was established based on the performance of the mesh generated by the adaptive method, defined as the 95th percentile error value of its polygons, thereby isolating the 5% of faces with the greatest deviations; and 3) this same threshold value was subsequently applied to the mesh generated by the uniform method in order to quantify the percentage of its faces that exceeded this error standard. This approach allows for a direct comparison of the prevalence of high-error areas between the two methods, using a quality standard derived from the adaptive method. To ensure the transparency and reproducibility of the research, the SideFX Houdini project, the Python analysis scripts, and the generated 3D models were made available in a public repository github.com/darciodfx/HBIMAnalysis.

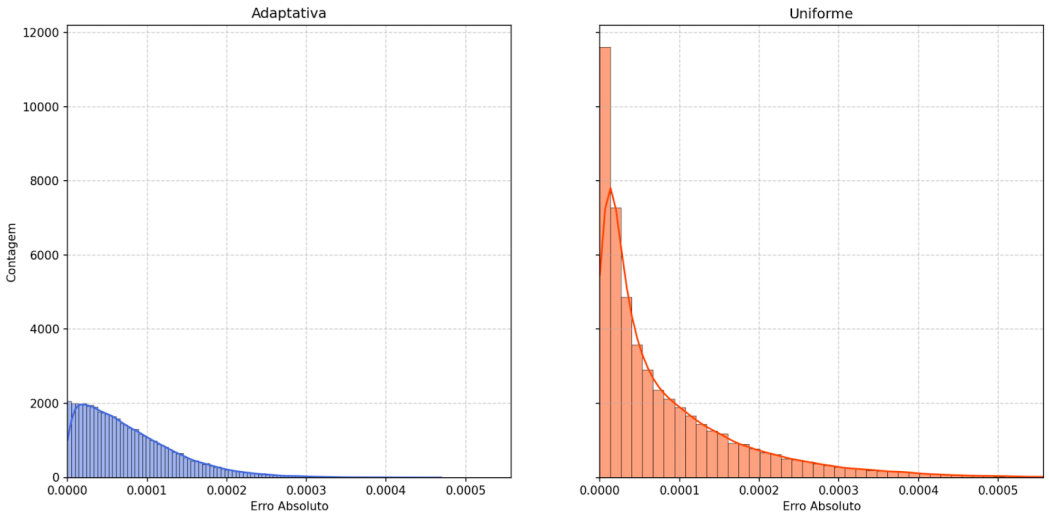
3. Results

The application of the optimization methodologies yielded six Level of Detail (LOD) models with distinct characteristics in terms of polygonal density and geometric accuracy. The quantitative results are presented sequentially below.

The two methodologies were applied to generate LODs with target polygon counts of 100,000, 80,000, and 60,000. Table 1 summarizes the final polygon counts and the processing times required by each pipeline in SideFX Houdini. It was observed that the adaptive method consistently required a longer processing time than the uniform method for all analyzed LODs.

Table 1 – Comparison of processing times for each generated LOD per model

	Target LOD (Polygons)	Method	Final Polygons	Processing Time(s)
Lion 1	100 000	Uniform	100 720	200
		Adaptive	100 000	274
	80 000	Uniform	80 401	174
		Adaptive	80 000	227
	60 000	Uniform	60 020	138
		Adaptive	60 000	171
Lion 2	100 000	Uniform	100 210	198
		Adaptive	100 000	271
	80 000	Uniform	81 201	172
		Adaptive	80 000	216
	60 000	Uniform	60 802	140
		Adaptive	60 000	167



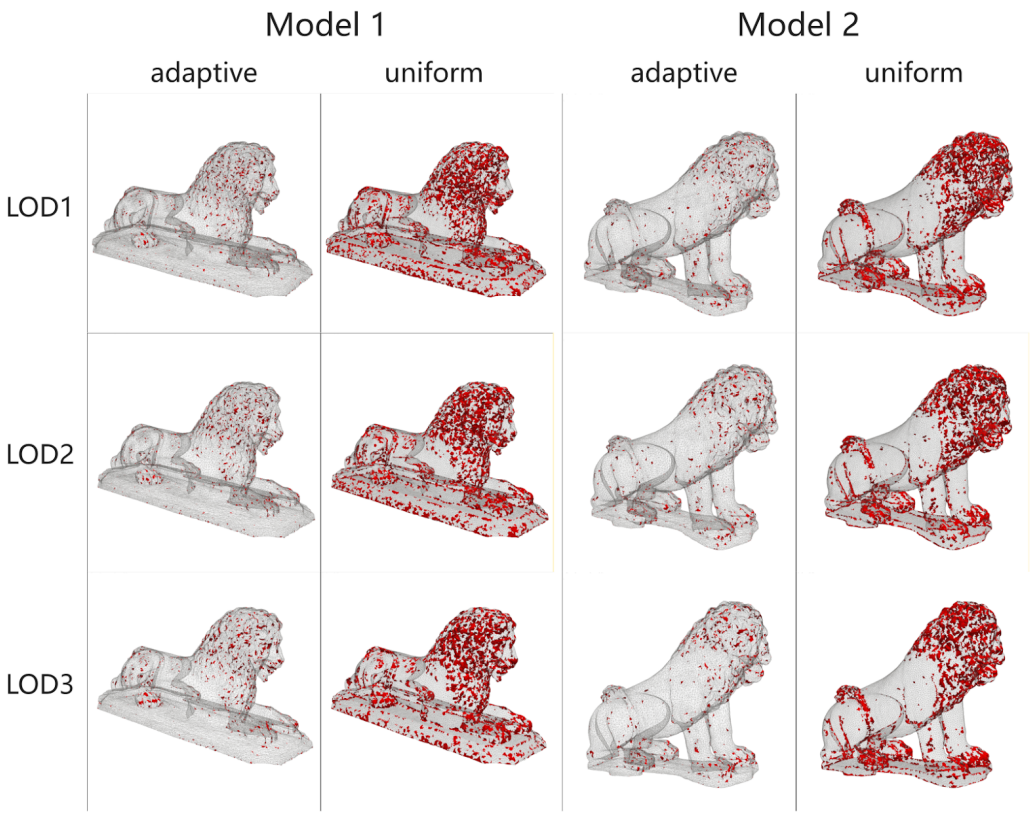
The comparison of the optimized models with the high-density reference mesh revealed significant differences in geometric accuracy. Table 2 presents the key error metrics for each LOD. The results indicate that, across all levels of detail, the adaptive decimation method consistently produced lower values for Mean Absolute Error (MAE), Standard Deviation (σ), Maximum Error, and the 95th Percentile.

Table 2 – Geometric accuracy statistics (units in meters) for the LODs generated for models 1 and 2

	Target LOD (Polygons)	Method	MAE	Standard Deviation (σ)	Maximum Error	95th Percentile
Lion 1	100,000	Uniform	0,00008275	0,00012731	0,00133629	0,00028494
		Adaptive	0,00007679	0,00009769	0,00046900	0,00019432
	80,000	Uniform	0,00009573	0,00014666	0,00114182	0,00032849
		Adaptive	0,00009040	0,00011477	0,00058602	0,00022870
	60,000	Uniform	0,00011633	0,00017671	0,00141270	0,00039383
		Adaptive	0,00011175	0,00014131	0,00069942	0,00028392
Lion 2	100,000	Uniform	0,00008002	0,00011852	0,00100580	0,00026333
		Adaptive	0,00006762	0,00008483	0,00046347	0,00016772
	80,000	Uniform	0,00009331	0,00013730	0,00144706	0,00030580
		Adaptive	0,00007943	0,00009935	0,00055832	0,00019751
	60,000	Uniform	0,00011504	0,00016848	0,00150104	0,00037435
		Adaptive	0,00009818	0,00012219	0,00069595	0,00024404

The analysis of the absolute error distribution corroborates the findings in Table 2, albeit with important nuances. Figure 4 presents the error histograms for the 100k-polygon LOD. The histogram for the uniform method (right) is characterized by an extremely sharp and elevated peak at error values near zero, indicating that a vast majority of its vertices possess a very low geometric deviation. In contrast, the histogram for the adaptive method (left) exhibits a considerably lower peak and a broader distribution, with a tail that tapers off more gradually than that of the uniform model. This pattern was observed consistently across all analyzed LODs.

Figure 4 – Comparative histograms of the absolute error distribution for the adaptive (left) and uniform (right) methods, for the 100,000-polygon LOD



The error prevalence analysis, which uses a threshold derived from the 5% of polygons with the highest error on the adaptive mesh, quantified the disparity in performance. Table 3 details the results for each LOD. For the 100,000-polygon LOD, with an error threshold of 0.00013079, it was found that 19.88% of the polygons on the uniform mesh exceeded this value, compared to 5.00% for the adaptive mesh.

Table 3 – Error prevalence analysis, using a common threshold derived from the adaptive mesh for each LOD

	Total polygons	Polygons (Adaptive)	Error Threshold	Polygons (Uniform)
Lion 1	100,000	5%	0,00014811	18.44%
	80,000	5%	0,00017367	18.08%
	60,000	5%	0,00021414	17.44%
Lion 2	100,000	5%	0,00013079	19.88%
	80,000	5%	0,00015324	19.73%
	60,000	5%	0,00018950	19.91%

This quantitative difference is visually confirmed in Figure 5, where the polygons exceeding the defined error threshold are shown in red.

Figure 5 – Spatial visualization of polygons with an error exceeding the threshold for all generated LODs

4. Discussion

The quantitative and visual results presented demonstrate the clear superiority of the adaptive decimation method over the uniform one for optimizing 3D meshes with complex geometries. The principal finding of this study lies in the relationship between error distribution and the overall model accuracy. As indicated in Table 2, the adaptive method consistently achieved a lower Mean Absolute Error (MAE). This is due to its ability to intelligently allocate the "polygon budget," preserving topological density in high-curvature areas—such as the lion's mane and facial contours—that are crucial to the object's visual identity.

In contrast, the uniform method, by reorganizing the mesh homogeneously, generates significantly larger errors in these same critical areas. This phenomenon explains the apparent paradox observed in the error histograms (Figure 4). The sharp peak in the uniform method's histogram signifies that it produces many polygons with near-zero error on flat surfaces, but at the cost of over-smoothing the details. The adaptive method, in turn, accepts a small, more distributed error across the entire surface to ensure the preservation of complex shapes, resulting in superior average performance. The error prevalence analysis (Table 3) quantifies this shortcoming compellingly: when using the same quality standard, the uniform mesh exhibited nearly four times as many "high-error" polygons.

Finally, the longer processing time of the adaptive method (Table 1) represents a classic trade-off between performance and quality. The additional computational cost stems from the extra steps of curvature calculation and attribute processing, an investment justified by the superior accuracy of the final model.

4.1 Implications for HBIM and Contribution to Knowledge

This study addresses the gap identified in the literature (Section 1.2) by providing a quantitative protocol for the comparative evaluation of mesh optimization techniques within the HBIM context. While studies such

as Wang et al. (2019) describe the theoretical benefits of adaptive decimation, our research provides empirical validation and concrete metrics that demonstrate its practical effectiveness.

The primary implication for HBIM practice is the validation of a workflow that enables the generation of significantly lighter and more efficient digital assets without compromising the geometric fidelity of complex ornamental elements. This directly addresses interoperability and performance bottlenecks in BIM software (Ismail et al. 2023), enabling the integration of richer, more detailed as-is models. Thus, a conceptual model is proposed for mesh optimization in HBIM that balances three factors: Geometric Accuracy, Computational Efficiency, and Detail Preservation. Our findings position adaptive decimation as the strategy that best balances these three pillars.

5. Conclusions

This study presented a quantitative workflow for the evaluation of 3D mesh optimization techniques in the context of Heritage Building Information Modeling (HBIM). The results consistently demonstrate the superiority of the adaptive decimation method over the uniform approach, particularly in terms of geometric accuracy and error distribution. By preserving critical high-curvature features while efficiently reducing polygonal density, the adaptive method achieved lower Mean Absolute Error (MAE), reduced variability, and fewer high-error regions across all Levels of Detail (LODs) analyzed.

The primary contribution of this work lies in the establishment of a reproducible and quantitative protocol for comparing mesh simplification strategies, addressing a gap in the HBIM literature. This protocol enables a more rigorous assessment of the trade-off between geometric fidelity and computational efficiency, which is essential for the integration of complex 3D assets into BIM environments.

From a practical perspective, the findings support the adoption of adaptive decimation as a more reliable strategy for optimizing high-resolution meshes of architectural heritage elements. This has direct implications for improving interoperability, reducing computational costs, and enabling the use of detailed as-is models within HBIM platforms.

Despite the consistent findings, some limitations should be acknowledged. Firstly, the study focused on a single type of object: an organic sculpture with high surface complexity. The magnitude of the adaptive method's superiority may vary for architectural elements with distinct characteristics, such as predominantly flat facades. Finally, the methodology was implemented in a specific commercial software (SideFX Houdini); although the principles are universal, the exact replication of the workflow on other platforms, particularly open-source ones, may present challenges.

Based on the identified limitations, the following directions for future work are suggested. First, the application and validation of the methodological protocol proposed herein to a broader range of architectural heritage typologies. Second, the investigation of analogous workflows using open-source software, such as Blender, to democratize access to the technique. The most promising avenue of research, however, would be to extend the pipeline beyond geometric optimization, exploring semi-automated methods for converting the optimized mesh into parametric and semantically rich objects, thereby completing the Scan-to-HBIM cycle.

Abstract: The conservation of historic buildings requires comprehensive data regarding their construction systems, geometries, and the degradation state of their components. The development of a Heritage Building Information Model (HBIM) is established as a methodology capable of integrating all the architectural information of a building into a single file, providing the necessary inputs for developing a maintenance plan. This article analyzes the modeling process and the challenges encountered regarding the Pinacoteca do Ceará—a building within the Complexo Cultural Estação das Artes in Fortaleza, a cultural and heritage facility of notable relevance to the city. The workflow adopted a Scan-to-BIM approach, utilizing a hybrid data capture strategy. The architectural survey was conducted using Laser Scanning for horizontally accessible areas, complemented by UAV-based digital aerial photogrammetry with SfM-MVS processing. Data processing involved the use of Leica Cyclone Register 360 software for TLS data and RealityScan for processing the UAV imagery. The final integration of the point clouds was performed in the CloudCompare software, resulting in a unified point model with millimeter-scale precision, an indispensable baseline for parametric modeling faithful to the geometric reality. During the process, overlaying the point cloud onto previous historical records revealed significant discrepancies, such as a lack of orthogonality in structural walls, alongside dimensional and typological variations in window and door frames that were absent from the original documentation. Identifying these asymmetries is crucial for the precise diagnosis of structural deformations and for planning custom-made components during restoration. In conclusion, mapping these inconsistencies through HBIM constitutes an essential digital representation for heritage safeguarding, overcoming the uncertainties inherent in traditional surveying methods.

Keywords: HBIM; Pinacoteca do Ceará; Scan-to-BIM; Heritage; Point Cloud.

1. Introduction

The maintenance and preservation of built cultural heritage has found in advanced digitalization a fundamental method for safeguarding buildings, as evidenced by **Ni et al. (2024)**. In this regard, Heritage Building Information Modeling (HBIM) establishes itself as more than just a three-dimensional modeling tool, but also a complex information management system. Unlike conventional BIM, which focuses on the design of new constructions, HBIM is based on the documentation of pre-existing buildings, integrating geometric, historical, and conservation status information into a parametric model that enables optimized preventive maintenance and future restoration interventions.

However, the effectiveness of this method faces a recurring logistical barrier: the inaccuracy of existing traditional data surveys. Frequently, the existing physical documentation of historical buildings does not correspond to the actual constructed geometry, as manual measurements can lead to cumulative errors and result in significant discrepancies with reality **(Barrile; Bernardo; Bilotta, 2022)**. Furthermore, these documents often ignore structural deformations, settlements, or modifications that occurred throughout the building's existence. This gap between the documentary record and the actual state of the building can compromise the planning of restoration and maintenance interventions, leading to quantitative errors and technical incompatibilities during construction.

Although technologies such as Laser Scanning have revolutionized architectural surveying by capturing geometries with millimeter precision, total capture still faces limitations in large-scale or volumetrically complex buildings. Laser Scanning, despite its pivotal role in geometric data capture, is still limited to the terrestrial scale and cannot achieve highly precise results for urban-scale equipment or hard-to-reach areas, such as roofs and elevated parapets. Frequently, these geometric gaps result in incomplete point clouds due to occlusions. This scenario mandates the adoption of a hybrid data capture strategy, combining distinct forms of secondary data capture to ensure the integrity and reliability of the Digital Twin, as seen in **Salah, Géczy, and Károlyfi (2026)**.

Given this context, the development of the HBIM model of the Pinacoteca do Ceará is detailed—a building of notable relevance to the built cultural heritage of the state of Ceará and part of the Complexo Cultural Estação das Artes in Fortaleza. The analysis documents the modeling strategies adopted in light of the building's available documentary collection and its eventual discrepancy with the geometry captured in situ, highlighting a comparison between pre-existing manual geometric records and the high-precision survey obtained via Laser Scanning and photogrammetry, as well as the recording of data provenance within the model elements.

2. Case Study

The Pinacoteca do Ceará, the central building of the Estação das Artes Cultural Complex, is characterized as a landmark of industrial railway heritage in Fortaleza, dating from the early 20th century. The pinacoteca, managed through a partnership between the Ceará Secretariat of Culture and the Mirante Institute, consists of seven warehouses remaining from the former Rede Ferroviária Federal S.A. (RFFSA). The building's relevance extends beyond its monumental scale, establishing itself as a center for cultural and artistic dissemination whose preservation is guaranteed by significant legal frameworks: municipal listing, which occurred on April 24, 1980, and state listing, on October 30, 1983, under Law No. 16,237.

Figure 01 - Main Facade of the Pinacoteca do Ceará

Source: Government of the State of Ceará

The recent intervention and restoration project, carried out by the Carvalho Araújo firm, adopted a design approach that values and highlights the pre-existing railway industrial elements to house a contemporary program. This requalification established the building as one of the most ambitious

architectural-urban regeneration processes in the capital of Ceará, transforming the railway architecture into a safeguarding device for the state's artistic and cultural memory. From a morphological and geometric standpoint, the warehouses are characterized by wide clear spans and exposed metallic structures. In contrast, the service and connection blocks exhibit contemporary languages that establish a dialogue with the pre-existing load-bearing masonry, while the facades present a highly complex rhythmic composition, marked by the repetition of frames and ornamental relief moldings.

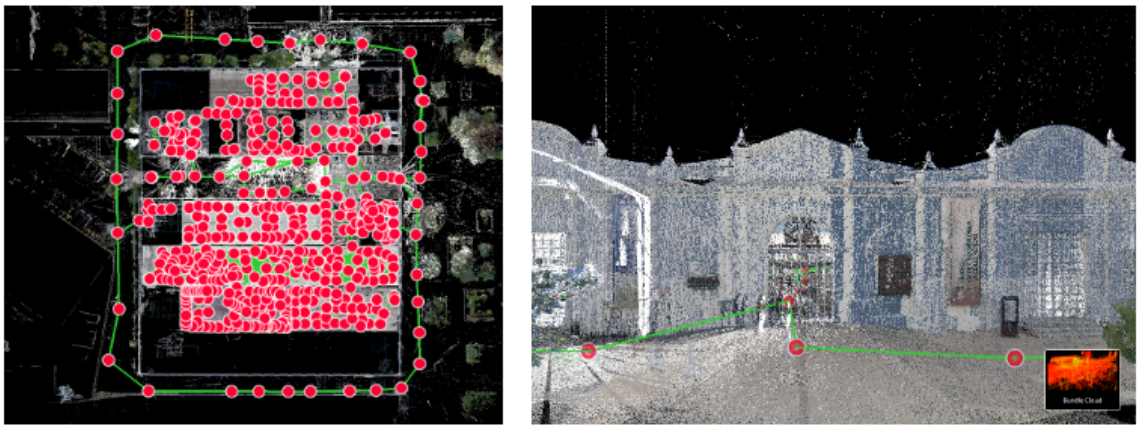
The development of the Pinacoteca's HBIM representation required the synthesis of a heterogeneous range of data. As primary sources, a high-precision digital survey was used, obtained through TLS (fundamental for the metric capture of internal spaces and ornamental details) and aerial photogrammetry, employed here to fill the occlusion gaps in roofs and elevated parapets. Complementarily, secondary sources consisting of the Pinacoteca's archives of previous interventions in 2D CAD format were utilized. The overlay of these sources revealed significant geometric discrepancies, particularly regarding the orthogonality and alignment of the main structural walls, evidencing the accumulation of errors inherent to the manual and analog surveying methods previously used.

The documentary workflow was structured to minimize such inconsistencies and ensure the fidelity of the final digital model. The processing of the collected data followed a rigorous sequence of interoperability among a specific series of software programs:

- **Leica Cyclone Register 360:** Used here for the registration, consolidation, and assembly of point cloud files originating from Laser Scanning.
- **Reality Scan:** Employed in processing the images captured by UAV for the generation of point clouds of the roofs through Structure-from-Motion/Multi-View Stereo processing.
- **CloudCompare:** Acted as the geometric fusion environment, enabling the registration of TLS and photogrammetry data into a single file.
- **Autodesk Recap:** Applied in the refinement, segmentation, and cleaning stage of the unified point cloud.
- **Autodesk Revit:** Final modeling platform, where the synthesis between the point clouds (primary data) and historical documentation (secondary data) is carried out.

3. Methodology

3.1 Data Collection



The methodological workflow followed for the Pinacoteca do Ceará was structured under a Scan-to-BIM approach, a process characterized by the transposition of real geometric data into a parametric digital environment. This transposition was divided into interdependent and consecutive stages, beginning with the field survey (data collection), progressing through computational processing, and ultimately culminating in the development of the HBIM representation.

3.1.1 Terrestrial Geometric Survey: Laser Scanning

The primary survey stage took place over a period of 15 days of technical visits to the Pinacoteca do Ceará, using the Leica BLK360 laser scanning equipment.

Taking into account the monumental scale of the building, the rhythmic succession of the industrial warehouses, and the complexity of its ornaments, the laser capture strategy was designed to mitigate occlusion zones. To this end, 601 setups (scanner positions) were carried out, strategically spaced across the interior of the warehouses, accessible service areas, and the external perimeter. Each capture cycle, set to a medium point density, required approximately 5 minutes, providing a detailed sampling of the masonry, metallic structural systems, and ornaments (Figure 02).

Figure 02 - Pinacoteca do Ceará viewed in the Cyclone Register 360 software with visible setups

Source: By the authors

3.1.2 Aerial Photogrammetry

Parallel to the terrestrial scanning, a photogrammetric survey was conducted using an Unmanned Aerial Vehicle (UAV), model DJI Mavic 3T Enterprise, during a single day of fieldwork at the study site.

This technique was essential for documenting the roofs and elevated parapets, areas invisible to the terrestrial laser scanner. High-quality photogrammetric images with adequate overlap were acquired (Figure 3), which were subsequently processed in the Reality Scan software. This process generated a triangle mesh in approximately 47 minutes, providing the fundamental geometric baseline for the building's roofs.

Figure 3 - Aerial photographs of the Pinacoteca do Ceará captured by drone

Source: By the authors

3.1.3 Documentary Survey and Secondary Data (CAD Base)

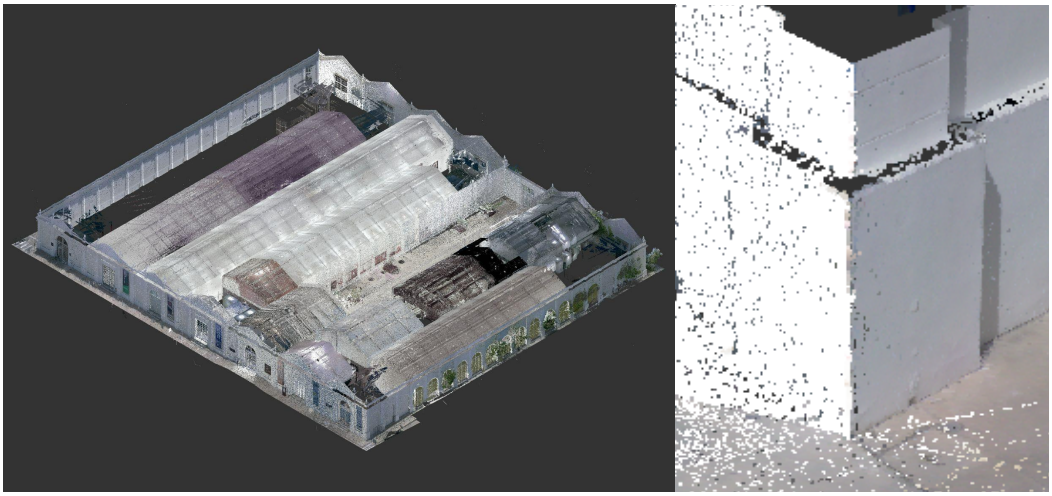
Beyond active reality captures, the methodology required the collection of secondary data. The use of pre-existing CAD documentation—composed of floor plans from complementary projects, such as hydraulic and electrical installations—was motivated by the impossibility of fully covering the building through laser scanning, due to the survey team's restricted access to specific areas of the Pinacoteca. Consequently, sectors such as service cores, restrooms, and pantries presented gaps in

the resulting point cloud, necessitating the collection and utilization of these secondary sources to subsequently ensure the completeness and volumetric integrity of the BIM model.

3.2 Data Processing and Integration

3.2.1 Registration, Photogrammetric Processing, and Unification

The initial processing of the laser scanning (TLS) data was carried out in the Leica Cyclone Register 360 software. The raw point cloud, resulting from the union of multiple scans, totaled 2,098,098,135 points, presenting a root mean square (RMS) error of 0.007 m. Due to the repetitive modularity of the Pinacoteca do Ceará's railway architecture, the purely automatic alignment algorithm was susceptible to incorrect geometric overlaps between homologous geometries. Thus, the manual registration of the setups was adopted. The procedure consisted of a visual pre-alignment, followed by an automatic mathematical refinement using the software's native Cloud-to-Cloud (C2C) algorithm. This process ensured the preservation of geometric fidelity and prevented spatial distortions and the propagation of errors along the succession of warehouses.



Concurrently, the data captured by the UAV was processed in the Reality Capture software to generate the aerial photogrammetric model. The processing was executed on a workstation equipped with an AMD Ryzen 9 7900X (4.70 GHz) processor, 32 GB of RAM, and an NVIDIA GeForce RTX 4070 (12 GB) graphics card. The photogrammetric reconstruction resulted in the generation of the point cloud in approximately 47 minutes, providing the fundamental geometric baseline for the building's roofs.

The consolidation of these multimodal datasets was performed in the CloudCompare software. To align the different scales and coordinate systems, the TLS point cloud was adopted as the absolute reference (spatial anchor), since its sub-centimeter precision is guaranteed in the surveying of interiors and facades. The photogrammetric cloud was imported and subjected to an initial alignment by selecting homologous points (point-pair picking), followed by a fine adjustment of translation, rotation, and scale using the Iterative Closest Point (ICP) algorithm. The final unified cloud, composed of the 601 terrestrial laser stations and the aerial survey, mitigated the individual visual restrictions of each method, consolidating an integral and highly reliable geometric base for the object of study.

3.2.2 Refinement, Segmentation, and Interoperability

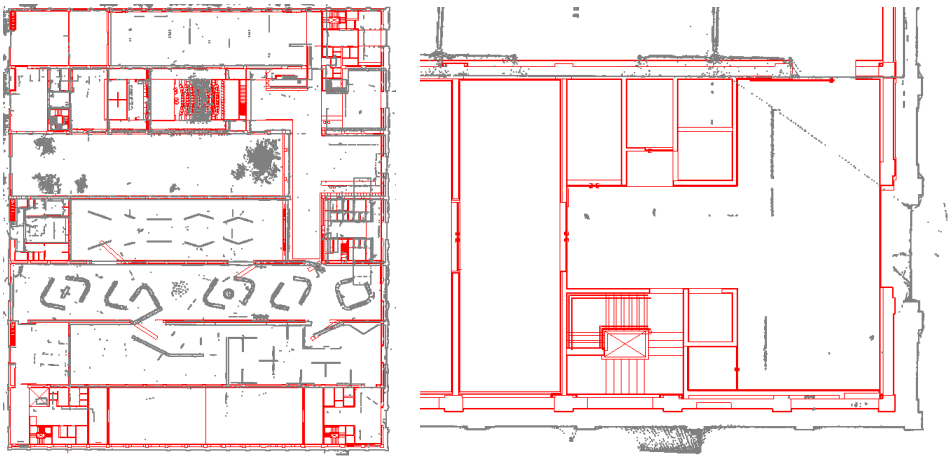
Before beginning the modeling process, the unified point cloud was imported into Autodesk ReCap, an environment dedicated to the manipulation and cleaning of spatial data. During this stage, "slicing" and the removal of noise and captured elements that do not add geometric value to the object of study—such as vegetation, vehicles, pedestrians, and adjacent buildings—were carried out. This cleaning process is vital for the computational optimization of the model, preventing the loading of unnecessary data and ensuring an unobstructed view of the building's geometry (Figure 4).

Figure 4 - On the left, the complete point cloud of the Pinacoteca. On the right, segmentation of the cloud, highlighting a single pillar to capture more specific details in a more optimized manner.

Source: By the authors

A fundamental aspect of this stage was the segmentation of the point cloud. The robust file was preserved for future use, while a copy was fragmented into smaller subsets with specific characteristics, enabling the diagnosis and isolated observation of elements such as facade ornaments, frames, and internal compartments. This division allowed the computer to process only the geometric fragment required for each modeling stage. With the point cloud refined, segmented, and optimized, the data constituted an ideal substrate for import into Autodesk Revit, the platform where parametric modeling commenced.

3.3 HBIM Representation



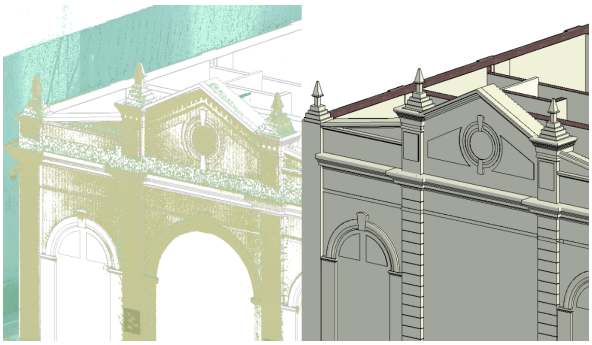
The development of the HBIM model for the Pinacoteca do Ceará was founded on the premise of achieving a more accurate modeling of the built reality, aiming to consolidate a precise database for the management and safeguarding of the heritage asset. To ensure the integrity and completeness of the model, a hybrid strategy was adopted, integrating direct reality capture via the Scan-to-BIM workflow with the use of secondary documentary sources (CAD) for areas with restricted access or incomplete capture coverage.

3.3.1 Definition of hybrid strategy (point cloud + CAD)

Upon overlaying the pre-existing CAD documentation onto the point cloud, significant geometric and dimensional divergences were identified, such as variations in the thickness of structural walls, discrepancies in usable areas, and alterations in the internal spatial configuration (Figure 5).

Considering the typology of the Pinacoteca do Ceará (characterized by wide open warehouses with peripheral service cores), a hybrid modeling strategy was adopted. The point cloud, obtained through laser scanning and aerial photogrammetry, was established as the primary geometric reference for large alignments and facades. For the service blocks, where access for reality capture was restricted, the CAD base was utilized with local adjustments anchored to reliable references from the point cloud. This decision is based on the premise that cumulative errors in traditional surveys tend to be more critical over large expanses, whereas smaller environments exhibit greater precision.

Figure 5 - Overlay of the CAD model (in red) onto the Point Cloud



Source: By the authors

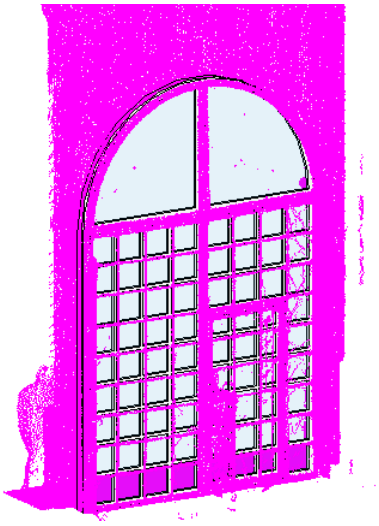
3.3.2 Parametric Modeling by Elements

After the consolidation of the point cloud and the definition of the integration guidelines with secondary data, the workflow focused on the BIM environment, using Autodesk Revit as the modeling software. The point cloud, linked to the project, served as a three-dimensional guide for geometry extraction. To enable technically precise modeling, section boxes and multiple transverse and longitudinal sections were systematically generated. These features allowed the tracing of baselines for walls and structural elements directly over the point cloud sections, ensuring that the model incorporated the asymmetries and the lack of orthogonality detected in the survey.

Unlike conventional modeling based on schematic plans, the process prioritized the creation of native geometries and Revit families that reflected the actual state of the heritage asset (Figure 6).

Figure 6 - Modeling of the Pinacoteca do Ceará's main facade captured via Laser Scanner overlaid on the Point Cloud.

Source: By the authors



In the process of representation by categories of constructive elements, the modeling workflow was segmented into distinct strategies, adapted to the geometric complexity and nature of each component of the Pinacoteca.

The walls were identified through the analysis of the voids between the captures of internal and external faces in the point cloud. The modeling strategy consisted of subdividing each wall into three distinct layers: two fixed finishes of 2.0 cm and a structural core of variable thickness, adjusted

according to the actual dimension detected in the cloud. This method allowed for the precise documentation of thickness variations throughout the building.

In the case of the frames, the procedure consisted of isolating specific cutouts from the original point cloud using Autodesk ReCap software. These cutouts were processed in CloudCompare to ensure format compatibility within the Revit family editing environment. From this, these cloud segments were used to base the modeling of the different types of frames (Figure 7).

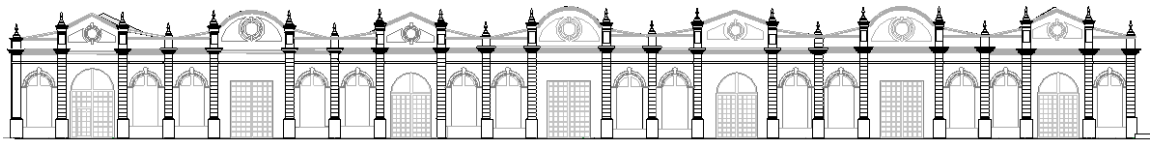


Figure 7 - Window and Door Modeling Process in Revit Using the Point Cloud

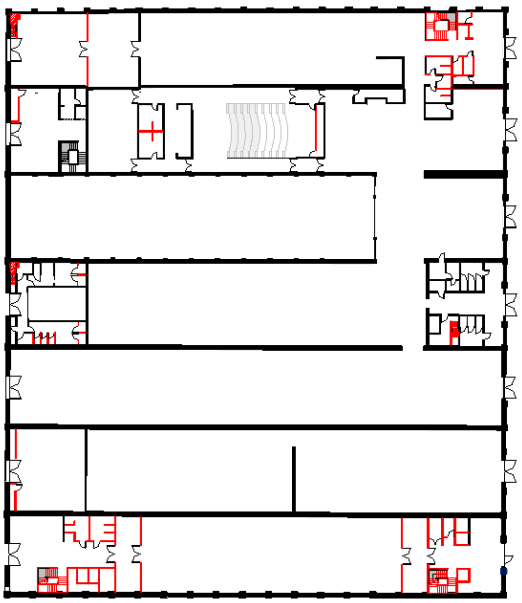
Source: By the authors

Regarding the ornaments, due to their singular and non-standardized geometry, Revit's in-place modeling tool was utilized. The process was supported by sections, views, and floor plans extracted directly from the point cloud, complemented by the visual aid of panoramic images captured by the laser scanner. Access to the 360° images recorded during the captures allowed for a detailed visual verification of textures and reliefs which, at times, are difficult to interpret solely through the point cloud.

Figure 8 - Modeling of the Main Facade of the Pinacoteca do Ceará in Revit

Source: By the authors



3.3.3 Characterization of Data Origin and Informational Reliability

To ensure the reliability of the information and the HBIM model, an intrinsic parameter was applied to the wall elements to characterize the provenance of each component. Thus, the origin of the element is recorded, safeguarding the precision of the point cloud survey process.

The use of this data field enabled the implementation of graphic override filters within the BIM environment, facilitating the visual identification of each geometry's origin in floor plans and sections. This methodological decision is fundamental for future asset management, as it allows researchers and managers to promptly identify which areas possess greater precision and which present higher

informational uncertainty due to access restrictions during the survey. Consequently, the model establishes itself not only as a geometric representation but as a technical record regarding the reliability of the Pinacoteca survey.

4. Results

The Scan-to-BIM workflow of the Pinacoteca do Ceará resulted in an HBIM model that is geometrically more precise and, unlike traditional surveys, allows for the inclusion of information intrinsic to the elements.

By overlaying the point cloud—generated by the integration of Laser Scanning and aerial photogrammetry—onto the CAD records, critical discrepancies were identified, such as the lack of orthogonality in structural walls and millimeter-scale variations in door and window openings. While imperceptible in conventional surveys, these are decisive for diagnosing pathologies and planning conservation interventions.

The effectiveness of the adopted hybrid strategy is manifested in the ability to fully represent the object, even in the face of access restrictions in certain sectors. To ensure the intellectual integrity of the model, the application of a data provenance filter was fundamental. This approach allowed each parametric component to be categorized according to its source of origin (point cloud or secondary documentation), granting the model the character of a historical and scientific record.

5. Final Considerations

The process of digitization and HBIM representation of the Pinacoteca do Ceará, using the Scan-to-BIM methodology, proved to be more than just an exercise in spatial representation; it also establishes itself as a rigorous protocol for the protection and safeguarding of built cultural heritage. The results obtained indicate that reality capture through Laser Scanning and photogrammetry is of paramount importance in overcoming the geometric inconsistencies typically found in traditional manual surveys. The resulting model is more than a mere visual representation; it is also a repository of deformities, misalignments, and real metrics that characterize the object's material identity accumulated over time (Alshawabkeh and Baik, 2024).

One of the central factors addressed in this research was the inconsistency of pre-existing documentation when faced with the complexity of a historical building. Over time, 2D CAD records or manual analog sheets tend to "idealize" the space, imposing orthogonalities and symmetries that very rarely survive the construction phase or the passing of years. In the case of the Pinacoteca, the identification of structural walls outside of orthogonal alignment demonstrated that old documentation, while valuable from a historical and documentary standpoint, is insufficient as a geometric database for interventions and management.

In this context, the article proposes that historical records be approached as complementary and secondary sources, useful for understanding internal materials, hidden systems, or smaller, specific areas. The primacy of point clouds over drawing ensures that the analysis of pathologies and restoration components is performed with the aid of a base that is millimetrically faithful to the original building. The union of active and passive sensors filled data gaps caused by occlusions, culminating in a model that ranges from the detail of facade ornaments to the complex volumes of parapets and roofs. Unlike BIM models generated for new constructions, where precision is assumed by the design, in HBIM, parametric elements possess their own provenance configuration. The introduction of parameters in the Pinacoteca model—characterizing elements modeled through laser scanning, aerial photography, or a historical plan—is a technical advancement. Such a distinction makes it explicit to heritage managers where the information is a faithful capture of reality and where it is merely a documentary inference. This clarity is fundamental for decision-making in maintenance and restoration works.

The produced HBIM representation transcends pre-existing passive documentation. By integrating non-orthogonalities and temporal deformations, the file transforms into an input for structural analysis. Unlike models generated through standard plans, which simulate ideal equilibrium

scenarios, the Digital Twin of the Pinacoteca allows for simulations that take real geometric deviations into account, enabling monitoring over time.

Furthermore, for the entities managing the facility, the model can also become a tool for asset management, building maintenance, and logistical information. The ability to aggregate conservation data into specific elements optimizes the planning of events such as painting cycles, roof cleaning, and component replacement, in addition to streamlining resources and ensuring the longevity of the Pinacoteca do Ceará.

As a next step, the study points to the need for standardizing the provenance parameters of the modeled data. The segmentation of recording methods across different buildings and contexts ultimately hinders comparisons between models. Therefore, it is proposed to develop a recording confidence metric to be applied universally to HBIM models created for the same purpose, even by different teams. This metric would enable researchers and maintenance agencies to quantitatively and qualitatively assess the degree of precision and reliability of entire digital collections.

Abstract: The preservation of built cultural heritage is frequently hindered by a lack of precise technical documentation, which is essential for restoration interventions and heritage management. Given the limitations of conventional methods in capturing complex geometries, this paper proposes and validates an operational multi-sensor acquisition framework for high-fidelity geometric documentation. The protocol is structured around the integration of reality-capture technologies to overcome challenges related to occlusion and scale, and was tested and validated at the Church of Nossa Senhora da Conceição de Almofala (Itarema/CE, Brazil), a nationally listed landmark characterized by demanding environmental and morphological conditions. The framework's methodology is organized into stages of pre-survey planning, technological zoning, and the integration of data from three complementary sensors: terrestrial laser scanning (TLS), mobile mapping (SLAM), and aerial photogrammetry via unmanned aerial vehicles (UAV). This workflow enabled the consolidation of a dense point cloud comprising approximately 639 million points with a residual metric error of only 0.003 m, ensuring the geometric completeness of both complex interiors and inaccessible roof structures. The results demonstrate that the proposed framework is effective in eliminating occlusion zones and generating a metrically reliable digital representation suitable for supporting Heritage Building Information Modeling (HBIM) processes. The primary contribution of this study lies in defining a systematized, transferable workflow that transforms raw multi-sensor geometric data into high-precision geometric information for the safeguarding and management of built heritage.

Keywords: HBIM, Multi-scanner Digitization, Digital Safeguarding

1. Introduction

Built cultural heritage documentation is a fundamental component of conservation, restoration, management, and long-term knowledge transmission, since interventions on historic buildings depend on reliable records of their geometry, materials, condition, and spatial organization (ICOMOS 1964; Antonopoulou and Bryan 2017; ICOMOS 2007). Traditional documentation methods based on manual survey, 2D drawings, photographic records, and descriptive reports remain valuable, but they are often insufficient when high geometric completeness, metric reliability, three-dimensional representation, and data reusability are required (Boardman and Bryan 2018; Oliveira 2008).

Recent advances in reality-capture technologies have significantly expanded the possibilities for heritage documentation. Terrestrial laser scanning (TLS), digital photogrammetry based on Structure-from-Motion (SfM), and mobile mapping systems based on Simultaneous Localization and Mapping (SLAM) can generate dense three-dimensional datasets with different balances of accuracy, speed, coverage, and operational flexibility, making them especially useful in complex historic environments. However, none of these technologies is universally sufficient on its own. Their performance depends on object scale, accessibility, surface properties, lighting conditions, occlusions, and the intended level of geometric detail, which makes methodological planning and sensor selection critical steps in the documentation process (Sammartano

and Spanò 2018; Remondino et al. 2014; Bedford 2017; Boardman and Bryan 2018). This issue is particularly relevant in historic buildings, where irregular geometries, inaccessible roof structures, narrow interiors, highly reflective surfaces, and environmental constraints frequently limit the effectiveness of single-sensor workflows (Themistocleous et al. 2015). For this reason, current best practice increasingly favors hybrid acquisition strategies in which different technologies are assigned to different zones or documentation tasks according to their technical suitability, and later integrated into a common spatial reference framework (ICOMOS 2007; Argasiński and Kuroczyński 2023).

Although Heritage Building Information Modeling (HBIM) has become an important framework for the structured representation and management of historic buildings, the quality of any future HBIM model depends directly on the reliability and completeness of the survey data from which it is derived (López et al. 2018). Accordingly, this research focuses on the preceding stage: the definition and application of a multi-sensor acquisition protocol capable of generating a consolidated point cloud suitable for supporting future scan-to-HBIM developments. This paper proposes a multi-sensor protocol for the geometric documentation of built heritage, organized into four articulated stages: pre-survey planning, technological zoning and field acquisition, multi-source registration and consolidation, and quality-oriented preparation of the final point cloud. The protocol is applied and discussed through the case of the Church of Nossa Senhora da Conceição de Almofala in Ceará, Brazil, a historic building whose morphology and environmental conditions provide a demanding testbed for hybrid acquisition. The paper's contribution lies in demonstrating how a structured acquisition protocol can support complete, metrically consistent, and operationally viable documentation in a complex heritage context.

2. Multi-sensor acquisition protocol

The documentation of built heritage through digital reality-capture technologies requires more than simply selecting appropriate sensors. It requires a structured operational workflow capable of ensuring geometric completeness, metric consistency, and traceability of results across successive stages. Based on current best practice in heritage survey (Antonopoulou and Bryan 2017; Boardman and Bryan 2018; Bedford 2017), the protocol proposed here is organized into four sequential and interdependent macrophases: (1) pre-survey planning and requirements definition; (2) technological zoning and sensor assignment; (3) field acquisition; and (4) multi-source registration, consolidation, and quality control. Each phase conditions the quality of the next, making them interdependent rather than merely sequential. (figure 1)

2.1 Pre-survey planning and requirements definition

Before any field operation begins, the documentation requirements must be formally defined. This includes establishing the expected geometric level of detail (LOD), the spatial extent of the survey, the sensors available, and the intended use of the resulting data (Groetelaars 2015; Bedford 2017). In the context of heritage documentation, the LOD determines the acceptable point spacing and the minimum positional accuracy of the final dataset, which in turn guides sensor selection and field strategy. For example, LOD 300 (compatible with intervention projects and standard HBIM) typically requires point spacing between 3 and 10 mm and a metric precision in the order of 5–10 mm, while LOD 400 (detail and ornament documentation) may require sub-3 mm resolution (Boardman and Bryan 2018; Bedford 2017).

A critical component of pre-survey planning is defining the geodetic control strategy. Georeferencing through a network of ground control points (GCPs) measured with a total station or GNSS equipment is the recommended practice, as it enables the dataset to be placed in an absolute spatial reference system, supports integration with cartographic data, and makes the results verifiable against independent measurements (Fryskowska 2017). The geometry of the GCP network matters more than the number of points alone: well-distributed control points across the building's vertical and horizontal extents are essential for constraining systematic errors in both TLS registration and SfM photogrammetric adjustment (Page et al. 2017).

However, a georeferenced control network is not always operationally feasible, due to access constraints, regulatory restrictions, budget limitations, or time pressures in the field. In such cases, it is still possible to produce a metrically reliable and internally consistent multi-sensor dataset by adopting a relative

registration strategy: one acquisition is designated as the fixed reference, and all others are aligned to it. The sensor chosen as the reference must have the highest intrinsic metric precision. Among the technologies typically used in heritage documentation, terrestrial laser scanning (TLS) has consistently demonstrated the highest internal metric accuracy, with point-positioning errors generally in the range of 1–6 mm, depending on distance and scanner model (Fryskowska 2017). As a consequence, when absolute georeferencing is unavailable, the consolidated TLS point cloud should be established as the fixed reference cloud, and all other datasets should be aligned to it. The TLS cloud should not be scaled or transformed; it remains the geometric ground truth of the relative coordinate system.

This two-tier approach preserves metric integrity in both scenarios while honestly acknowledging the difference between absolute accuracy (position in a global reference system) and relative accuracy (internal geometric consistency of the dataset). For most conservation, documentation, and HBIM-preparation purposes, high relative accuracy is the primary requirement (Antonopoulou and Bryan 2017).

2.2 Technological zoning and sensor assignment

A key methodological decision in multi-sensor survey design is the spatial assignment of each technology to the building zones for which it is best suited. This technological zoning approach is grounded in the complementary nature of the available sensors: each technology has specific strengths and limitations regarding range, accuracy, occlusion tolerance, accessibility, and operational speed.

TLS is the most appropriate technology for zones requiring high metric accuracy at close to medium range: interior spaces, façades, and structurally significant elements where precise dimensional data is essential (Boardman and Bryan 2018; Bedford 2017). SLAM mobile scanning is best deployed for general volumetric capture of circulation spaces, interior-exterior transitions, and areas where speed is operationally critical but millimetric precision is not the primary requirement (Sammartano and Spanò 2018). UAV photogrammetry (SfM) is a viable technology for inaccessible zones such as roof surfaces, tower tops, and upper cornices, while also providing important chromatic and textural information (Themistocleous et al. 2015; Remondino et al. 2014). Table 1 summarizes the technology–zone assignment logic that informs the protocol.

Table 1 – Technology–zone assignment matrix for multi-sensor heritage documentation: recommended sensor allocation by spatial zone, documentation priority, and acquisition strategy.

Zone	Priority	Assigned technology
Interior spaces (general)	Speed, continuity	SLAM
Interior details, altars, ornaments	Metric accuracy	TLS
Façades and exterior walls	Metric accuracy, color	TLS
Roof surface and upper coverage	Coverage, accessibility	UAV (SfM)
Tower tops and inaccessible upper zones	Coverage, accessibility	UAV (SfM)
Interior–exterior transitions	Geometric continuity	SLAM

The occlusion zones specific to each building (defined by its morphology, height, and spatial organization) must be identified during pre-survey reconnaissance and explicitly addressed in the zoning plan. The fundamental principle is that the limitations of each technology must be compensated by the strengths of another, so that the composite dataset achieves spatial continuity without relying on any single sensor to cover the entire building.

2.3 Field acquisition

The field acquisition sequence follows the zoning plan, but should also be ordered to maximize the value of each step. The recommended sequence is: SLAM first, to establish a rapid global volumetric context; UAV second, to capture the inaccessible upper zones; and TLS last, to provide the metric ground-truth layer for registration.

SLAM acquisition should begin with a closed-loop trajectory that connects interior and exterior spaces in a single continuous pass. Closed-loop trajectories are essential for SLAM-based systems because they allow the algorithm to detect the return to a previously mapped location and use that constraint to correct drift errors accumulated during the scan (Sammartano and Spanò 2018). The SLAM output is a dense, continuous but less precise point cloud that serves primarily as a volumetric connector between the higher-accuracy datasets.

UAV photogrammetric acquisition should be planned in two complementary flight modes: nadir (gimbal at 90°) for systematic roof coverage and accurate orthorectification, and orbital (oblique, 45°–60°) for upper façade areas, cornices, eaves, and tower surfaces that neither ground sensors nor the nadir pass can capture. To ensure reliable SfM convergence, a minimum frontal overlap of 75–80% and a lateral overlap of at least 60% are recommended; higher overlaps are particularly important in orbital flight modes around complex architectural volumes, where surface texture variability and convergent viewing angles increase the risk of keypoint-matching failures (Bedford 2017). If GCPs are available, they should be distributed to cover the full vertical extent of the building, not just the ground plane, to constrain photogrammetric distortions across all elevations (Fryskowska 2017). When operating under challenging illumination conditions (such as strong solar radiation on highly reflective surfaces), acquisition should be planned according to sun position to mitigate overexposure and keypoint-detection failures in SfM/MVS processing (Remondino et al. 2014).

TLS acquisition should follow a station plan that ensures a minimum 30% overlap between adjacent scans, which is necessary for reliable scan-to-scan registration and error minimization (Boardman and Bryan 2018). Stations should be positioned to provide redundant coverage of structurally and architecturally significant zones, and to include areas already captured by SLAM and UAV, enabling cross-sensor validation. Where reflective surfaces challenge laser return quality, HDR scanning (multiple exposure intensities per station) can help recover surface detail.

2.4 Multi-source registration, consolidation, and quality control

The processing stage transforms heterogeneous raw data into a single, geometrically coherent and quality-assessed point cloud. This is the most methodologically sensitive stage because systematic errors in any dataset propagate into the final product if not detected and corrected.

TLS registration and consolidation should be performed first, as this dataset forms the metric backbone of the final model. Individual scans can be aligned through several methods, depending on available resources and field conditions: (a) target-based registration, using artificial retro-reflective markers or natural reference objects placed at known positions to establish geometric correspondences between scans; (b) automatic cloud-to-cloud registration, where algorithms detect and match geometric features across overlapping scans without the need for physical markers, reducing field setup time but requiring sufficient geometric complexity in the scene (Shao et al. 2019); and (c) hybrid registration, combining a manual or visual coarse pre-alignment (in which the operator positions scans into approximate spatial correspondence using identifiable architectural features) with a subsequent ICP-based fine adjustment that iteratively minimizes point-to-point or point-to-surface distances to convergence. Regardless of the method used, a global bundle adjustment should follow individual scan pairing to distribute residual errors across all scan positions rather than accumulating them sequentially. The output should be assessed using a quality report that documents per-scan overlap, link strength, and maximum registration error; an RMS registration error below 5 mm is generally acceptable for LOD 300 documentation.

SfM photogrammetric processing should include bundle adjustment of camera positions and orientations, followed by dense multi-view stereo (MVS) reconstruction. If GCPs are available, they are introduced at this stage to constrain the photogrammetric model to the absolute or relative reference system. If GCPs are not available, the photogrammetric model is processed in its own coordinate system and subsequently aligned to the TLS reference cloud.

Multi-sensor integration is performed by aligning SLAM and SfM outputs to the fixed TLS reference cloud. The alignment should follow a progressive three-step strategy: coarse manual alignment, semi-automatic point-pair picking using unambiguous architectural features (corners, ridge lines, eave edges), and fine iterative closest point (ICP) refinement. The TLS cloud is kept fixed at all stages; only the SLAM and SfM clouds are transformed. Post-fusion cleaning includes spatial subsampling to remove redundant points at zones of overlap, topological filtering to eliminate disconnected islands, and statistical outlier removal (SOR). The consolidated point cloud should be evaluated with respect to three quality criteria: (a) registration accuracy, expressed as maximum and mean registration error; (b) spatial coverage, assessed visually and by identification of residual occluded zones; and (c) point density consistency, to ensure homogeneous coverage across zones surveyed by different sensors.

The final product is a georeferenced (or TLS-anchored) multi-source point cloud with documented provenance, verified registration metrics, and explicit notation of any residual limitations. This dataset constitutes the primary input for subsequent semantic segmentation and HBIM representation workflows (Dore and Murphy 2017).

3. Case study: Church of Nossa Senhora da Conceição de Almofala

The Church of Nossa Senhora da Conceição de Almofala, located in Itarema, Ceará, Brazil, was erected in 1712 and is listed as national heritage by the Instituto do Patrimônio Histórico e Artístico Nacional (IPHAN, process no. 1000-T-79, 1980) (figure 2). The building is notable for having been buried under mobile coastal dunes between 1897 and the 1940s, a process that subjected the masonry fabric to exceptional geomorphological stress and contributes to its ongoing significance as both an architectural and cultural landmark. The church follows a colonial plan composed of a single nave, a lateral sacristy, and a bell tower rising above the main façade, with a two-pitch ceramic tile roof that is structurally complete but partially degraded. The exterior surfaces are finished in whitewashed lime render, producing characteristically high surface reflectance.

As a validation environment for the proposed protocol, Almofala concentrates several categories of constraint that are representative of difficult heritage survey conditions. Morphologically, the vertical mass of the bell tower creates significant occlusion zones for any ground-based sensor, while the sloped roof surface and its upper cornices are entirely inaccessible to terrestrial instruments. Internally, the transition between the nave, the altar, and the sacristy generates spatial continuity challenges that fixed-station sensors cannot easily resolve without a high number of setups. Environmentally, the coastal setting introduces persistent aeolian instability that limits UAV operational windows, and the combination of intense solar radiation and high surface albedo on the whitewashed façades creates overexposure conditions that challenge both photogrammetric keypoint detection and laser intensity homogeneity. The convergence of these morphological and environmental constraints, which affect all three sensor families in distinct ways, makes the Church of Almofala a demanding yet representative testbed for verifying the

practical applicability, robustness, and complementarity of the multi-sensor acquisition protocol described in Section 2. (figure 2)

Figure 2 – The Church of Nossa Senhora da Conceição de Almofala today. Source: Project archive.

4. Application of the protocol at Almofala

4.1 Pre-survey decisions

Prior to fieldwork, the scope of documentation was defined in alignment with the project team's conservation and research objectives. The target level of detail was established at LOD 300 for the architectural body as a whole, with localized LOD 400 coverage for the altar's high-complexity interior elements and carved wooden ornamentation (Figure 3). The survey was designed to produce a geometrically complete, chromatically accurate, and metrically consistent point cloud of the entire building, including all façades, the roof surface, the bell tower, and the interior nave, suitable to serve as the primary geometric input for future HBIM development. A georeferenced geodetic control network was not established during this campaign due to operational constraints. Accordingly, the consolidated TLS point cloud was designated as the fixed metric reference, and all other datasets were aligned to it, following the relative registration strategy described in Section 2.2. The three sensors mobilized were the Leica BLK360 (TLS), the Leica BLK2GO (SLAM), and the DJI Mavic 3T Enterprise (UAV photogrammetry, SfM). (Figure 4)

Figure 3 – the altar's high-complexity interior elements and carved wooden ornamentation

Figure 4 – (a) BLK 2Go, (b) BLK 360 e (c) Drone DJI Mavic 3T Enterprise. Source: Project archive

4.2 Technological zoning

The morphological and environmental constraints identified in Section 3 directly informed the sensor-to-zone assignment. The interior nave was assigned to SLAM for rapid volumetric capture, while the altar-mor and carved ornamental elements were assigned to TLS at maximum resolution density, given the priority of metric accuracy for these architecturally significant components. All exterior façades were assigned to TLS, with HDR scanning mode activated to compensate for the high albedo of the whitewashed lime render under direct solar radiation; façade capture was concentrated during periods of oblique natural light to preserve shadow detail in relief elements such as cornices and portals. The roof surface and the upper

sections of the bell tower, both inaccessible to ground sensors, were assigned exclusively to UAV photogrammetry. Interior-to-exterior spatial transitions were covered by SLAM as a geometric connector between the TLS interior and exterior setups.

4.3 Field acquisition sequence

Phase 1 — SLAM (BLK2GO). The SLAM acquisition was conducted as the first field operation to establish the building's global volumetric context. The operator followed a continuous closed-loop trajectory that began and ended at the same physical point, circling the exterior perimeter and passing through the interior nave via the main entrance. The closed-loop constraint allowed the SLAM algorithm to detect and correct accumulated drift errors at closure. The full trajectory was completed in approximately 15 minutes, yielding a continuous but moderate-density point cloud covering both interior and exterior volumes. (Figure 5)

Figure 5 – Performing SLAM (BLK2GO). Source: Research archive.

Phase 2 — UAV photogrammetry (DJI Mavic 3T Enterprise). The aerial acquisition was organized in two complementary flight modes. A nadir flight (gimbal at 90°) provided systematic coverage of the roof surface, yielding precise orthometric data on the condition of the ceramic tiles and the exact building footprint. An orbital flight executed three 360° passes around the church at varying altitudes, with the gimbal inclined between 45° and 60°, plus three additional focused passes at tower height to capture the bell tower faces, eave edges, and upper cornices. Flight operations were concentrated during meteorological calm windows to mitigate aeolian instability. A total of 470 images were captured, of which 466 were successfully aligned. Despite planning for favorable lighting conditions, the high albedo of the façades produced homogeneous textures and localized overexposure in sections of the orbital imagery, resulting in insufficient keypoint detection for SfM convergence. These areas were corrected by manually introducing control points tied to identifiable surface features (microfissures, weathering marks, and tile boundaries), thereby ensuring correct triangulation and restoring geometric continuity in the affected zones. (figure 6)

Figure 6 – Sample of nadir flight images (left); Sample of orbital flight (right). Source: Research archive.

Phase 3 — TLS (Leica BLK360). Fixed-station TLS scanning was performed last, providing the metric reference layer for the entire registration workflow. A stations were deployed, distributed across two fronts: interior stations concentrated on the altar and ornamental woodwork at maximum density, and exterior stations covering all façades at high resolution. Station placement ensured a minimum inter-scan overlap of 30%, sufficient for reliable scan-to-scan registration. HDR mode was applied at all exterior stations to balance the radiometric response between the intensely lit lime-render surfaces and the deep shadows at corbels and portals. (figure 7)(figure 8)

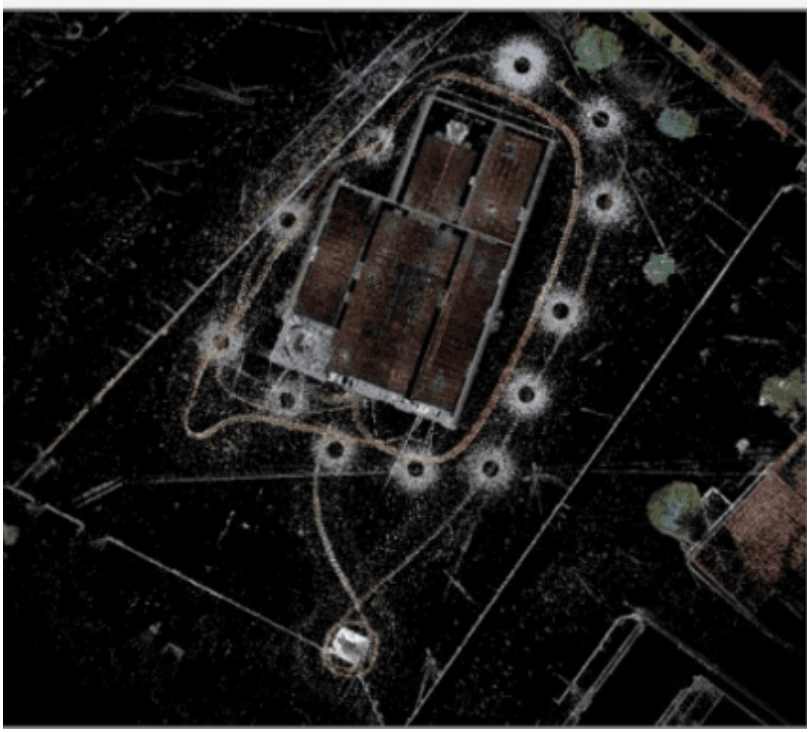

Figure 8 – TLS path (Leica BLK360). Source: Research archive.

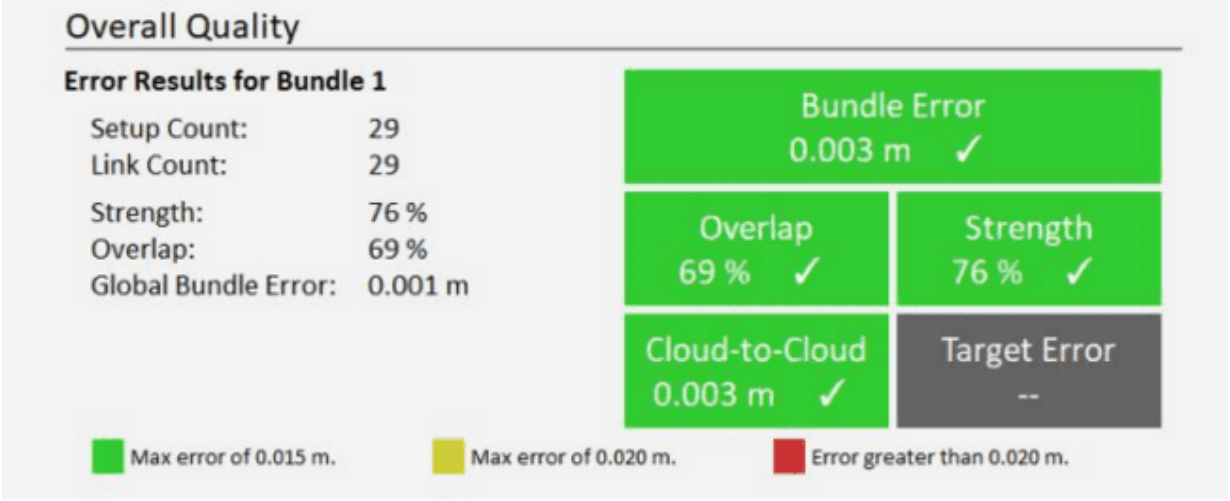
4.4 Processing, registration, and consolidation

TLS and SLAM consolidation: The 26 TLS setups and 2 SLAM trajectories (all captured with Leica ecosystem equipment) were imported into Leica Cyclone REGISTER 360, which enabled native interoperability between the two sensor types within a single project environment. The registration workflow followed three steps: manual visual pre-alignment using overlapping geometric features; automatic ICP-based fine registration, generating per-link quality reports; and global bundle adjustment to minimize cumulative error across all connections. The consolidated terrestrial cloud exhibited approximately 430 million points, with a mean scan overlap of 69% and a maximum registration error of 0.003 m. (figure 9)



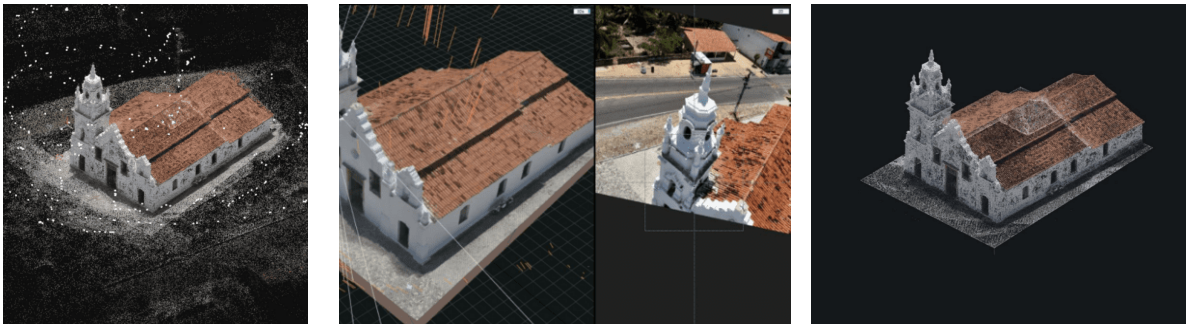


Figure 9 – Excerpt from the report generated by Cyclone REGISTER 360 for the terrestrial scan clouds. Source: Developed by the authors.

SfM photogrammetric processing: The 466 aligned images were processed in RealityScan using a standard SfM/MVS pipeline: SIFT-based keypoint detection, tie-point matching, bundle adjustment for camera orientation, and dense MVS reconstruction. A bounding box was applied prior to dense reconstruction to exclude surrounding elements. The resulting photogrammetric cloud contained approximately 288 million points, covering the roof surface, the bell tower, and the upper portions of all façades, with dense chromatic information. (figure 10)

(a) (b) (c)

Figure 10 – (a) Sparse cloud with tie-points and camera positions; (b) Process of manual control point insertion in RealityScan software; (c) Aerial photogrammetry result. Source: Developed by the authors.

Multi-sensor integration: Final fusion of the terrestrial and aerial datasets was performed in CloudCompare 2.13.1. The consolidated TLS cloud was established as the fixed reference. The SfM cloud was aligned using the hybrid three-stage strategy described in Section 2.5: coarse manual positioning, semi-automatic point-pair picking at six unambiguous architectural features (tower corners, ridge lines, eave extremities), and ICP fine refinement configured with a target RMS tolerance of 1.0×10^{-5} and a random sampling of 50,000 points per iteration. Post-fusion homogenization was performed using spatial subsampling at a 10 mm minimum inter-point distance, followed by topological filtering (Label Connected Components), statistical outlier removal (SOR), and manual trimming of residual artifacts. The final consolidated point cloud comprises approximately 639 million points, with smooth spatial transitions between the terrestrial and aerial layers and no identified residual occlusion zones in architecturally significant areas (Figure 11).

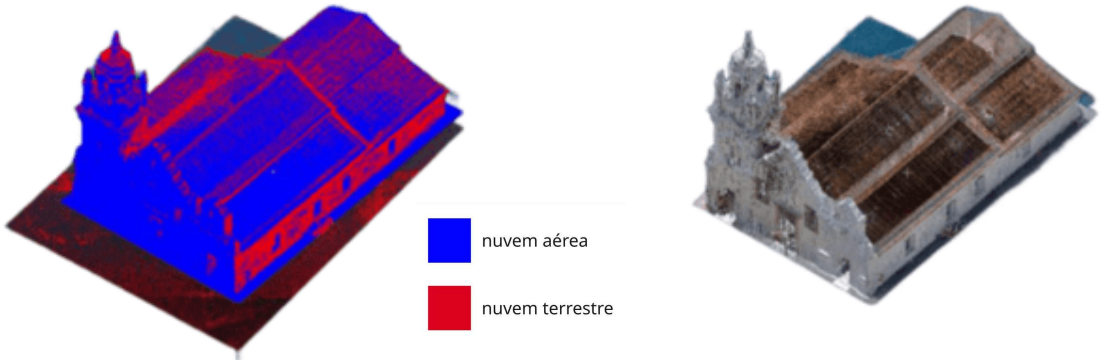

Figure 11 – Consolidated cloud. On the left, color-coded by source (terrestrial cloud/aerial cloud); on the right, with RGB coloring.

4.5 Results and quality assessment

The application of the protocol at the Church of Almofala produced a geometrically continuous, multi-source point cloud of the complete building in its current state of conservation. The maximum registration error of 0.003 m confirms metric consistency within the consolidated dataset at a level appropriate for LOD 300 documentation and compatible with the precision requirements for future parametric HBIM

representation. The sequential sensor deployment (SLAM for volumetric context, UAV for inaccessible upper zones, TLS for metric ground truth) demonstrated effective complementarity: the occlusion zones specific to each sensor were systematically compensated for by the coverage strengths of the others, and no single technology would have been capable of producing equivalent spatial completeness independently. Limitations acknowledged include the absence of absolute georeferencing, which restricts the dataset to a relative coordinate system and prevents direct integration with cartographic or topographic datasets without a subsequent alignment operation; and the manual correction required in the SfM photogrammetric model due to surface overexposure, which introduces a degree of interpretive intervention in the aerial point cloud that should be documented as part of the survey paradata (Bentkowska-Kafel and Denard 2016).

5. Conclusion

This paper proposed a structured multi-sensor acquisition protocol for the geometric documentation of built cultural heritage, organized around four interdependent stages: pre-survey planning and requirements definition, technological zoning and sensor assignment, sequential field acquisition, and multi-source registration with quality-oriented consolidation. The protocol was applied to the Church of Nossa Senhora da Conceição de Almofala, a nationally listed heritage building in Ceará, Brazil, whose morphological complexity and demanding coastal environment provided a representative and rigorous context for validation.

The results show that the structured combination of TLS, SLAM-based mobile scanning, and UAV photogrammetry, each assigned to the building zones for which it is technically most appropriate, can produce a metrically consistent and spatially complete dataset under conditions in which any single-sensor strategy would produce significant coverage gaps. The final consolidated cloud of approximately 639 million points, with a maximum registration error of 0.003 m, confirms that the workflow is operationally viable and produces data at a quality level compatible with LOD 300 heritage documentation requirements.

Two limitations must be explicitly acknowledged. First, the absence of a georeferenced geodetic control network restricts the dataset to a relative coordinate system, sufficient for documentation and conservation purposes but requiring a subsequent alignment operation before integration with absolute cartographic references. Second, the manual introduction of control points during SfM processing, which is necessary due to surface overexposure, constitutes an interpretive intervention that must be recorded as part of the survey paradata to ensure scientific transparency and reproducibility. Both limitations are consistent with real-world operational constraints and do not invalidate the protocol; rather, they illustrate the importance of explicit quality reporting and honest documentation of methodological decisions.

The primary contribution of this work is not the documentation of a specific building, but the definition of a transferable acquisition framework applicable to other heritage structures that present similar challenges of occlusion, inaccessibility, and environmental constraints. The resulting point cloud constitutes a geometrically reliable and traceable dataset suitable to serve as the primary input for future scan-to-HBIM workflows, in which the raw geometry produced here would be progressively enriched with semantic, material, historical, and conservation data to support the long-term management of the built heritage asset. Future research should address integrating a georeferenced control network from the first campaign stage, systematically quantifying per-zone coverage completeness, and defining explicit acceptance criteria for each sensor's contribution to the consolidated dataset.

Abstract: Wattle and daub (tabique) structures are widespread throughout the country and have particular relevance in the North of Portugal, in which they are used in all regions and type of buildings.

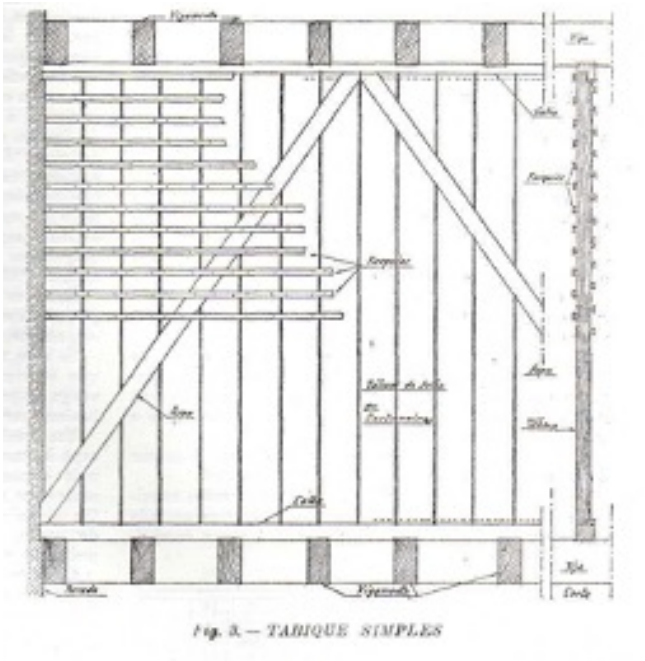
These wooden-based structures, nailed with horizontal wooden laths, constitute the basis for interior compartment division in bourgeois urban buildings, palace houses and vernacular architecture. The type of wood and care in construction of these elements differs accordingly and variations are also encountered, such as the use of braided plant fibres as a structural element. Often, as a lateral façades or attics (less commonly as main façades), *tabiques* were also employed, with a rendering or, most frequently, schist slates as a final finishing.

The interest of this paper is, however, to provide information on the mortars that filled the space between laths and acted as a render providing a uniform finishing for these walls. For this purpose, a series of samples were taken from the various regions of northern Portugal, encompassing rural and urban areas. Sampling also considered both external and internal structures.

The analysis of the samples implied fragmentation and removal of fibres, division between binder and aggregate and determination of the composition of binder and aggregate fractions.

Results showed a variety of solutions linked to the availability of local materials and also to the possibility of incorporating air lime, when this product wasn't accessible locally. The use of these findings is of particular interest for the preservation of *tabique* structures in the present intervention actions.

Keywords: Lime mortars; Earth Mortars; Tabique walls; Preservation



1. Introduction

Wattle and daub (*tabique* – Figure 1) systems are common in Portugal, with extensive use throughout the whole country, but with special predominance in the north and centre as well as in all urban areas. These partitions have a long history, and their use encompasses rural dwellings and urban houses, mainly in interior divisions, but also, less often, as external walls.

This building element combines a lightweight timber framework with an infill of interwoven wooden strips (wattle), typically made from local wood species. The structural frame, often composed of vertical posts and horizontal members, provides stability, while the wattle lattice acts as a support for the daub (Figure 1). The daub is a composite material traditionally made from a mixture of earth, clay, sand, straw, or, otherwise, a lime-based mortar, and left to dry, forming a solid wall infill. This technique is valued for its use of locally available, low-cost materials and its adaptability to regional climates. Mortars play a crucial role in both the filling and rendering stages: earth-based mortars are locally sourced and provide compatibility with the timber structure and breathability, while lime-based mortars are often linked to more relevant buildings (or

urban) and structures and/or applied as external renders to improve durability and weather resistance, maintaining relevant characteristics such as vapour permeability. Mortars in *tabique* elements have the purpose of helping to protect the structure while maintaining its ability to regulate moisture.

Figure 1 – Simple *tabique* wall (Leitão, 1896)

2. Historical observations on Tabique mortars in Portugal

Inside the built spaces, lime was applied as an element of filling and finishing partitions, which is the main type of partition inside the houses. In these elements, it is possible to find several examples of the use of fibres in the composition of the lime coating. To fill the slats between the partitions, a mortar of lime and sand was used in a 1:1 ratio (Leitão, 1896) that needed to be spooned in order to ensure its adhesion to the wooden structure. As a finish, various techniques – *fresco, fingido, escaiola* – were employed by specialized artisans.

The same author mentions earth-based mortars (Figure 2), stating that: "*Além das argamassas citadas,...,, que são as de que se faz mais vulgar applicaçào, ha também as argamassas de terra, que podem ser empregadas em casas pobres de campo*." Regarding the choice of the earth to be used in these mortars, Leitão infers that it shouldn't be too clayey, for fear of subsequent cracking (due to shrinkage). Furthermore, he explains that the earth shouldn't be too sandy either, or this could result in the lack of necessary cohesion. In terms of the execution procedure, he goes on to state that earth should be mixed with water to form a homogeneous paste after a thorough removal of stones and fibres. Proportions of earth versus sand are given as 3:1, presumably in terms of volume.

Figure 2 – *Tabique* wall with earth mortars (filling and rendering)

3. Further results of current studies

Although research on these partitions has been performed (Cardoso, 2013; Cepeda et al, 2010; Pinto et al, 2011), there was a definite knowledge gap concerning a more extensive overview in terms of the composition and characteristics of filling and rendering mortars, signifying the generation of doubts in conservation/rehabilitation actions.

In order to address this issue, recently, a Master thesis, Costa, 2021, produced as outcome research on the traditional plastering mortars used as wall coatings on *tabique* walls in Northern Portugal, aiming to support compatible conservation and rehabilitation of vernacular built heritage. This work encompassed a survey on existing buildings, including on-site sampling and documentation, complemented by bibliographic research and interviews with craftsmen to capture empirical know-how.

As a further complement, Soares et al, 2024, presented a series of results regarding studies of *tabique* mortars. The study was based on 49 samples and the results indicated mortars with earth or air lime as the main binders; considering the air lime mortars, some also incorporated clayey sand,

In continuity, a recent study on the porosity of *tabique* mortars in Portugal conducted by Soares et al, 2024, concluded that earth mortars usually present more porosity than lime mortars and the addition of fibres (vegetable fibres, mainly straw) increases this porosity, especially in terms of larger pores. This has a direct influence on the behaviour of renders, generating higher permeability.

4. Composition of tabique mortars in Northern Portugal

The results expressed in this paper encompass a set of two sampling and testing campaigns. The first campaign, exclusive to Northern Portugal was executed by Costa in 2021 and resulted in a Master Thesis (Costa, 2021). The second campaign is part of the PhD Thesis of Soares, which embraces the whole national territory and the results of which have already been partially published (Soares et al, 2024(1); Soares et al, 2024(2)). The junction of these two campaigns allows for a more extensive overview of *tabique* mortars in Northern Portugal.

4.1. Sampling

Sampling encompasses the work carried out by Costa, 2021 and Soares. Costa, 2021, collected 30 mortar samples and another 40 samples were subsequently sampled by Soares. The sampling area was delimited to the north of Portugal, including mortars from: Porto, Lamego, Guiães, Boassas, Fermentãos, Salzedas, Aveiro, Guimarães, Cinfães, Vila Real, Alfândega de Fé, Mondim de Basto, Braga, Mogadouro, Póvoa de Varzim, Esposende, Vila do Conde, Espinho.

These samples were collected from both interior and exterior *tabique* walls. The size of the samples collected varied according to the state of conservation of the building (Figure 3). A complete set of testing procedures was performed incorporating physical and mechanical characteristics and composition. In some cases, the sample size was small and therefore testing procedures were adapted. For the specific purpose of this paper, mortar composition tests and results will be described and analysed.

Figure 3 – External *tabique* in need of conservation

4.2 Testing procedures

The characterization tests of the samples were carried out in the laboratories of Itecons and the University of Aveiro (UA), in accordance with the applicable rules and procedures.The employed methodology took into account current methods for the testing of historical mortars (Velosa et al, 2010).

To characterise the sampled mortars, the following analytical methods and tests were used:

Acid dissolution was performed based on ASTM-C 25-11e1 and by the methodology suggested by some authors (Alvarez et al, 1999; Jedrzejewska, 1960) to dissolve carbonates (calcite, magnesite and dolomite) and create a residue composed by the aggregate fraction. Hydrochloric acid was used to guarantee a residue composed mainly by siliceous sand. Results give an approximate value of binder/aggregate ratio, as the used acid dissolution technique dissolves carbonates and partially dissolves soluble silica. The obtained residue was dried until constant mass was achieved. Particle size distribution by dry sieving was performed on the residue obtained from acid dissolution according to standard BS 3406-2.

X-Ray Diffraction (XRD) provided qualitative information on the crystalline mineral phases existent in the samples. For this analysis, mortars were crushed and dried at a low temperature. This analysis was performed on the fraction below 75µm to allow a more thorough analysis of the binder. The equipment used was a Panalytical X-Pert Pro X-Ray Diffractometer.

4.3 Results and discussion

Results indicate a predominance of lime-based mortars, either composed by pure lime or a lime/earth mix (Table 1). In the first sampling procedure (Costa, 2021), lime-based mortars presented a most common mass ratio of 1:3, with aggregates mainly in the fine sand to medium sand range. A smaller set of earth-based mortars, some incorporating straw, occurs mainly inland; in these mortars the fine fraction (below 63µm) is significant. XRD/XRF results point to the widespread use of locally available materials (siliceous aggregates derived from granitic and metamorphic sources), while interviews confirmed traditional mixes and adjustments to modify setting and workability.

Table 1 – Binder fraction in analysed mortars

Sampling	Number samples	Lime	Earth	Lime and Earth
Costa, 2021	30	13	9	8
Soares, 2024	40	17	18	5

The second campaign produced distinct results, due to the amount of earth mortars encountered. However, similarly to the first campaign it is evident that earth filling and rendering plasters are more common inland. The use of lime follows a similar pattern, with pure lime mortars and lime/earth mixes, most probably due to the type of sand (*saibro*) used for these purposes.

According to Figure 4, which shows the soluble percentage of mortars and their insoluble residue, great differences can be found in these mortars. Clearly, very low solubility is linked to earth mortars. Mortars with lime have solubility ranges that can also be quite low when small amounts of air lime were used, mostly coupled with the use of clayey sand. High solubility ranges, of over 25%, corresponding to lime:sand ratios (in mass) richer than 1:3, which are less common.

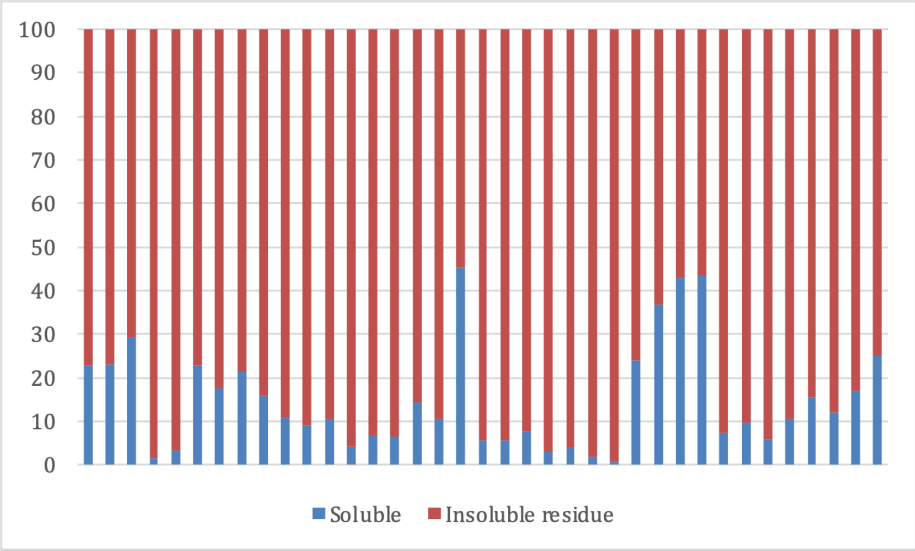


Figure 4 – Soluble and insoluble residue of mortars

The amount of earth mortars found in a very good conservation state demands a closer look at these materials. Although not common to all earth mortars, vegetable fibres, usually straw, are often found. Figure 4 shows two samples taken from Salzedas (filling of external partition) and Fermentãos (filling of internal partition).

Figure 5 – Earth and straw mortars (Salzedas and Fermentãos)

Chemical composition (XRF) results of earth mortars from the second campaign, shown in Figure 6 and the corresponding particle size division, portrayed in Figure 7, provide further information on these materials.

Although it is clear that the same type of composition corresponds to specific locations, linking locally sourced materials to the analysed buildings, it is curious that this is not completely reflected in terms of particle size, opening the possibility for sieving of earth prior to execution, in some cases.

The amount of clay can also be quite high, a few times over 60%. In these cases XRD results showed the predominance of kaolinite, which may attend to the adequate behaviour of filling materials and renders. The use of fibres, however, doesn't seem to have a direct link to either clay percentage or its mineralogical composition.

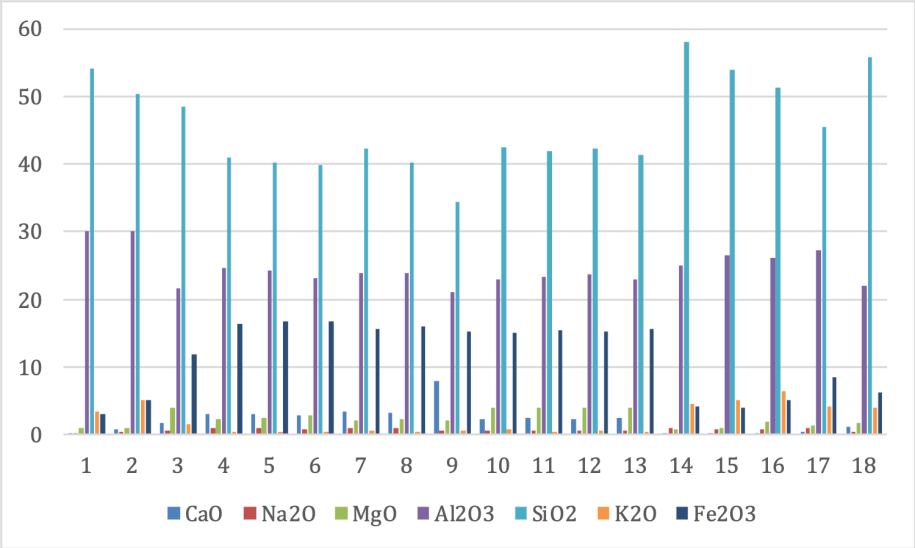

Figure 6 -Chemical composition of earth mortars

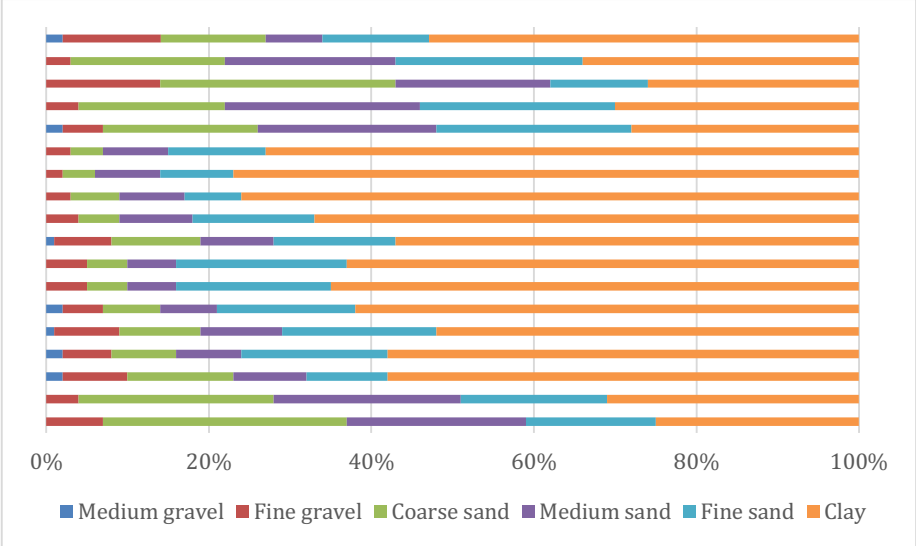

Figure 7 – Particle division of earth mortars

Conclusion

Tabique filling and rendering mortars in Northern Portugal are mainly lime based or comprised by earth as binding materials. In the case of lime-based mortars, there is a high variation in the percentage of lime used, but there is a predominance of 1:3 mass ratio. In terms of earth mortars, these are more common in interior regions and may contain fibres. Earth seems to be locally sourced and, sometimes, sieved. Mostly, mortars, whichever composition, were found in a very good conservation state. Workmanship may be a clue towards this conclusion.

Overall, the findings corroborate written and oral knowledge and highlight these mortars as low-impact, largely reversible solutions, informing heritage-compatible repair strategies and potential development of pre-dosed mixes.

Acknowledgments

This work was developed within the scope of the project "Sustainability of innovative wattle and daub mortars" (COMPETE2030-FEDER-00845500), co-funded by the European Regional Development Fund (ERDF) through the Support System for the Creation of Scientific and Technological Knowledge, under the Innovation and Digital Transition Program (COMPETE 2030). Abstract: Historical facades exhibit complex degradation patterns strongly influenced by external environmental factors. The preservation of these structures has traditionally relied on visual inspections and qualitative assessments, which often lack scalability, generalization, and real-time monitoring capabilities. Recent advances in digital technologies, particularly machine learning (ML), artificial intelligence (AI), and building information modelling (BIM), bring forward new opportunities for more accurate, efficient, and quantitative approaches for façade assessment and mapping.

A significant portion of the historic built environment is made of stone, with granite being the predominant material in northern Portugal. Historic stone facades are affected by physical, chemical, and biological degradation mechanisms, namely salt crystallisation, biocolonisation, and, in colder regions, freeze-thaw cycles. Moisture content plays a critical role in these processes, as it governs many of the weathering mechanisms responsible for long-term material deterioration, posing substantial challenges to conservation strategies.

This paper presents the framework of a research project aimed at developing a tool for assessing and mapping the degradation state of historical building facades through AI-based analysis of photographic and thermal imaging data. Computer vision techniques are used to extract relevant features from visible and infrared images, which are then integrated into machine learning models for a comprehensive assessment of the conservation state of facades.

An experimental campaign was setup using small-scale wall specimens with embedded and fully characterised defects. Preliminary results are presented and discussed under different setups and environmental conditions. The analysis focuses on temperature evolution within regions of interest and on thermal contrast between defective and flawless areas. The results demonstrate the potential of thermal imaging not only as a non-destructive diagnostic technique, but also as a source of structured data for advanced models aimed at the automated detection of façade degradation.

Keywords: Infrared thermography; façade inspection; defect detection; image segmentation; heritage conservation.

1. Introduction

The assessment of degradation in building façades, particularly in historical constructions, remains a complex and largely manual process. Inspection campaigns typically rely on visual surveys and expert judgement, which, although effective in many cases, are inherently subjective, difficult to reproduce, and not easily scalable to large building stocks.

Infrared thermography (IRT) has been widely adopted as a non-destructive technique capable of revealing subsurface anomalies such as moisture accumulation, delamination, voids, and thermal bridges. Its ability

to provide rapid, full-field measurements makes it particularly attractive for façade diagnostics (Maldague, 2001; Grinzato *et al.*, 2002). However, in most practical applications, thermographic inspection is still based on qualitative interpretation of thermograms, which limits its objectivity and integration into systematic assessment frameworks.

In recent years, several studies have explored the use of quantitative thermographic approaches for defect detection in building envelopes (Bauer *et al.*, 2016; Garrido *et al.*, 2022). These methods typically rely on the analysis of temporal temperature evolution and the extraction of features such as thermal contrast, phase delay, or cooling rates. Such methods aim to reduce subjectivity and improve robustness under varying environmental conditions. However, their application is often limited to controlled scenarios, and the integration of these indicators into automated workflows remains a challenge.

At the same time, computer vision techniques have been increasingly applied to the inspection and condition assessment of building façades and masonry structures. These approaches enable the automated detection and classification of defects based on image data, reducing the need for manual interpretation. Recent studies have demonstrated the potential of both traditional image processing and machine learning techniques for identifying cracks, detachments, and surface degradation in building elements (Wang *et al.*, 2019; Wang *et al.*, 2024).

In the context of heritage conservation, digital and image-based methodologies have also been explored to support preventive maintenance and monitoring strategies (Masciotta et al., 2019). However, the application of these techniques to thermographic data remains limited, particularly in approaches that combine physically-based thermal analysis with image-based segmentation within a unified framework. The RiskMap project is developed within this context, aiming to create a framework for assessing and mapping degradation risks in building façades using visual and thermal data. A central requirement of this framework is the ability to detect and localise defects based on image-derived features automatically.

Within the project the framework proposes a thermography-driven workflow for automated façade defect detection that bridges thermal feature analysis with image-based segmentation. The approach is demonstrated on a controlled experimental dataset with embedded defects, enabling a systematic evaluation of thermal features and their suitability for automated detection. By linking feature extraction to segmentation, the work provides a step towards the integration of thermography into scalable façade risk mapping systems.

2. RiskMap framework

The RiskMap project is conceived as an integrated framework for the assessment and mapping of degradation risks for building façades, combining multi-source data acquisition with advanced processing and analysis techniques.

The framework is designed to support the transition from isolated inspections to continuous, data-driven assessment workflows. It integrates information from different methods, including visible imagery, infrared thermography, and contextual building data, to generate spatially explicit representations of façade condition and associated degradation risks.

The overall workflow can be structured into the following steps:

- Data acquisition – collection of visual and thermal data using appropriate sensing technologies, either in controlled environments or in real-world conditions. This step includes fixed sensors, mobile platforms, and aerial systems;
- Pre-processing – correction and normalization of raw data to account for environmental effects, sensor characteristics, and acquisition conditions. This step ensures the comparability and consistency of the data;

- Feature extraction – derivation of relevant indicators from the acquired data, capturing patterns associated with degradation mechanisms. This includes both spatial and temporal thermal and visible features;
- Automated detection and segmentation – identification and delineation of anomalous regions based on extracted features. This step transforms raw data into actionable information by highlighting areas of potential concern;
- Risk mapping – aggregation of detected anomalies and defects into a spatial framework, enabling the generation of condition maps and supporting decision-making processes. This stage may be linked to BIM or digital twin platforms.

Within this pipeline, thermographic data plays a critical role in detecting subsurface defects that are not visible in standard imagery. However, its effective integration into automated workflows depends on the definition of robust and transferable features, as well as on the development of reliable segmentation methods. Figure 1 shows the pipeline and the highlighted section represents the focus of this work, where thermographic data are processed through feature extraction and image-based segmentation to support automatic defect detection.

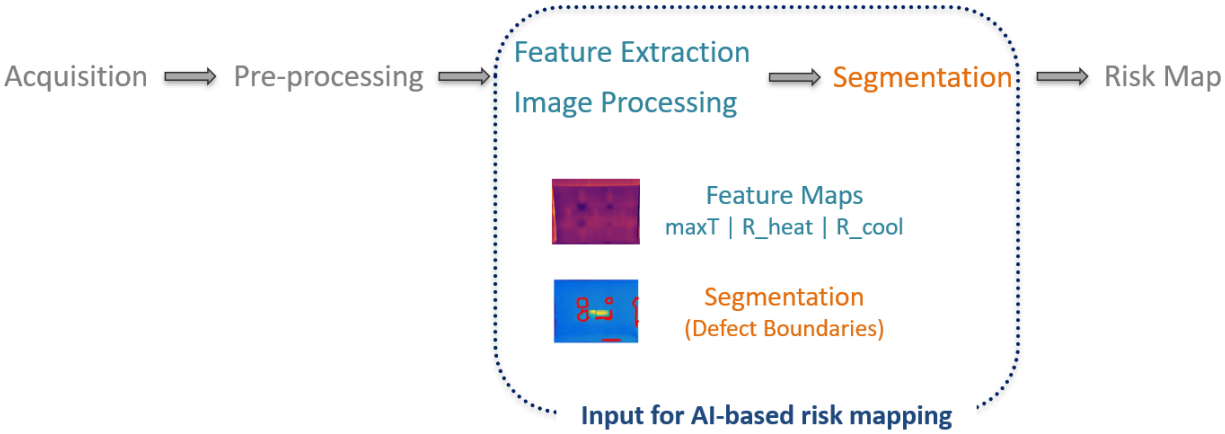

Figure 1 – Conceptual workflow of the RiskMap framework

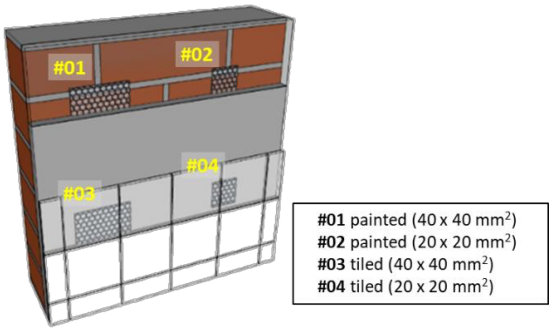


The present work focuses on the intermediate stages of this framework, namely the extraction of thermographic features and their use in automated defect segmentation. These stages are essential for enabling the transition from data acquisition to meaningful risk mapping outputs.

3. Experimental dataset

To support the development and validation of the proposed workflow, an experimental dataset was obtained using a laboratory-scale wall specimen (0.90 x 0.60 m^2) specifically designed to include subsurface defects with known geometry, size, and location.

The specimen was constructed to reproduce typical façade configurations and includes two distinct surface finishes: a painted surface (top half of the wall) and a ceramic-tiled surface (bottom half of the wall). This configuration also enables the evaluation of the influence of surface properties on thermal behaviour and defect detectability.

Artificial defects were embedded within the wall during construction using bubble wrap, providing a controlled reference for validation. These defects simulate common façade anomalies, such as voids or detachments, and allow a direct comparison between detected and actual defect locations (Figure 2).

a) 

b) 

Figure 2 – Experimental setup: a) wall specimen scheme with the defects; b) infrared thermographic recording setup

Active infrared thermography was employed to generate measurable thermal contrasts. An external infrared heat source was used to induce a controlled heating phase, followed by a natural cooling phase. Thermal images were acquired at regular intervals throughout both phases, resulting in time-resolved thermographic sequences.

In this experimental campaign, the following devices were used: (i) an infrared camera, to capture thermal images, (ii) an emissometer, to determine the emissivity of the surfaces, (iii) a 2500 W infrared lamp as external heat source.

The acquisition protocol was designed to ensure repeatability and comparability between experimental runs. All data were recorded in radiometric format, enabling quantitative analysis at the pixel level.

The resulting dataset is particularly suitable for the objectives of this work for two main reasons: controlled conditions allow the systematic evaluation of thermal features and their sensitivity to different factors, such as surface finish and heating configuration; known and reliable reference data that enables the validation of segmentation results and the assessment of detection accuracy.

In the context of this study, the dataset is used not only to analyse thermographic behaviour but also to support the development of two complementary approaches: (i) the extraction of thermal indicators for quantitative analysis, and (ii) the application of an image-based segmentation pipeline for automatic defect detection.

4. Thermal data analysis and feature extraction

To characterise the thermal behaviour of the wall specimen and support the interpretation of defect-related anomalies, a quantitative analysis of the thermographic data was performed. The acquired thermal images were organised into a three-dimensional dataset T(x,y,t), where *x* and *y* represent spatial coordinates and *t* the acquisition time. This representation enables the analysis of both spatial and temporal thermal variations.

To enhance defect-related thermal signals and remove noise, a baseline normalization procedure was applied. The thermographic image acquired before the heating phase was used as a reference and subtracted from all subsequent images:

$$T'(x,y,t) = T(x,y,t) - T_{baseline}(x,y) \quad (1)$$

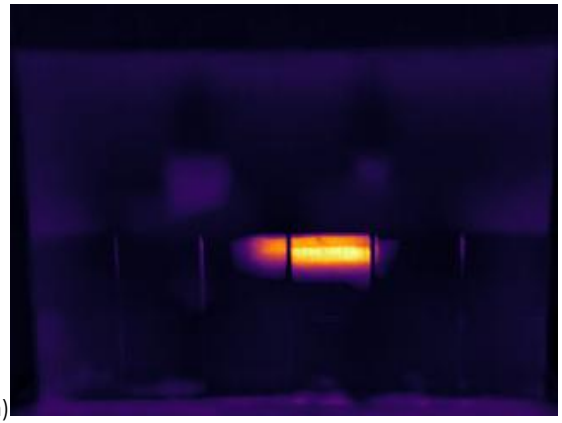
This normalization process reduces the influence of initial temperature distributions and highlights transient thermal effects associated with heat transfer. Based on the normalized data, a set of pixel-wise thermal indicators was computed to capture different aspects of the thermal response.

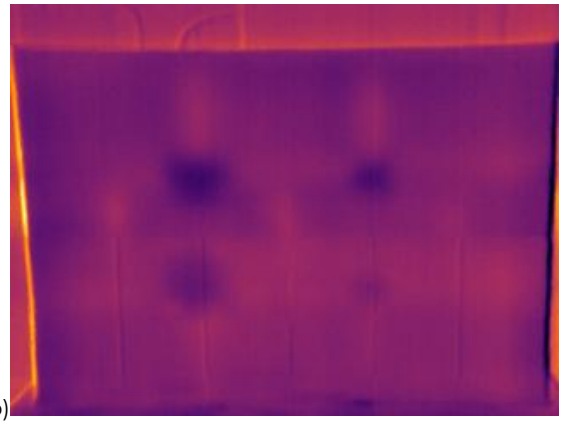
The computed indicators reveal distinct thermal patterns between defective and non-defective regions. Figure 3 presents representative maps of the maximum thermal contrast (maxT) and cooling rate (R_cool) obtained from the experimental dataset. Maximum thermal contrast highlights pixels exhibiting the strongest thermal response, which are expected to correspond to subsurface defects and is defined as the maximum measured temperature in each pixel throughout the entire experiment; cooling rate is defined in equation (2) and estimated using linear regression over the corresponding time intervals.

$$R_cool\ (x,y) = dT'(x,y,t)/dt) \tag{2}$$

Defective regions are visible as localized anomalies, particularly in the painted surface finishing (top half of the specimen), where higher thermal contrast can be observed.

During the heating phase, the thermal response is strongly influenced by the spatial distribution of the heat source, leading to marked thermal patterns. As a result, indicators such as maximum thermal contrast and heating rate may be affected by global gradients unrelated to subsurface defects. In contrast, during the cooling phase, the thermal response becomes primarily governed by intrinsic material properties. Defective regions typically exhibit slower cooling rates due to differences in heat transfer, resulting in improved contrast relative to intact areas. This behaviour is consistent with previous findings reported in the literature (Freitas et al., 2014).





a)  b) 

Figure 3 – Pixel-wise thermal indicators derived from the experimental dataset: (a) Maximum thermal contrast (maxT); (b) Cooling rate (R_cool)

The influence of surface properties is also evident in the results. In the painted surface, defects are more clearly distinguishable due to higher thermal contrast. On the other hand, the ceramic-tiled surface presents lower contrast and increased variability, which can be attributed to differences in surface reflectivity and thermal properties. Despite these surface-related challenges, cooling-based indicators still allow the identification of defective regions, confirming their robustness under different surface conditions.

The extracted thermal indicators provide quantitative insight into the thermal behaviour of façade elements and support the interpretation of degradation mechanisms. Although these indicators are not directly used in the segmentation procedure presented in this work, they can play an important role in understanding the physical basis of defect detectability and in guiding the selection of relevant processing strategies in future work.

5. Automatic defect segmentation

While the analysis of thermal indicators provides important insight into the physical behaviour of defective and intact regions, the implementation of automated detection requires complementary processing strategies. To enable the automated identification of defective areas, an image-processing-based segmentation approach was developed.

5.1 Segmentation pipeline for defect detection in thermographic images

The developed pipeline operates directly on thermographic images, exploiting chromatic and spatial information to map and outline anomalous regions, and consists of three main stages: (i) preprocessing, (ii) threshold-based segmentation, and (iii) morphological post-processing.

The segmentation pipeline begins with image preprocessing to enhance defect-related patterns, while reducing noise and illumination inconsistencies. At first, image contrast was enhanced based on histogram equalization using Contrast Limited Adaptive Histogram Equalization (*Zuiderveld*, 1994). This method operates on small regions (ceramic tiles dimension), increasing local contrast, while mitigating noise amplification in homogeneous areas. Thus, it allows for normalizing the frequency distribution and compensating for non-uniform illumination. To further reduce stochastic fluctuations introduced during contrast enhancement, a median filter was applied. This filtering step reduces noise while preserving edges and smoothing the image texture, improving the robustness of subsequent segmentation. Threshold-based segmentation was performed using Otsu's method (*Otsu*, 1979), which automatically determines the optimal threshold by minimising intraclass variance between background and foreground (regions of interest). This results in a binary mask highlighting candidate regions of interest. The use of a global threshold ensures computational efficiency while maintaining robustness across frames with similar thermal conditions.

To improve the spatial coherence and structural integrity of the segmented regions, a sequence of morphological operations was applied:

- Noise removal: elimination of small isolated regions;
- Morphological closing: filling of internal gaps and merging of neighbouring regions;
- Dilation: expansion of the boundaries of the segmented regions to ensure complete coverage of defect areas.

Additionally, a margin near the image borders was excluded to avoid artifacts caused by background elements and edge effects. This ensures that segmentation is restricted to the relevant wall-specimen area and improves the reliability of the results.

A key component of the proposed pipeline is the selection of the most appropriate colour space and the most representative channel. For thermographic images associated with the heating phase, the segmentation process was applied in two steps:

1) Removal of the heating source: the chromatic component of the Red (R) channel in the RGB colour space was used to identify and mask the region corresponding to the heating lamp. This step reduces the influence of the external heat source and enhances the contrast between defective and non-defective areas, preventing false detection.

2) Defective region detection: the defective regions were segmented using the Hue (H) channel of the HSV colour space. The use of the H channel is particularly advantageous, as it separates chromatic information from luminance and saturation effects. This allows the identification of defects based on colour variations associated with thermal gradients due to heterogeneities.

As a result, defective regions can be identified as localized variations in the chromatic signature, often corresponding to thermal hotspots.

This approach was observed to produce consistent segmentation results across multiple frames and experimental runs, as discussed in Section 5.2.

5.2 Segmentation results

The consistency and robustness of the proposed segmentation pipeline was evaluated when applied to multiple thermographic sequences acquired under similar experimental conditions as described in section 2.

Figure 4 presents a sequence of segmentation results obtained during the heating phase for a representative experimental run. The detected regions show a stable spatial correspondence with the known location of the embedded defects. Although some variability is observed across frames, the main defective areas are consistently identified throughout the sequence.

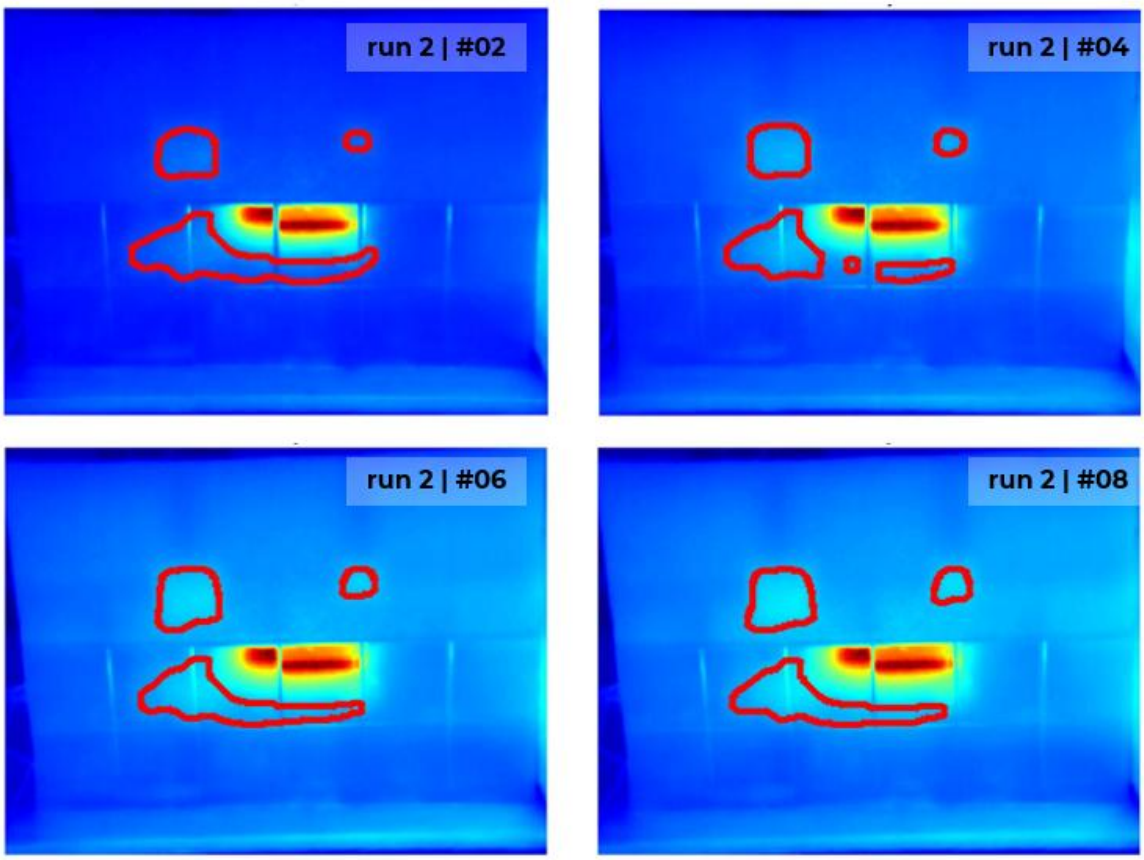


Figure 4 – Temporal evolution of segmentation results during the heating phase

To further assess repeatability, Figure 5 compares segmentation results obtained from two independent experimental runs under similar conditions. Overall, the results demonstrate a good level of agreement in terms of defects localization and general shape, confirming the robustness of the proposed approach. Moreover, it can be noticed that across different experimental runs, the segmentation results reliably indicate higher defect detectability on the painted surface than on the ceramic-tiled surface. These findings confirm that the nature of the wall surface finishing material may pose an additional challenge to the application of the proposed methodology, potentially requiring future adaptations to the experimental protocol and/or data processing strategy according to the material under analysis.

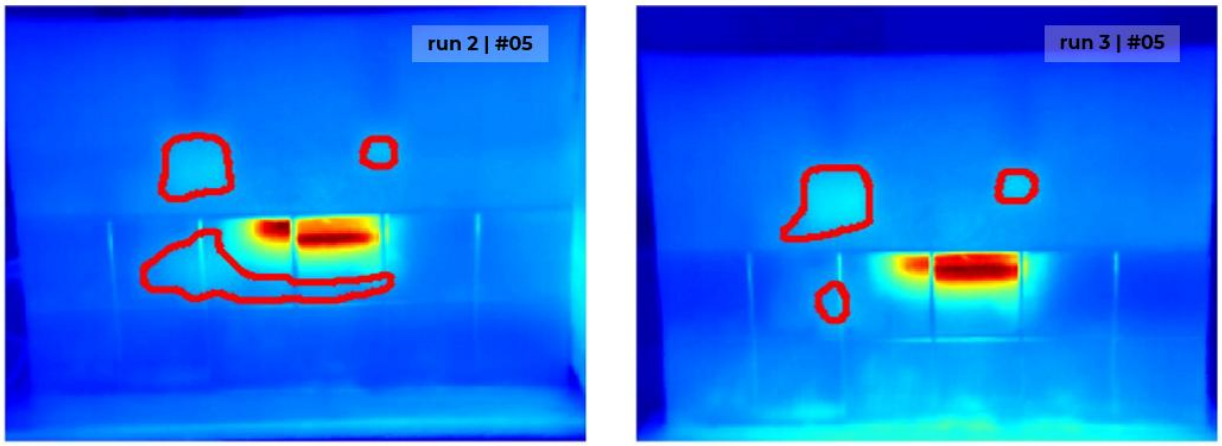

Figure 5 – Comparison of segmentation results between independent experimental runs

Despite these positive results, some limitations can be observed. In particular, small false-positive regions may appear, especially in areas with low thermal contrast or influenced by boundary effects. Additionally, slight variations in the extent of the segmented regions are observed across time and between runs, reflecting the sensitivity of the method to thermal conditions and surface properties.

Overall, the results demonstrate the feasibility of integrating image-based segmentation into thermography-driven workflows for automated façade assessment.

6. Discussion

The results presented in this study highlight the relevance of combining thermographic analysis with image-based segmentation for the automated detection of façade defects. The observed differences in defect detectability between surface types can be explained by their distinct surface reflectivity and thermal properties, which is particularly observable in the ceramic-tiled area reducing defect identification and segmentation performance.

Moreover, the analysis of thermal indicators (Section 4) provides a clear physical interpretation of defect detectability. Cooling-based indicators were shown to offer improved robustness under non-uniform heating conditions, as they are primarily governed by intrinsic material properties rather than external excitation. This finding is consistent with previous studies and reinforces the importance of considering temporal thermal behaviour in façade diagnostics.

On the other hand, the segmentation approach (Section 5) demonstrates that chromatic information in thermographic images can be effectively exploited for automated defect detection. The use of the HSV colour space, and particularly the Hue channel, enables the separation of chromatic variations associated with thermal gradients from luminance effects, improving robustness under non-uniform heating conditions. This confirms the suitability of colour-based representations for thermographic image analysis in controlled scenarios. Moreover, the results obtained across multiple frames and independent experimental runs indicate that the method is robust with respect to temporal variability and acquisition conditions. The consistent localisation of defects supports the applicability of the approach in controlled environments and suggests potential for extension to more complex scenarios.

However, some limitations must be acknowledged. The presence of false-positive detections in areas with low thermal contrast indicates sensitivity to noise and to local thermal variability due to differences in the surface properties. Additionally, the extent of the segmented regions varies slightly across time and between

runs, reflecting the dynamic nature of heat transfer processes and the influence of environmental conditions.

Another important limitation is the reliance on controlled heating conditions and known experimental configurations. In real-world applications, factors such as solar radiation, wind, and material heterogeneity may introduce additional variability, requiring further adaptation of the methodology.

These limitations suggest that further developments are required to improve robustness and generalisation. In particular, the integration of adaptive thresholding strategies, multi-temporal analysis, or ML-based approaches may enhance detection accuracy under more variable conditions. Despite these limitations, the proposed approach represents a step towards the integration of thermographic data into automated façade assessment frameworks. The combination of physically meaningful indicators and image-based segmentation provides a complementary perspective that can support more robust and scalable analysis.

7. Conclusions

This paper presented a thermography-driven workflow for the analysis and automated detection of defects in building façades, within the context of the RiskMap project framework. The proposed approach integrates thermal data analysis with an image-based segmentation pipeline, enabling the direct identification of defective areas in thermographic imagery.

The main contribution of this work regards the combination of quantitative thermographic analysis and automated defect detection. A segmentation pipeline based on contrast enhancement, thresholding, morphological operations, and colour space selection is proposed. Thus, relying on the physical interpretability of thermal indicators gathered/allied with a segmentation strategy based on chromatic information, the proposed workflow provides a structured and reproducible approach for façade condition assessment. An experimental campaign conducted on a wall specimen with induced and controlled defects was used to generate a dataset for evaluating both the thermal behaviour of the specimen and the performance of an image-based segmentation approach. The analysis of thermal indicators showed that cooling-related features provide more robust information for defect detection, particularly under non-uniform heating conditions, while the segmentation pipeline enables consistent and spatially coherent defect localisation across time and independent experimental runs. In particular, higher defect detectability was observed in painted surfaces compared to ceramic-tiled surfaces.

Although some limitations were identified, particularly regarding false positives and sensitivity to thermal variability, the proposed approach shows strong potential for the integration of thermographic data into automated façade inspection/assessment workflows.

Future work should focus on extending the proposed methodology to real-world scenarios, integrating combined multi-modal data sources and ML techniques to improve defect detection reliability and generalisation.

Abstract: Wattle and daub is a traditional construction system characterised by a timber framework infilled and coated with mortars based on earth, lime, and natural aggregates, exhibiting good thermal performance. Nevertheless, its susceptibility to moisture, biological degradation of timber elements, and inadequate past interventions has led to significant deterioration of this type of construction.

The rehabilitation of wattle and daub walls plays a crucial role in the preservation of traditional built heritage and should be guided by the principles of compatibility, reversibility, and minimal intervention.

The use of compatible mortars formulated with traditional binders and materials of natural or recycled origin is essential for rehabilitation interventions. Several studies have shown that the incorporation of waste materials into rehabilitation mortars can enhance their mechanical and environmental performance, thereby contributing to sustainability. Thus, the rehabilitation of wattle and daub walls should be regarded not only as a heritage conservation action but also as an opportunity for the development of sustainable and technically appropriate construction solutions.

This study is part of an ongoing research project focused on the development of lime-based mortars incorporating waste materials for the rehabilitation of wattle and daub walls.

The present paper reports the results of an experimental campaign carried out to characterise lime mortars incorporating eggshell waste to assess their suitability for application in the rehabilitation of wattle and daub walls.

Keywords: Lime mortars; Wattle and Daub Walls; Eggshell Residues; Heritage rehabilitation

1. Introduction

Wattle and daub construction represents one of the most widespread traditional building techniques across various regions of the world, particularly in rural and vernacular architecture. This system, typically composed of a timber framework (wattle) infilled with an earthen or lime-based mixture, reflects the use of locally available materials and low-energy construction methods. Despite its historical significance and environmental advantages, this type of construction is highly susceptible to degradation due to moisture, biological activity, and mechanical damage, which poses significant challenges for conservation and rehabilitation efforts.

Lime mortars have long been recognized as compatible materials for the repair of traditional structures, owing to their vapor permeability, flexibility, and chemical compatibility with original substrates. In recent decades, increasing attention has been given to improving the performance of lime-based materials while maintaining their sustainability and compatibility. This has led to the exploration of alternative additives and

waste-derived materials that can enhance mechanical properties and durability without compromising the ecological footprint of the construction process.

In this context, a research project is currently under development within the scope of a collaboration between the University of Aveiro and Itecons, funded by the Foundation for Science and Technology (FCT). The main objective of this project is the formulation of sustainable mortars for the rehabilitation of wattle and daub walls. One of the key strategies to enhance the sustainability of these mortars is the incorporation of waste materials as partial replacements for either the binder or the aggregates. This approach contributes, on the one hand, to reducing the volume of waste sent to landfills and, on the other hand, to decreasing the consumption of non-renewable natural resources. By promoting the valorization of residues within construction materials, this research aligns with the principles of circular economy and sustainable development in the built environment.

Eggshell residues emerge as a promising secondary raw material. Generated in significant quantities by the food industry, eggshell waste is primarily composed of calcium carbonate ($CaCO_3$), similar to limestone, which is the main constituent of lime. The reuse of eggshells in construction materials aligns with circular economy principles by diverting waste from landfills and reducing the demand for virgin raw materials. Previous studies have indicated that finely ground eggshell powder can influence the microstructure, setting behaviour, and mechanical strength of cementitious and lime-based systems.

Although eggshell production is very high and its characteristics are very interesting, there is still limited use of this waste product. In Portugal, some use is observed in agriculture, namely as an alkalizing corrective (to correct the pH of acidic soils), as a component in agricultural fertilizer, and as a source of calcium for laying hens (increasing egg production and shell quality).

In other countries other applications have been found:

- The powder resulting from the prior dissolution of the bark in acetic acid is indicated as a remedy for osteoporosis and other diseases of the human joints, King'ori (2011)

- Calcium carbonate for fertilizers, animal feed, heavy metal removal and paper treatment with membrane separation; use of calcium oxide (CaO) as a catalyst in biodiesel production; purification of calcium carbonate; production of hydroxyapatite. Oliveira et al. (2013).

The incorporation of eggshell residues into lime mortars for the rehabilitation of wattle and daub walls presents a novel approach that combines heritage conservation with sustainable material innovation. However, the effects of such incorporation on the physical, mechanical, and durability properties of lime mortars, particularly in the context of traditional earthen-lime systems, remain insufficiently understood.

Therefore, this study aims to investigate the feasibility of using eggshell residues as a partial replacement or additive in lime mortars intended for the rehabilitation of wattle and daub constructions. The research focuses on evaluating the influence of eggshell incorporation on key performance indicators, including workability, mechanical strength, porosity, and durability, while ensuring compatibility with traditional materials and techniques.

The present study reports the preliminary findings of an experimental campaign aimed at the development of hydraulic lime mortars incorporating waste-derived materials

2. Experimental campaign

2.1 Compositions analysed

To assess the feasibility of replacing part of the sand with eggshell waste (ES) in hydraulic lime (NHL 3.5) mortars, four mortars were formulated. The selected mix ratio for all formulations was 1:4 (lime:sand). Two different types of sand (S1 and S2) were used. Thus, two reference mortars without waste were prepared, and two mortars were formulated in which the waste was introduced as a replacement for 25% of the sand.

Table 1 shows the compositions and proportions of the prepared mortars.

Table 1 – Components and proportions of the mortars

Designation	Hydraulic lime	Sand S1	Sand 2	Eggshell	Proportion
H_S1	X	X			1:4:0
H_S1_ES	X	X		X	1:3:1
H_S2	X		X		1:4:0
H_S2_ES	X		X	X	1:3:1

2.2 Characterization of raw materials

Before being incorporated into the mortars, the eggshell residues, that came from the food industry, did not undergo any prior treatment; they were not washed, nor was the organic membrane removed; they were simply oven-dried at a controlled temperature of 100 °C ± 5 °C until all moisture was completely removed.

After this process, the dried eggshells were ground in a jaw crusher equipped with a 4 mm sieve, aiming to obtain particles with suitable granulometry for incorporation into the mixtures.

Following this treatment, the eggshells and the other raw materials were characterized.

2.2.1 Particle size analysis

The particle size analysis of the sands and eggshells was performed in accordance with the standard EN 933-1:2012 - Tests on the geometric properties of aggregates - Part 1. Figure 1 shows the particle size distribution curves obtained.

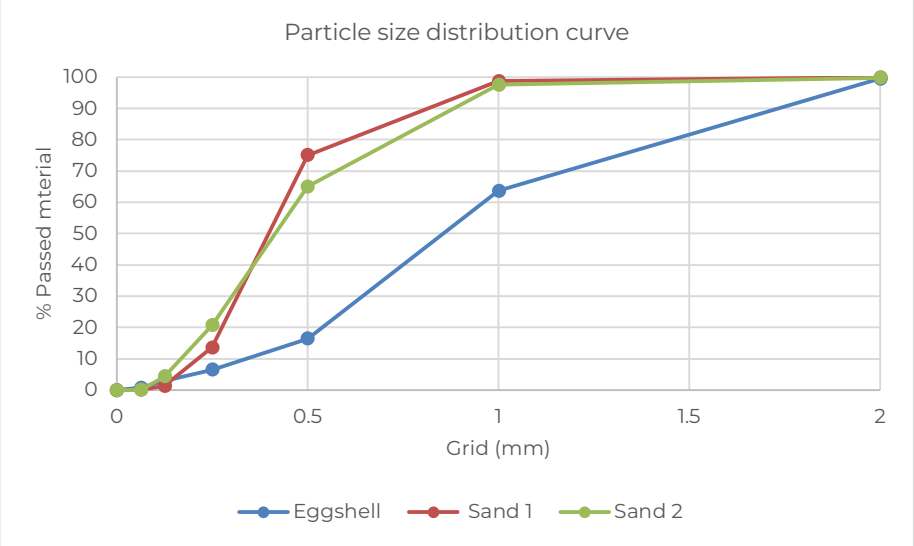

Figure 1 – Granulometric curves of sand and eggshell

2.2.2 Loose bulk density of the constituents

To determine the density of the aggregates (sand and eggshells), the method described in standard EN 1097-3:1998 - Tests on the mechanical and physical properties of aggregates - Part 3: Determination of density and void volume was used.

Table 2 presents the results obtained for the density of the various components.

Table 2 – Loose bulk density of the constituents

	Sand S1	Sand S2	Eggshell	Lime
Loose bulk density (kg/m³)	1487.22	1389.05	854.21	750

2.2.3 Determination of the density and water absorption of aggregates

The determination of bulk density and water absorption of the aggregates was carried out in accordance with the EN 1097-6:2022 standard (IPQ, 2024), which establishes the test methods for evaluating the physical properties of aggregates intended for use in mortars, concrete, and other construction materials.

Table 3 presents the results obtained for the bulk density and water absorption of the various components.

Table 3 – Bulk density and water absorption of the constituents

	Sand S1	Sand S2	Eggshell
Bulk density (kg/m³)	2636	2601	2336
Water absorption (%)	0.138	1.309	3.211

As can be observed from the obtained results, the shell residues are significantly lighter and exhibit higher water absorption capacity, which is expected to influence the properties of mortars incorporating them, particularly regarding their porous structure.

2.3 Mortar Preparation

For the development of the laboratory tests, 24 (twenty-four) prismatic specimens with dimensions of 40 × 40 × 160 mm were cast, in accordance with the applicable standard recommendations. Six specimens were produced for each formulation. After casting, the specimens were subjected to a curing period of 28 days under suitable controlled environmental conditions.

After the curing period, the specimens were used to perform laboratory tests aimed at determining open porosity, apparent bulk density by immersion, water absorption by capillarity. For the water vapour permeability test, in accordance with ISO 12572:2016 – Hygrothermal performance of building materials and products – Determination of water vapour transmission properties, sixteen cylindrical specimens were prepared with a diameter of 106 mm and a thickness of 15 mm.

These tests were carried out to characterize the performance and durability of the different mortar formulations, allowing a comparative analysis between them and contributing to the evaluation of their technical feasibility in lime mortars intended for the rehabilitation of wattle and daub constructions

2.4 Properties of mortars in the fresh state

2.4.1 Consistence of Fresh Mortar

For the characterization of fresh mortars, the standard EN 1015-3:1999 (IPQ, 1999): Methods of test for mortar for masonry - Part 3: Determination of consistency of fresh mortar (by flow table), was used, which specifies the method for determining consistency by spreading. This test aims to evaluate the fluidity and workability of the mortar, essential parameters to ensure proper application and performance in the laying and coating process.

The results obtained for the consistency of all mortars are presented in table 4.

Table 4 – Consistency of the mortars

Mortar	Consistency (mm)
H_S1	167.68
H_S1_ES	177.92
H_S2	179.17
H_S2_ES	176.14

It is observed that all formulations presented flow spread values within the target range (175 ± 10 mm).

2.5 Properties of mortars in the hardened state

2.5.1 Open porosity and apparent density

Apparent density translates the simple direct relationship between the dry mass of a specimen and the volume it occupies, while open porosity represents the relationship between the volume of pores in the sample and the total volume. The determination of these properties was carried out in accordance with the procedures established in the standard EN 1936:2006 – Test methods for natural stone – Determination of real and apparent density and total and open porosities.

The results for apparent specific gravity are presented in Figure 2 and for open porosity are presented in Figure 3.

Based on the obtained results, it can be concluded that the incorporation of eggshell waste into the mortar mixtures resulted in a reduction in bulk density. This behaviour is consistent with the physical properties of the constituent materials, as the bulk density of processed eggshell residues is significantly lower than that of conventional natural sand aggregates. Consequently, the partial replacement of sand with eggshell-derived material results in a lighter composite matrix, reflecting its lower specific mass.

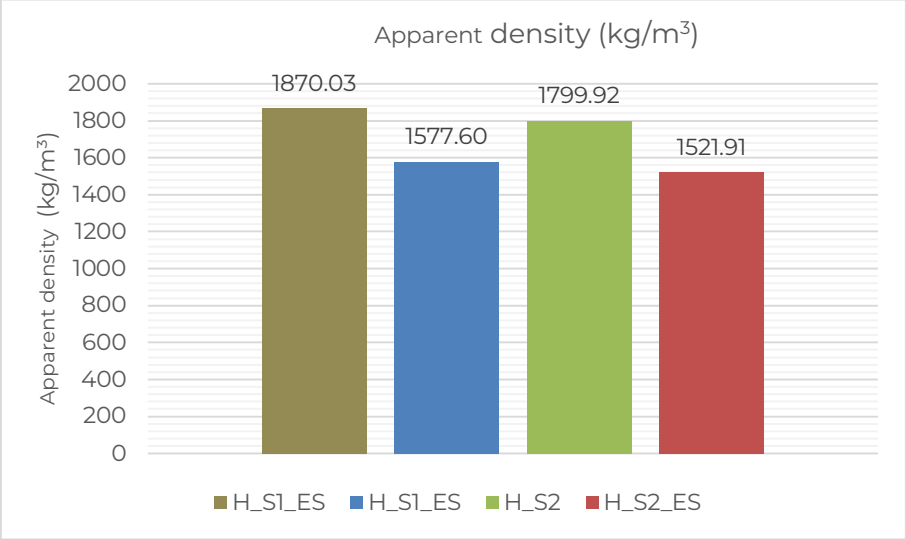

Figure 2 – Apparent density of the mortars

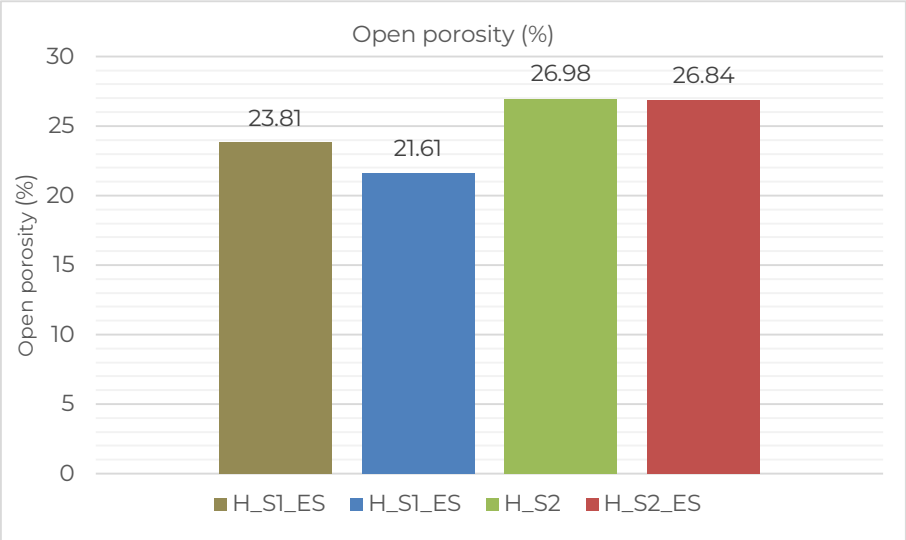

Figure 3 – Open porosity of the mortars

2.5.2 Water absorption by capillarity

The capillary absorption coefficient gives us an indication of the water absorption capacity of a mortar when placed in contact with a layer of water. The determination of water absorption by capillarity was carried out in accordance with the procedures established in the standard EN 1015-18:2002 – Methods of test for mortar for masonry - Part 18: Determination of water absorption coefficient due to capillary action of hardened mortar.

The results for water absorption curves are presented in Figure 4 and for water absorption coefficients of the mortars are presented in Table 4.

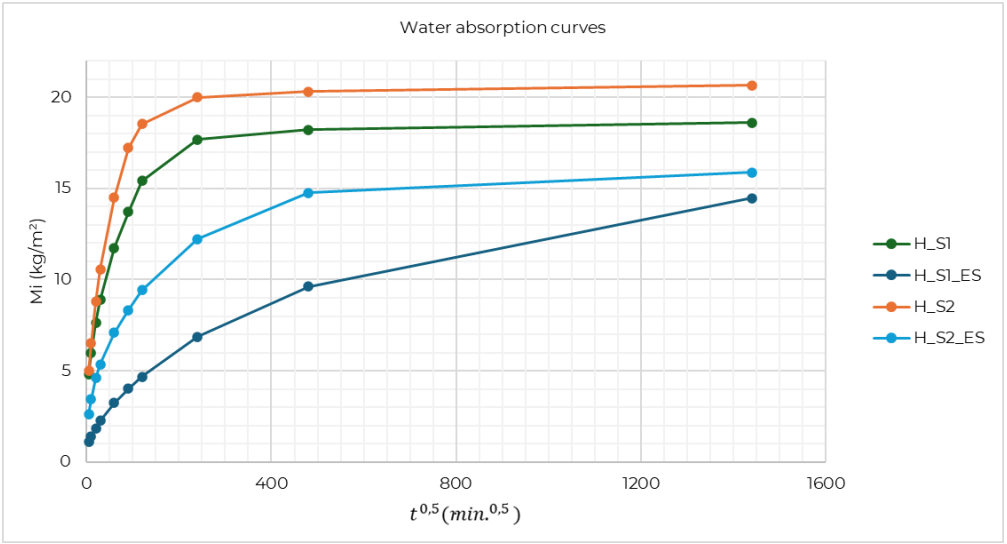

Figure 4 – Water absorption curves of the mortars

Table 4 – Water absorption coefficients of the mortars

Mortar	Water absorption coefficients [kg/(m².min^{0,5})]
H_S1	1.244
H_S1_ES	0.418
H_S2	1.750
H_S2_ES	0.769

The incorporation of eggshell waste into the mortar formulations resulted in a significant reduction in the water absorption coefficient. This behaviour agrees with the observed trends in open porosity, which likewise exhibited a decrease with the introduction of eggshell-derived material. Such findings suggest that the inclusion of this residue contributes to a densification of the pore structure and a reduction in capillary connectivity within the matrix. Consequently, the diminished absorptive capacity can be attributed to the modification of the microstructural characteristics of the mortar, leading to a less accessible pore network and enhanced resistance to water ingress.

2.5.3 Water vapour permeability

The determination of water vapour permeability was carried out in accordance with the procedures established in the standard ISO 12572:2016 – Hygrothermal performance of building materials and products – Determination of water vapour transmission properties. This parameter reflects a material's ability to allow water vapor to pass through it, was determined in accordance with the aforementioned standard, and the wet cup method was used.

The results for water vapour permeability coefficients are presented in Figure 5.

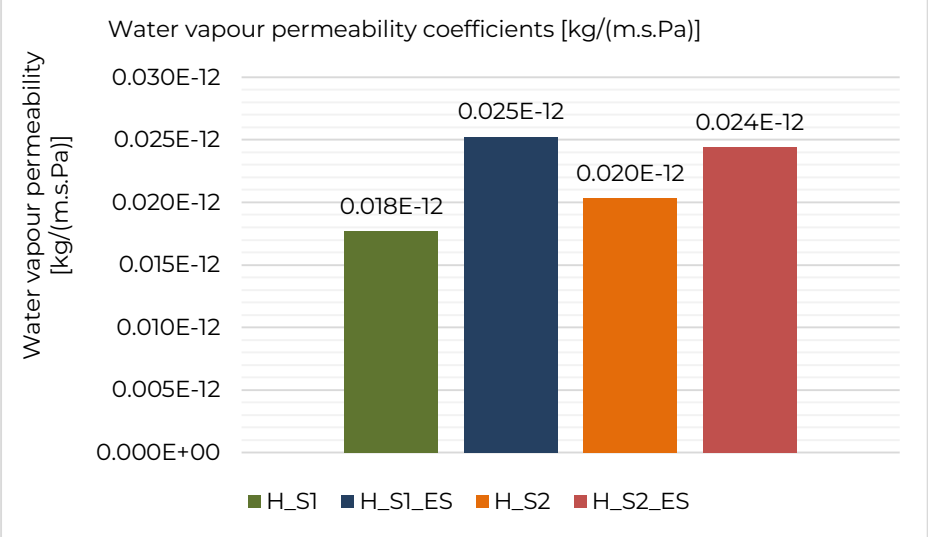

Figure 5 – Water vapour permeability coefficients of the mortars

The results indicate that the incorporation of the residues promoted an increase in water vapor permeability. This outcome was not initially anticipated, particularly considering the reductions observed in both water absorption and open porosity. However, this apparent discrepancy can be attributed to modifications in the structure and distribution of pores within the mortar matrix. Specifically, while total open porosity and

capillary absorption may decrease, the connectivity and morphology of the finer pores may be altered to facilitate vapor diffusion. Such microstructural changes are not fully elucidated by conventional porosity or absorption measurements and would require more detailed characterization techniques, such as mercury intrusion porosimetry, to provide a comprehensive understanding of pore distribution and size.

3. Conclusions

Eggshell waste has attracted considerable interest in the scientific community due to its chemical and physical properties. The fact that its composition is primarily calcium carbonate makes this byproduct appealing as a substitute for some of the mineral calcium carbonate used in the manufacture of many materials, thus making them more sustainable.

This paper presents the characterization of hydraulic lime mortars intended for the rehabilitation of partition walls. Two reference mortars were analysed without the introduction of residues and with two different types of sand, and two other mortars with the introduction of residues replacing 25% of the each sand.

In this study, it was possible to conclude that the introduction of eggshells into mortars, in general, was advantageous, as it allows for a reduction in the amount of aggregate while maintaining the required functional characteristics. The characterization performed allowed us to conclude that the introduction of eggshells reduced bulk density, porosity and the capillarity coefficient, while increasing vapor permeability.

For a more complete characterization, it will still be necessary to carry out some more tests, namely:

- determination of the mechanical strengths;

- determination of the dynamic modulus of elasticity (through measurement of the fundamental resonance frequency) which corresponds to the rate of change of deformation of a given material when subjected to stress;

- determination of the drying index which indicates the rate at which water is lost over time — essentially, it describes its drying kinetics.

- determination of adhesion to the substrate which indicates the ability of the mortar to adhere to and remain bonded to the substrate.

- determination of thermal conductivity which reflects the ability of the mortar to allow a flow of heat to pass through it.

Mapping technical façade elements under low-intensity seismicity to support risk-informed urban decision-making

Elena CANTATORE[1], Fabio FATIGUSO[2]

[1] Politecnico di Bari, Bari, Italy, elena.cantatore@poliba.it
[2] Politecnico di Bari, Bari, Italy, fabio.fatiguso@poliba.it

Abstract: Building façades constitute a critical spatial interface between urban open spaces and their users, where technical façade elements (TFEs) directly mediate everyday safety conditions. This is especially evident in historic urban areas, where tourist exposure is higher. Despite growing evidence from recent earthquakes, façade-related components remain largely underrepresented in conventional seismic risk frameworks, particularly under low-intensity and low-to-moderate seismicity, where cumulative damage processes and environmental degradation can increase outdoor vulnerability. This study proposes an operational framework for the systematic characterisation, qualification and spatialisation of façade-related TFEs, to support preventive decision-making. The methodology is grounded in two complementary knowledge sources: (i) the critical integration of regulatory and technical references, used to define a unified taxonomy and catalogue of façade elements; and (ii) the comparative analysis of real damage patterns observed during recent seismic events. This empirical analysis supports the identification of prevalent vulnerability patterns across different TFEs, and specifically elements exhibiting early sensitivity under low-intensity seismic actions. The classified TFEs and their associated attributes are structured into a minimum dataset for implementation within a GIS-based environment, enabling georeferenced mapping and aggregation of façade-related vulnerabilities. Therefore, element typologies, relative importance and prevalent damage classes are combined into a coherent qualitative classification system. This enables the rapid identification of potential critical façade elements without reliance on complex numerical modelling. Furthermore, the spatialised information provides a valuable decision-support layer for policymakers, facilitating the identification of urban open sub-areas characterised by reduced safety levels for users in outdoor. Overall, the systematisation and assessment of outcomes from façade to district scale offer a scalable and transferable tool for urban surveys, supporting the prioritisation of recurring vulnerability classes within façade element taxonomies. The framework is finally tested in a historic urban context, demonstrating its capability to capture differentiated vulnerability patterns across façade fronts.

Keywords: Technical Façade Elements (TFEs), Low-intensity seismicity, GIS-based mapping, Vulnerability, Urban open space safety.

1. Introduction

Building façades represent a critical spatial boundary between urban open spaces and their users, where Technical Façade Elements (TFEs), typically designed to serve interior functions, may significantly affect the everyday safety conditions of outdoor occupants. This interaction becomes particularly relevant in historic urban contexts, characterised by dense built fabrics, narrow streets, and highly frequented public spaces, where user exposure to potential hazards is significantly increased (Bernabei et al. 2021).

Within this interface, TFEs—such as balconies, cornices, parapets—constitute elements whose failure may directly affect users occupying adjacent open spaces, including streets and squares. Their role is therefore not limited to building performance but extends to the broader dimension of urban safety (Cheraghi and Behnam 2026; Mannucci *et al.* 2022; Lu *et al.* 2019). Traditional seismic risk assessments have predominantly

focused on structural behaviour and, more generally, on the seismic response of entire façades. However, increasing evidence from post-earthquake observations highlights the vulnerability of façade elements, particularly under low-intensity and low-to-moderate seismicity. In these contexts, cumulative damage processes, material ageing, and environmental degradation can progressively reduce damage activation thresholds, leading to early failure mechanisms even in the absence of significant structural distress (Rodgers *et al.* 2025; Miranda *et al.* 2012; Perrone *et al.* 2019; Merino *et al.* 2023).

Despite this evidence, façade-related elements remain marginal within conventional risk assessment frameworks, which rarely consider their interaction with user exposure in urban open spaces. This limitation is particularly critical in historic centres, where the spatial morphology of the built environment amplifies the consequences of localised failures. In such contexts, urban policymakers are required to ensure the safe use of public open spaces while also supporting effective spatial reorganisation and emergency evacuation planning (Cantatore *et al.* 2023; Ruggiero *et al.* 2021).

Given the relevance of façades and the scale of streets and squares as public open spaces, the management of façade vulnerability requires a multi-dimensional approach capable of collecting, assessing, and managing detailed information on TFEs, as well as capturing the broader system of buildings and blocks shaping urban open areas. The integration of façade-scale observations with spatial analysis tools represents a key opportunity. Geographic Information Systems (GIS) enable the organisation, aggregation, and visualisation of TFE-related data, supporting the identification of spatial vulnerability patterns across urban open spaces. This facilitates the transition from element-based observations to district-scale interpretations, providing a robust basis for preventive decision-making and risk-informed urban management.

1.1 Recent experiences and regulatory framework in managing Façade Technical Elements

The role of non-structural elements in seismic risk has progressively gained attention in both technical guidelines and scientific literature.

Eurocodes and the Italian Technical Standards for Construction (NTC 2018) acknowledge the relevance of architectural and façade components for building occupant safety (Audisio *et al.* 2026). This aspect is further emphasised in CARTIS-based applications, where non-structural elements play a significant role in building vulnerability assessment and support large-scale post-event data collection and interpretation (Del Carlo *et al.* 2025; Zuccaro *et al.* 2015). However, these regulatory frameworks mainly address classification, design, and assessment from a building-oriented perspective, with a primary focus on indoor conditions rather than providing operational tools for outdoor safety management.

A complementary line of research is represented by post-earthquake observational studies (O'Reilly *et al.* 2024; Baird and Ferner 2017; Sheshov *et al.* 2022), which analyse damage to façade elements through the interpretation of debris, cracks, and failure mechanisms generated by seismic events. These studies extend the understanding provided by regulatory frameworks, particularly for buildings not originally designed according to seismic criteria, such as historic constructions. As such, they provide valuable insights that require further systematisation to effectively support outdoor user safety management.

Moreover, studies conducted in areas characterised by recurrent low-magnitude seismicity, such as the Campi Flegrei, highlight the role of cumulative damage processes in progressively reducing the reliability of façade elements. These analyses often focus on sub-components of TFEs (e.g., plasters and decorative elements), emphasising how their state of decay contributes to the overall vulnerability of façades. In these contexts, the concept of damage threshold becomes particularly relevant, as certain elements may exhibit early sensitivity to seismic actions well below those typically considered in structural design (Liberotti *et al.* 2026; Castelluccio *et al.* 2021; Gaudiosi *et al.* 2020).

1.2 Work aim

Building on the above considerations, existing approaches remain predominantly building-oriented and

focused on high-intensity seismic scenarios, leaving the indoor–outdoor interface only partially explored, particularly in terms of outdoor effects induced by secondary debris. In particular, the combined role of element classification, its relevance (in terms of potential consequences), and damage thresholds (in terms of activation conditions) is rarely formalised within simplified assessment frameworks suitable for the rapid management of outdoor urban safety. This gap highlights the need for approaches capable of integrating qualitative classification systems with spatial analysis tools, enabling the transition from façade-level observations to urban- and district-scale vulnerability mapping. Such approaches can support policymakers in managing outdoor user safety under both ordinary and extraordinary use of outdoor open areas.

Within this context, the present work aims to address this gap by proposing a GIS-based tool for the collection and systematisation of TFEs and their main attributes, enabling the spatial management of vulnerability information and outdoor safety conditions. To achieve the aim, two preliminary activities are developed: (i) the classification of TFEs, based on the integration of thematic guidelines and normative frameworks; and (ii) the definition of a simplified qualification matrix based on relevance and observed damage patterns, to identify vulnerability classes of TFEs and supporting decision-making processes.

Accordingly, Section 2 presents the methodological framework; Section 3 illustrates the results, including the classification of TFEs (Section 3.1), the vulnerability qualification matrix (Section 3.2), the GIS-based data model for TFE codification and qualification (Section 3.3), and its application to a real case study (Section 3.4). Finally, Section 4 discusses the main outcomes and conclusions.

2. Methodology for the Characterisation and Qualification of Façade Elements

To achieve the outlined objectives, the study adopts a three-phase methodology, each phase addressing a specific sub-objective of the research. In detail:

- Phase 1 focuses on the identification and codification of Technical Façade Elements (TFEs) associated with building façades, based on national and international regulatory frameworks addressing non-structural elements. Specifically, the Italian Technical Standards for Construction (NTC 2018) and the CARTIS form (sub-section 3.2 of the form) (Reluis and Protezione Civile, n.d.) are analysed and systematised to derive a synthetic and consistent list of TFEs, accounting for façade-specific characteristics. In addition, the American FEMA E-74 guidelines (Federal Emergency Management Agency (FEMA) 2012) are included to extend the analysis beyond the national context. Each TFE class is assigned a specific code, contributing to the definition of a unified taxonomy.
- Phase 2 aims to develop a simplified tool for assessing the prevalent intrinsic vulnerability patterns of TFEs. The tool is structured as a two-dimensional matrix that classifies the codified TFEs according to: (i) their relevance to user safety (Relevance Index – R-index), and (ii) their prevalent damage behaviour (Prevalent Damage Index – PD-index). The R-index is derived from design prescriptions and criteria embedded in the adopted regulatory frameworks (CARTIS, NTC, FEMA), while the PD-index is defined based on literature and grey sources documenting observed damage to TFEs under seismic and low-intensity events. The attribution of the R-index was based on the primary consequences associated with the failure of each TFE. Elements whose failure may directly threaten users occupying adjacent public spaces were classified as High relevance, whereas elements mainly associated with service interruption or localised functional impacts were assigned to the Medium relevance class. Similarly, the PD-index was derived from the comparative interpretation of observed damage patterns across the analysed case studies. Elements repeatedly exhibiting instability, detachment, or damage under low-to-moderate seismic actions were classified as Early-sensitive, while those predominantly activated under stronger shaking conditions were assigned to the High-threshold class. The empirical basis includes: the 2016 Central Italy seismic sequence (Norcia–Amatrice) (Pagan 2021; Perrone *et al.* 2019), the bradyseismic activity in Campi Flegrei (2009–2023) (Castelluccio *et al.* 2025) —also supported by photographic evidence from daily newspapers—and the Christchurch earthquakes

(2010–2011) (Commission 2012), where façade-related failures caused significant casualties in outdoor spaces. For each index, two qualitative levels are defined, resulting in a simplified matrix describing the prevalent vulnerability of TFEs in relation to damage activation thresholds.

- Phase 3 builds upon the results of the previous phase by integrating the TFE codification and the vulnerability matrix into a GIS-based model. This phase enables the spatial representation of TFEs and their distribution along façades, supporting the development of a synthetic and queryable decision-support system for policymakers. In this context, TFEs are analysed according to their spatial characteristics (point, linear, or areal), allowing the definition of a minimum dataset for GIS implementation that extends the information associated with their codification. The resulting data structure is organised at the façade level, linking the geographical position of façades with their associated TFE attributes.

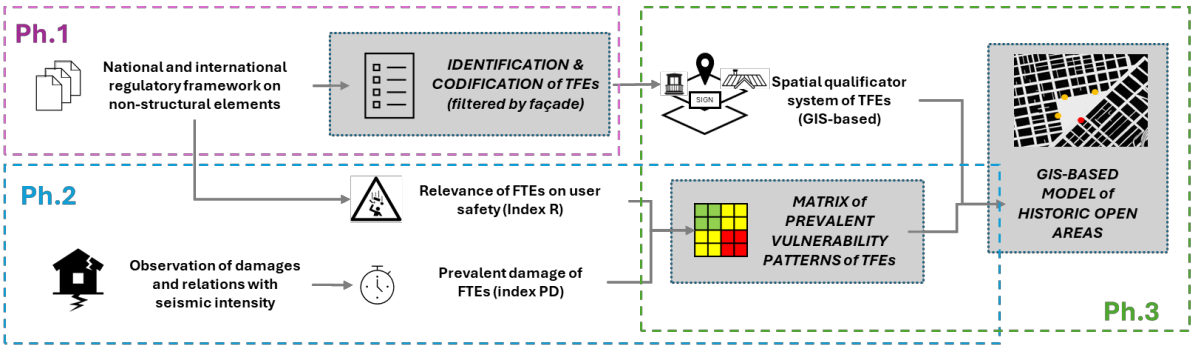

Figure 1 – Schema of activities involved in the pursued method, defined for each sub-aim (grey blocks) and phase

To illustrate the outcomes of the methodology, Section 3 presents the results of the three phases, with particular emphasis on the third phase through its application to a representative area of the historic centre of Bari (Southern Italy).

3. Results

The results of the methodology are structured according to the three phases described in Section 2, leading to a coherent system for the classification, qualification, and synthesis of Technical Façade Elements (TFEs).

3.1 Classification of façade elements

The first outcome consists of a unified taxonomy of TFEs derived from the integration of CARTIS forms, NTC 2018, and FEMA E-74 guidelines.

As shown in Table 1, the classification includes non-structural elements identified within the regulatory frameworks, grouped into architectural (A), mechanical (M), and content-related (C) categories. The codification of TFE types is limited to elements that exhibit a direct interaction with façades. Accordingly, a filtering process is applied to identify only those components that interact with the building envelope and may pose a risk to adjacent public spaces.

Each element is therefore assessed in terms of façade admissibility, and only the admissible subset is retained for subsequent analyses (Tables 2–3, Figure 2).

The integration of multiple sources enables the extension of the classification beyond purely architectural components, incorporating systems and elements that influence both safety and functionality.

Table 1 – Codification of Technical Façade Elements and associated source

Code	Element name	Source	Façade admissibility	Code	Element name	Source	Façade admissibility
-	Non-structural partitions	CARTIS / NTC	No	A11	Emergency stairs / walkways	NTC	Yes**
A02	Roof covering (tiles)	CARTIS	Yes*	A12	Canopies / signs	NTC	Yes
A03	Chimneys / vertical protrusions	CARTIS	Yes	M01	Façade systems (gutters, AC units)	NTC	Yes
A04	Balconies	CARTIS	Yes	-	Internal systems	NTC	No
A05	Cornices	CARTIS	Yes	M03	Elevators	NTC	Yes**
A06	Parapets	CARTIS	Yes	M04	HVAC systems	FEMA	Partial***
-	Light suspended ceilings	CARTIS	No	M05	Escalators	FEMA	Yes**
-	Heavy suspended ceilings	CARTIS	No	-	Fire protection systems	FEMA	No
-	Light false vaults	CARTIS	No	-	Equipment (medical/industrial)	FEMA	No
-	Heavy false vaults	CARTIS	No				

* included only when interacting with façade edges, **included only if external, ***included only when externally mounted

3.2 Qualification of TFEs according to relevance R-index and PD index towards the definition of the synthetic matrix of TFEs vulnerability

The second result concerns the definition of the simplified matrix to describe the vulnerability of the identified FTEs.

First of all, the Relevance Index (R-index) is derived from regulatory frameworks. As summarised in Table 2, each TFE is assigned a qualitative level of importance (High or Medium), based on its potential impact on user safety and building functionality.

Architectural elements directly exposed to public spaces (e.g., balconies, cornices, parapets) are consistently classified as high relevance due to their direct life-safety implications. Conversely, most mechanical systems are classified as medium relevance, as their failure generally affects functionality rather than immediate safety. This classification provides a simplified yet robust interpretation of regulatory prescriptions, translating them into an operational assessment tool.

Then, the definition of the Prevalent Damage Index (PD-index) follows, deriving it from the comparative analysis of real seismic events. Table 3 summarises the main damage mechanisms identified across the case studies of Central Italy (2016), Campi Flegrei, and Christchurch. The analysis highlights two main behavioural patterns:

- Early-sensitive elements (PD = E), which exhibit damage under low-to-moderate seismic actions (e.g., balconies, cornices, façade systems);
- High-threshold elements (PD = H), which are activated only under stronger shaking or after cumulative damage processes. This distinction confirms the importance of considering not only the severity of damage but also the activation threshold, especially in low-intensity seismic contexts.

Table 2 – Classification of the Identified TFEs in coherence with the R-index classes (High or Medium)

Code	Element name	R class	Code	Element name	R class
A04	Direct exposure and high risk of falling elements	High	A11	Critical for evacuation safety	High
A05	High mass elements prone to detachment	High	A12	Local hazard, limited extension	Medium
A06	Overturning risk toward public space	High	M01	Limited mass, localized risk	Medium
A03	Local collapse with direct hazard	High	M04	Functional relevance, limited direct hazard	Medium
A02	Falling elements affecting pedestrians	High			

Table 3 – Classification of the Identified TFEs in coherence with the PD-index classes (Early sensitive=E or High-threshold=H)

Code	Source	Explanation	PD class	Code	Source	Explanation	PD Class
A04	Campi Flegrei + Christchurch	Early activation under low shaking	E	A03	Norcia + Christchurch	Collapse at higher intensity	H
A05	All cases	Frequent early detachment	E	A02	Norcia	Damage after cumulative effects	H
A06	Campi Flegrei	Instability at moderate intensity	E	A11	Christchurch	Damage only in strong events	H
A12	Campi Flegrei	Early localized failures	E	M04	Christchurch	Moderate-to-high activation threshold	H
M01	Campi Flegrei	Detachment at moderate acceleration	E	A03	Norcia + Christchurch	Collapse at higher intensity	H

This distinction emphasises the importance of considering not only damage severity but also activation thresholds, particularly in low-intensity seismic contexts.

The integration of the R-index and PD-index results in a four-class qualitative matrix, presented in Figure 2. This matrix represents the core outcome of the methodology, enabling the identification of distinct vulnerability patterns, defined as follows:

- High R – Early PD: elements with high impact and early damage activation (most critical – Vulnerability Class A);
- High R – High PD: elements with severe consequences but higher activation thresholds (critical under higher seismic intensity – Vulnerability Class B);
- Medium R – Early PD: elements with frequent damage but limited consequences (low impact but rapid activation – Vulnerability Class C);
- Medium R – High PD: elements with limited relevance and higher resistance (low impact and high activation threshold – Vulnerability Class D).

Overall, the matrix provides a simplified yet effective decision-support tool, enabling the rapid identification of vulnerability patterns associated with façade elements.

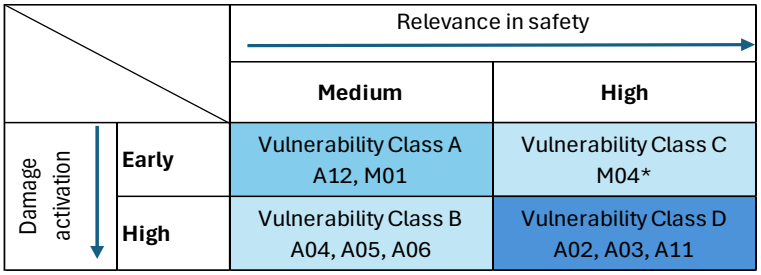

Figure 2 – Simplified matrix of the identified TFEs in coherence with R-index and DP-index qualification and distributed in coherence with the identified Vulnerability Classes

3.3 Census structuring and GIS-oriented data model

In continuity with the methodological framework described in Section 2, the set of Technical Façade Elements (TFEs), previously classified and qualified, is further processed through a data abstraction procedure aimed at enabling their systematic census and spatial implementation. Rather than introducing new descriptive categories, this phase translates the previously defined TFEs into a structured data model, ensuring consistency with the classification system and the associated indices (R-index and PD-index).

As a first requirement, the codified TFEs are characterised according to:

- geometric abstraction, whereby each TFE is associated with a simplified spatial typology (areal, linear, or point-like), enabling a homogeneous representation of heterogeneous elements. Table 4 summarises the adopted approach.
- relational structuring, through which TFEs are organised into a dataset linking spatial references, typological attributes, and vertical distribution (storey levels).

Within this framework, TFE contents associated with each façade are interpreted as a spatial interface, discretised both horizontally (façade units) and vertically (storey levels), allowing multiple TFEs to be assigned to the same spatial entity.

Table 4 – Set of minimum data for geometric abstraction of the identified TFEs

Type of TFE	Geometric content n.1	Geometric content n.2	Geometric content n.3
Punctual	n. of elements for each floor [*TFECode_n*]		
Linear	n. of elements for each floor [*TFECode_n*]	length/height of the element in each floor [*TFECode_l*]	
Aereal	n. of elements for each floor [*TFECode_n*]	length of the element in each floor [*TFECode_l*]	depth/height of the elements in each floor [*TFECode_h*]

Regarding spatial referencing, the organisation of metadata within the GIS environment follows a hierarchical “one-to-many” structure:

- each building, typically identified through a cadastral open-source layer (polygon), is assigned a unique Building_ID;
- each Building_ID is associated with a set of façades, represented through point or line geometries and uniquely identified by a Façade_ID;

- for each façade (Façade_ID), attribute tables are structured to collect TFE-related data (Table 4) for each storey level.

With reference to vulnerability-related information, each spatial unit (Point_ID) within the district is enriched with an aggregated attribute derived from the vulnerability matrix, corresponding to the highest vulnerability class among the TFEs identified on the associated façades. This enables the direct spatial representation of alert levels within the GIS environment.

3.4 Application on the ancient core of Bari

To demonstrate the applicability of the proposed approach, the methodology is implemented in a representative area of Bari's historic core. This context is characterised by high tourist activity and narrow streets, increasing exposure and risk for outdoor users. Its historical development results in recurring building typologies and limited variability in TFE distribution. The case study is further supported by the local seismic classification, characterised by predominantly low-intensity events. Figure 3 illustrates the extent of the analysed area. The dataset covers the southern portion of the historic core, including more than 200 façades, typically developed over three to four storeys above ground. Besides, Figure 4 shows the structure of FTEs metadata collected at the scale of each façade, highlighting the granularity at the floor scale.

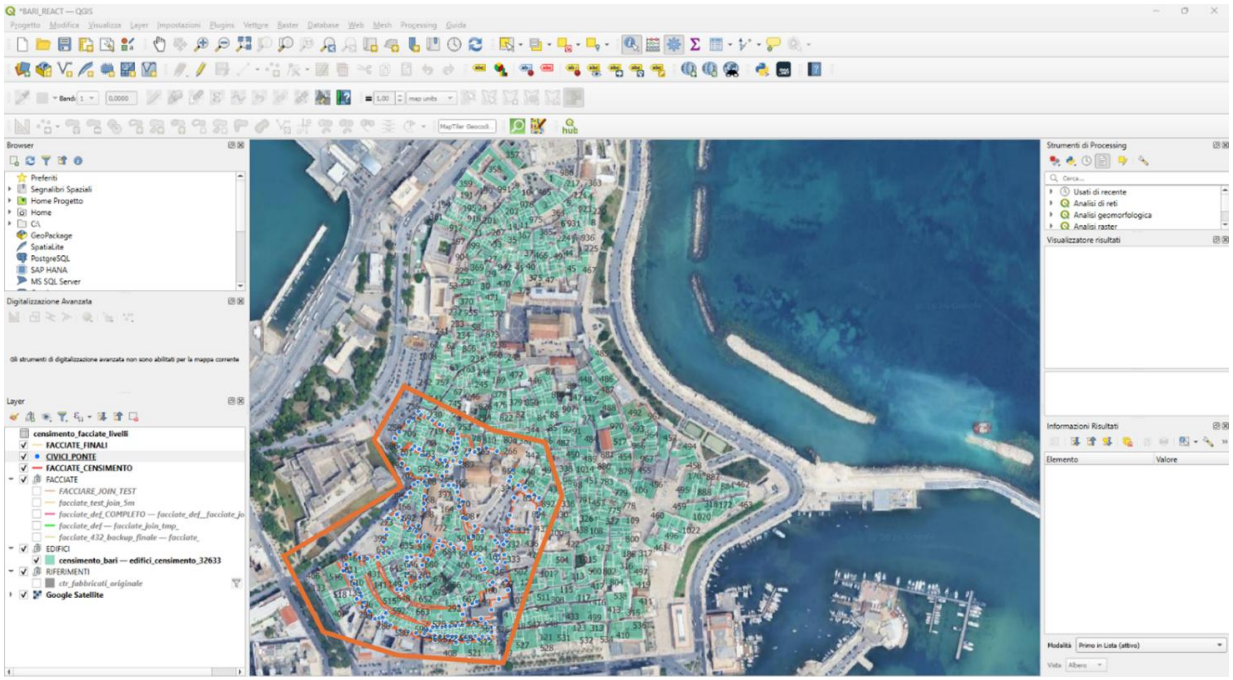

Figure 3 – Perimetration of the sub-area of the ancient core of Bari (orange polygon), analysed with the described approach

A more detailed focus is provided in Figure 5 for Piazza dell'Odegitria, a key open space within the investigated area. This square represents a highly polarised urban space, characterised by the presence of the Cathedral and multiple commercial activities, which significantly increase pedestrian flows and tourist presence. The analysis shows that most façades surrounding the square are characterised by Vulnerability Class C elements (low impact but early activation), mainly due to the widespread presence of parapets, typically located in the upper portions of façades.

At the same time, the georeferenced classification highlights localised exceptions, including façades characterised by Vulnerability Class A elements. These differentiated vulnerability patterns provide relevant

insights for urban safety management. In particular, the presence of higher vulnerability classes along specific edges of the square suggests the need for targeted planning strategies, including the optimisation of evacuation routes and the management of pedestrian flows during both ordinary conditions and emergency scenarios. This is especially relevant in the context of low-intensity seismic events, where early damage activation of TFEs may still pose significant risks to outdoor users.

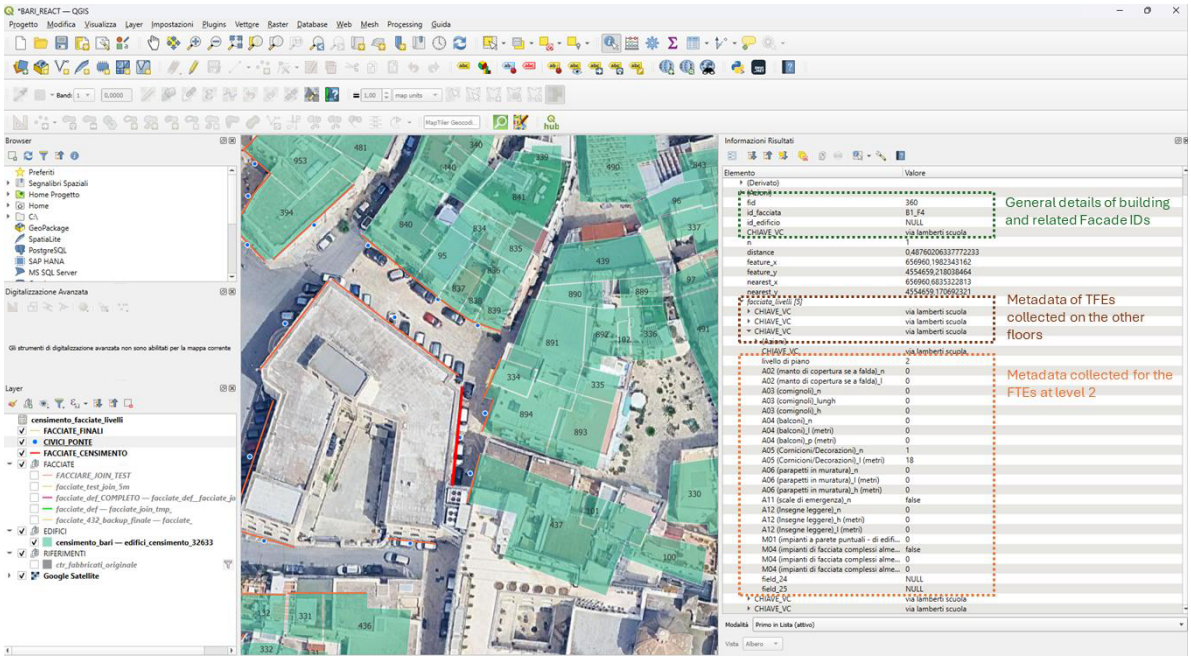

Figure 4 – Overview of TFEs contents gathered in the GIS-Based environment and details of multi-dimensional scale of the collected metadata

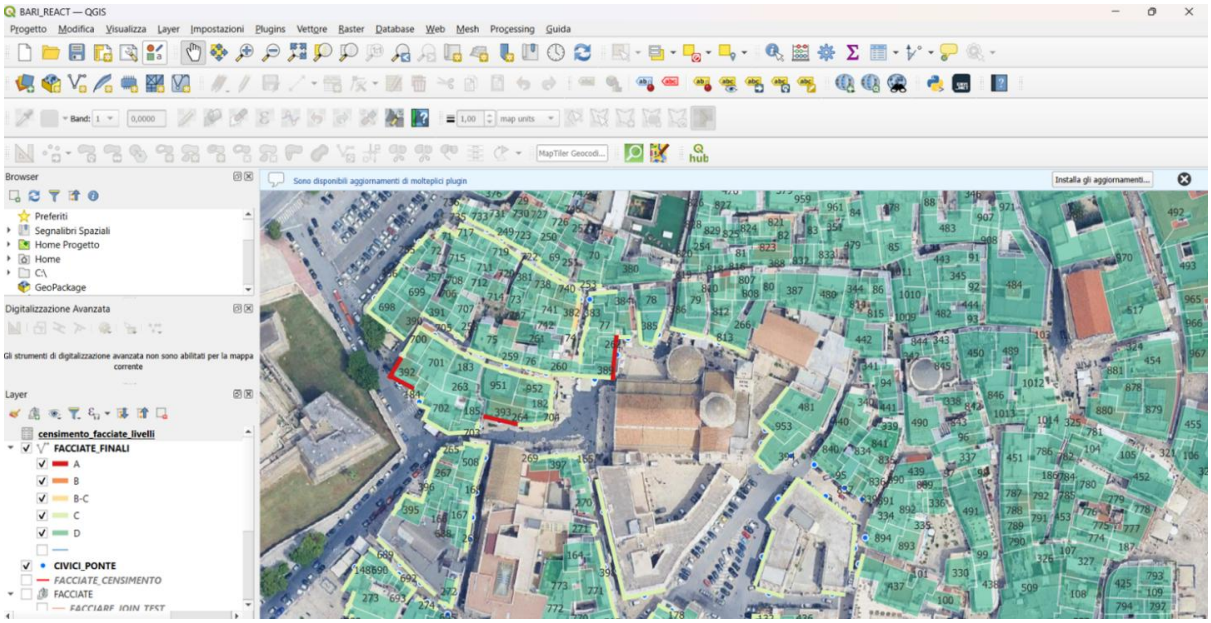

Figure 5 – Distribution of Vulnerability Classes of TFEs in facades distributed along the borders of Piazza dell'Odegitria

4. Discussion and Conclusions

The proposed framework highlights the relevance of Technical Façade Elements (TFEs) as interface components in the assessment of outdoor urban safety, particularly under low-intensity seismic conditions. By focusing on non-structural elements as conceived in national and international regulatory frameworks, the study addresses a dimension of seismic risk that is often overlooked in conventional approaches yet directly affects users in everyday urban environments.

The adoption of a qualitative and screening-level methodology, based on the combined use of the Relevance Index (R-index) and the Prevalent Damage Index (PD-index), enables the rapid qualification of TFEs. This approach allows the translation of façade-level observations into structured information, supporting consistent and scalable assessments without the need for complex modelling tools. As a screening-oriented approach, the proposed framework intentionally simplifies the complexity of façade behaviour by two qualitative indices and four vulnerability classes. The resulting classification does not explicitly account for factors such as material degradation, connection details, maintenance conditions, or local amplification effects, which may influence the actual performance of TFEs. Moreover, the vulnerability classes were derived from the interpretation of regulatory references and recurring damage observations rather than from statistically calibrated fragility functions. Therefore, they should be interpreted as relative indicators supporting prioritisation and preventive decision-making rather than as quantitative measures of failure probability.

The integration of the dataset within a GIS-based environment represents a key advancement of the proposed framework. The spatialisation of vulnerability levels (A–D) allows the identification of clusters of critical conditions and supports the interpretation of façade-related vulnerability in relation to urban open spaces, particularly streets and squares characterised by high levels of user exposure. Thus, the methodology enables a shift from building-scale analysis to a more comprehensive district-scale perspective.

The application to the historic urban context of Bari confirms the capability of the framework to capture differentiated vulnerability patterns across façade fronts, highlighting the role of both element typology and spatial configuration in defining safety conditions. In particular, higher vulnerability levels are frequently associated with elements characterised by both high relevance and low damage thresholds, located in areas of intense pedestrian use.

From an operational perspective, the proposed approach provides a useful decision-support tool for public administrations, facilitating the prioritisation of interventions and the identification of urban sub-areas characterised by reduced safety conditions. The possibility of aggregating data from the façade scale to the district scale enhances its applicability within urban survey and monitoring processes. In this context, the framework can support not only emergency planning but also promote local suggestions in preventive maintenance strategies to private owners and organize different levels of priority of interventions for public buildings aimed at reducing long-term exposure to façade-related risks.

Although tested in a historic Mediterranean context, the methodology is designed to be transferable to other urban environments, provided that local regulatory references and context-specific TFE characteristics are appropriately integrated.

Finally, the integration of façade-related vulnerability with the spatial configuration of urban open spaces opens further perspectives for the analysis of user exposure and movement patterns. In this sense, future developments may include the incorporation of geometric and morphological parameters, as well as dynamic data related to pedestrian flows, supporting more advanced applications in evacuation planning and the design of safer pedestrian mobility strategies.

In line with validation purposes, future activities may take into account the opportunity to investigate the validation of the proposed classes through post-event damage inventories and broader urban case studies. At the same time, the relevance of the users' safety in outdoor environments, future research can take

advantage of these synthetic results to combine the analysed seismic-induced vulnerability on outdoor users with other kinds of hazards, such as heatwaves, to reflect the opportunity to test multi-safe places.

Abstract: Ex ante seismic vulnerability assessment plays a central role in preventing damage to exposed assets and becomes particularly relevant when intended to support public administrations in the large-scale planning of seismic risk mitigation strategies. In such contexts, the large number of buildings to be analysed requires the adoption of rapid assessment approaches that, while forgoing advanced and time-consuming analyses, allow the evaluation of extensive building portfolios through a limited set of structural and typological parameters capable of capturing their expected seismic behaviour.

By applying and comparing two large-scale seismic vulnerability assessment methods for masonry buildings, both based on the Vulnerability Index, this study highlights the operational potential of these tools while critically examining the inherent sources of error and uncertainty embedded in their formulation. The objective is to raise awareness of the need for a careful and informed interpretation of the results, especially when they serve as a basis to support decision-making processes and prioritize mitigation interventions.

The analysis focuses on a sample of masonry buildings located in the municipality of Campotosto, a small town in the province of L'Aquila (Central Italy) severely affected by the 2016–2017 seismic sequence. The work contributes to a broader effort toward the progressive refinement of large-scale assessment methodologies, ultimately enhancing the reliability and robustness of territorial-scale seismic vulnerability analyses.

Keywords: Seismic risk management, Vulnerability index methods, Historic centres, Uncertainty quantification

1. Introduction

Large-scale vulnerability assessment represents a fundamental tool for supporting seismic risk mitigation policies and territorial emergency planning, especially in historic urban areas characterized by vulnerable masonry building stocks (Blyth, et al. 2020). In this context, the need to analyse a large number of structures within limited timeframes has promoted the widespread use of rapid assessment procedures based on simplified and empirical approaches. Among them, Vulnerability Index methods are currently recognised as one of the most effective and operational solutions for territorial-scale applications due to their simplicity, reduced data requirements and ability to provide damage scenarios useful for decision-making processes.

Despite their extensive application and validation in the literature, large-scale vulnerability assessment methods remain intrinsically affected by different sources of error and uncertainties. These may derive from the adopted analytical formulations, the engineering judgment of data, as well as the assumptions related to seismic input parameters. Since the outcomes of these methodologies are often used to prioritise mitigation strategies and allocate economic resources, understanding their limitations becomes essential for a correct interpretation of the results.

Within this framework, the present study focuses on the identification and critical appraisal of the main sources of uncertainty affecting large-scale seismic vulnerability assessment methods for masonry buildings. This objective is pursued through the comparison of two well-known and widely validated VI-based approaches proposed by (Ferreira, Vicente, et al. 2013) and (Brando, et al. 2017) with application to a sample of buildings located in the municipality of Campotosto (L'Aquila, Italy).

This work presents a synthesis of the main results from a broader study on the analysis of the main sources of error and uncertainties affecting large-scale seismic vulnerability assessment approaches. A more comprehensive discussion and additional results are provided in (Masciotta, Mancini, et al. 2025).

The paper is organised as follows. Section 2 outlines the methodologies adopted to estimate the seismic vulnerability of the historic centre under investigation. Section 3 presents the case study of Campotosto along with the results from the vulnerability assessment. Finally, Section 4 discusses the sources of errors and uncertainties associated with the adopted methods, and Section 5 summarises the main conclusions of the study.

2. Materials and Methods

As highlighted by (Baquedano-Juliá, et al. 2024), index-based methodologies have experienced significant development over the last years. Their simplicity, cost-effectiveness and time-efficiency make them particularly suitable for large-scale risk analysis, especially in developing contexts where economic and skilled human resources for heritage protection are limited. In light of these advantages and considering the need to analyse a large building sample while investigating the inherent sources of uncertainty affecting large-scale methods, two widely validated approaches are selected, namely the methodologies proposed by (Ferreira, et al. 2013) and by (Brando, et al. 2017). Although developed in different contexts and calibrated using post-earthquake damage data from distinct regions, both approaches share a common methodological framework for the seismic vulnerability assessment of masonry buildings. They are based on the computation of a Vulnerability Index (VI) obtained through the evaluation of the main structural features and seismic-related deficiencies of buildings, typically collected via rapid in situ surveys. The VI provides a quantitative representation of the physical and structural characteristics of each building and is subsequently used to estimate expected damage levels through vulnerability functions. A detailed description of the two methodologies is provided below.

2.1 Vulnerability index method by Ferreira et al.

The method proposed by (Ferreira, et al. 2013) builds upon the (GNDT 1994) II level approach originally developed for Italian masonry structures. It was subsequently adapted to the Portuguese traditional building stock by (Vicente, et al. 2011) and later refined and calibrated by (Ferreira, et al. 2013) according to the damage observation from the 1998 Azores earthquake (Ferreira, et al. 2017). The method allows for the estimation of a seismic vulnerability index for each building through the weighted evaluation of 14 parameters, each representing a key aspect influencing the global seismic response of the structure. As reported in **Table 1**, these parameters are grouped into four categories to highlight their differences and relative importance. For each parameter, a class C_{vi} of growing vulnerability (A, B, C and D) is assigned, along with a corresponding weight, varying from 0.5 for less influential parameters up to 2.5 for the most significant ones. A comprehensive description of the classification criteria and weighting scheme of the method is provided in (Eudave, et al. 2022).

Finally, the seismic vulnerability index (I_{vf}^*) is computed according to Eq. 1, yielding values in the range of 0 to 750, which are subsequently normalised (I_v) as reported in Eq. 2.

$$I_{vf}^* = \sum_{i=1}^{14} C_{vi} \cdot p_i \tag{1}$$

$$I_v = \frac{I_{vf}^* \cdot 100}{750} \quad (2)$$

For each building, I_v is then used to derive the vulnerability factor (V) (Eq. 3) and consequently estimate the mean damage grade (μ_D) (Eq. 4), which also depends on the macroseismic intensity (I) – defined according to EMS-98 scale, and on the ductility factor (Q) – which accounts for the structural typology of buildings and is assumed equal to 3.0. The resulting μ_D value ranges from 0 (no damage) to 5 (complete or near-collapse damage).

$$V = 0.592 + 0.0057 \cdot I_v \quad (3)$$

$$\mu_D = 2.5 + \left[3 \times tanh\left(\frac{I + 6.25 \cdot V - 12.7}{Q}\right)\right] \quad (4)$$

Table 1 – Parameters, classes and weights associated with the vulnerability index *(Ferreira, et al. 2013)*

Parameter	Class C_{vi}				Weight p_i	Relative weight over the I_v
	A	B	C	D		
Group 1. Structural building system						50/100
BP1. Type of resisting system	0	5	20	50	2.50	
BP2. Quality of the resisting system	0	5	20	50	2.50	
BP3. Conventional strength	0	5	20	50	1.00	
BP4. Maximum distance between walls	0	5	20	50	0.50	
BP5. Number of floors	0	5	20	50	0.50	
BP6. Location and soil conditions	0	5	20	50	0.50	
Group 2. Irregularities and interactions						20/100
BP7. Aggregate position and interaction	0	5	20	50	1.50	
BP8. Plan configuration	0	5	20	50	0.50	
BP9. Height regularity	0	5	20	50	0.50	
BP10. Wall façade openings and alignment	0	5	20	50	0.50	
Group 3. Floor slabs and roofs						18/100
BP11. Horizontal diaphragms	0	5	20	50	0.75	
BP12. Roofing system	0	5	20	50	2.00	
Group 4. Conservation status and other elements						12/100
BP13. Fragilities and conservation status	0	5	20	50	1.00	
BP14. Non-structural elements	0	5	20	50	0.75	

2.2 Vulnerability index method by Brando et al.

Similarly to the previous approach, the method proposed by (Brando, et al. 2017) aims to estimate the potential earthquake-induced damage in masonry buildings by evaluating 14 key parameters (**Table 2**) associated with their main sources of vulnerability. Each parameter is initially assessed through two distinct scores: a fragility score (v_{kf}), representing its contribution to increasing seismic vulnerability, and a protection score (v_{kp}), accounting for features that mitigate vulnerability. These scores are combined with a weighting coefficient that reflects the relative influence of each parameter on the structural response to seismic actions, as expressed in Eq. (5). Both the scoring system and the weighting coefficients were calibrated based on observed damage to traditional masonry buildings following the 2009 L'Aquila earthquake. Further details can be found in (Brando, et al. 2017) and (Rapone, et al. 2018).

In this case, the seismic vulnerability index (i_v), ranging from 0 (no vulnerability) to 1 (maximum vulnerability), is computed for each building according to Eq. 5. The value is then converted into the vulnerability factor (V) using the polynomial function expressed in Eq. 6. Finally, V is used to estimate the mean damage grade (μ_D)

according to Eq. 7, which is defined based on the formulation proposed by (Lagomarsino and Giovinazzi 2006).

Table 2 - Parameters and respective weights associated with the vulnerability index *(Brando, et al. 2017)*

Vulnerability Parameter (P_k)	Vulnerability type	Weight (ρ_k)
P1	Position	1.5
P2	Number of stories	1.5
P3	1st mode mechanism	1.5
P4	2nd mode mechanisms	1.0
P5	Arches	1.0
P6	Vaults	1.0
P7	Slabs	1.0
P8	Thrusting forces	0.8
P9	Presence of added structures	0.5
P10	Stairs	1.0
P11	Irregularities	0.8
P12	Non-structural elements	0.5
P13	Site effects	1.5
P14	Non-seismic external hazard	0.3

This formulation relates the expected damage to the seismic input (I), expressed in terms of macroseismic intensity (I) – defined according to MCS scale, as well as to the vulnerability factor (V) and the ductility coefficient (Q), which is assumed equal to 2.3 unlike Ferreira's approach. In line with empirical large-scale vulnerability assessment methods, the μ_D value ranges from 0 (no damage) to 5 (collapse or near-collapse).

$$i_v = \frac{1}{6} \cdot \frac{\sum_{k=1}^{14} \rho_k \cdot (v_{kf} - v_{kp})}{\sum_{k=1}^{14} \rho_k} + 0.5 \tag{5}$$

$$V = a + b \cdot i_v + c \cdot {i_v}^2 + d \cdot {i_v}^3 = 0.53 + 1.16 \cdot i_v - 4.00 \cdot {i_v}^2 + 4.21 \cdot {i_v}^3 \tag{6}$$

$$\mu_D = 2.5 \cdot \left[1 + tanh\left(\frac{I + 6.25 \cdot V - 13.1}{Q}\right)\right] \tag{7}$$

The application of the aforementioned methodologies to a selected sample of buildings enabled their comparative evaluation and provided the basis for investigating the sources of error and uncertainty inherent in large-scale vulnerability assessment methods, which are further discussed in Section 4.

3. Seismic vulnerability assessment of the historic centre of Campotosto

3.1 Description of the case study

Campotosto is a small town located in the central Italian Appenine, in the province of L'Aquila. The historic centre was severely affected by the 2009 and 2016-2017 earthquakes, leaving the community struggling to return to normal, particularly after the seismic event of 18 January 2017. The municipality was chosen as the case study due to its high seismic risk, resulting from both its geographical setting and the vulnerability of its building stock, factors that have been also highlighted in previous studies (Cocco, et al. 2019), (Brando, et al. 2020), (Masciotta, et al. 2024).

Following the 2009 L'Aquila earthquake, the urban centre of Campotosto was subdivided into three areas (A, B and C) according to their different lithological features, in accordance with the reconstruction plan. Due to the condition of the historic centre at the time of the survey, which was affected by extensive demolition and reconstruction activities, the analysis focused on Zone B, for which 60 buildings were selected to ensure a good representativeness of the different building typologies within the case study area.

(Figure 1A). The seismic vulnerability assessment was performed based on the data collected during the survey. The investigated building stock is relatively homogeneous in terms of structural and construction features. As can be seen in (Figure 1B), it mainly consists of aggregate poor-quality masonry built with local sandstone. The structural units have an elongated rectangular plan and develop over two- or three- storeys above the ground. The external walls have an average thickness of approximately 0.70 m and are typically characterised by a three-leaf arrangement. The internal core is unstable and composed of filling material, while the external leaves are made of irregular size stones bonded with weak mortar. Inadequate transverse connections are also frequently observed. In addition, the poor interlocking between orthogonal walls and the absence of seismic devices encourage independent wall behaviour. Concerning the floors, they mainly consist of flexible or semi-rigid systems weakly connected to the vertical walls, thus hindering the effective redistribution of horizontal seismic forces. Additional vulnerability factors observed include misalignment of floors and roofs between adjacent structural units, enlargement of openings, and plan or elevation modifications carried out over time using materials different from the original ones.

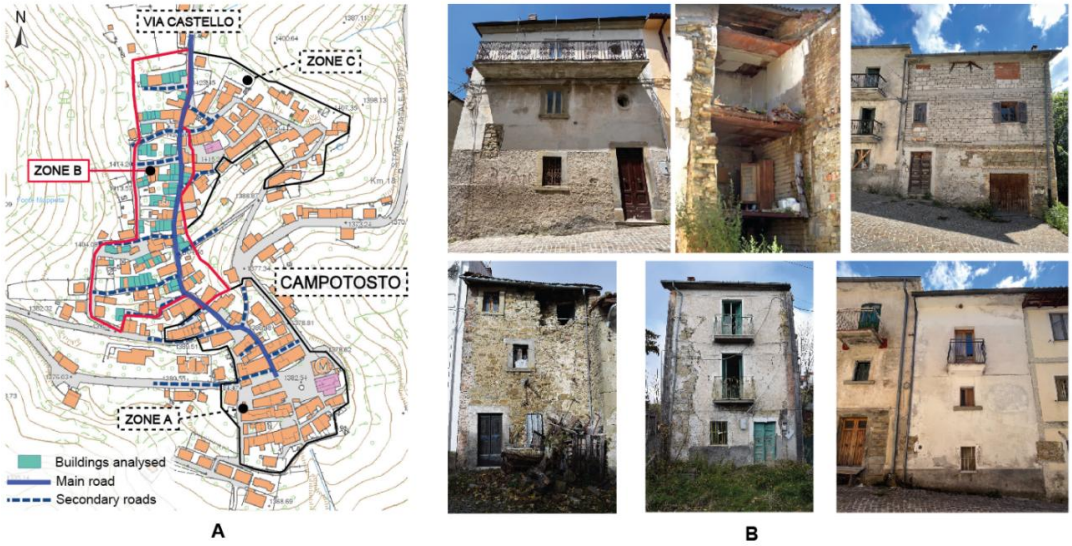

Figure 1 - Subdivision of the municipal area into zones according to the reconstruction plan following the 2009 L'Aquila earthquake. Identification of the area of interest with the buildings analysed (A). Structural features of the buildings in the historic centre

3.2 Seismic vulnerability assessment and comparison with observed damage

The vulnerability assessment of the 60 masonry buildings selected in the historic centre of Campotosto was carried out using the two VI methods outlined in Section 2. First, the vulnerability index and the mean damage grade were evaluated according to the different formulations, taking into account the seismic intensity (I) recorded during the 18th January 2017 seismic event, which INGV rated as VIII. Afterwards, the estimated damage was compared with that observed during the fieldwork and classified according to the five damage levels of the EMS-98 macroseismic scale (Grünthal 1998). To enable this comparison, the observed discrete damage grades (D_i) were converted into mean damage grades (μ_D) by applying the correspondence proposed by (Bramerini , et al. 1995).

For visualisation purposes, two graphs are produced to easily compare observed and estimated damage for each building as a function of its vulnerability index, each representing one of the two adopted methods (Figure 2). For each building, the observed damage is expressed in terms of mean damage grade (μ_D), defined as the average between the upper and lower bounds of the range associated with the assigned damage level. It should be noted that, in Figure 2A and B, the points representing the observed damage exhibit a variation along the abscissa because they are related to the vulnerability index computed according to the specific method considered. Figure 2 reveals that the two approaches exhibit different

trends in terms of damage estimation. While Ferreira's method shows a gradual increase in mean damage with increasing vulnerability index, Brando's method yields μ_D values that remain approximately constant for $i_v < 0.5$.

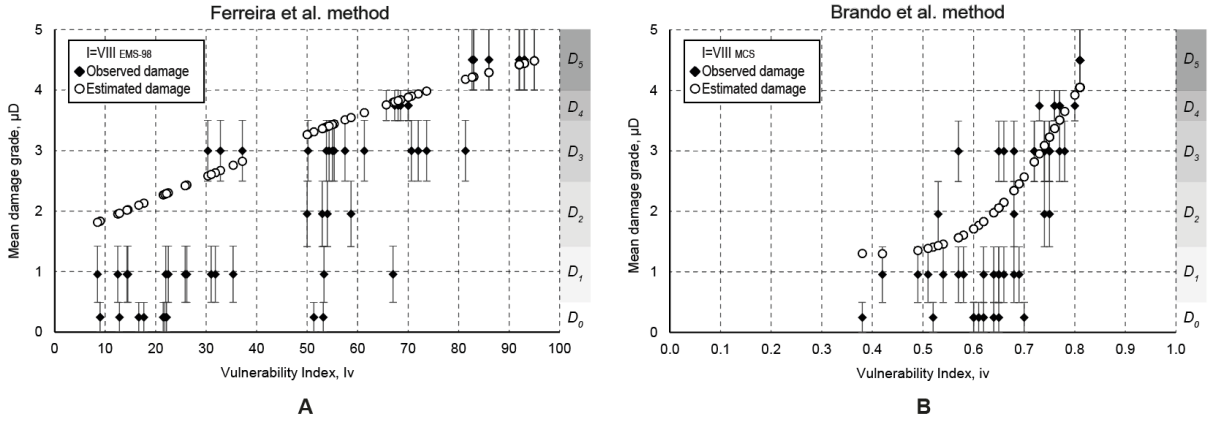

Figure 2 - Observed mean damage grades versus estimated damage grades: comparison between VI methods proposed by Ferreira et al. (A) and Brando et al. (B)

A more detailed comparison between observed and estimated damage shows that Ferreira's method tends to overestimate lower damage grades (D_0, D_1 and D_2) while providing more accurate predictions for higher damage levels (D_3, D_4 and D_5). This behaviour can be attributed to limitations in the analytical formulation (Eq. 4). For example, even for $I_v = 0$ and $I_{EMS98} = VIII$, the resulting $\mu_D = 1.54$ exceeds the upper bound of the D1 range ($D_1 = \{0.5 \leq \mu_D < 1.42\}$), thereby preventing the correct identification of D_0 and D_1. As a consequence, damage tends to shift toward higher classes, particularly D_2. A better agreement between observed and predicted damage is found for $I_v > 30$. A similar tendency is observed for Brando's method, which also overestimates low damage grades (D_0 and D_1), due to the inherent limitations of the formulation (see Eq. 7). However, a good agreement is achieved for $i_v > 0.7$, which corresponds approximately to the threshold between damage levels D_2 and D_3, indicating higher reliability in predicting moderate-to-severe damage (D_3, D_4 and D_5). As can be seen in Figure 3 the spatial distribution of the results indicates that both methods provide the same damage level for approximately half of the analysed buildings. More specifically, Ferreira's approach provides damage predictions consistent with the observed damage for 47.7% of the analysed buildings, while the remaining cases are characterized by damage overestimation. By contrast, Brando's method shows agreement with the observed damage for 50% of the buildings, whereas overestimation occurs in 38.3% of cases and underestimation in 11.7%.

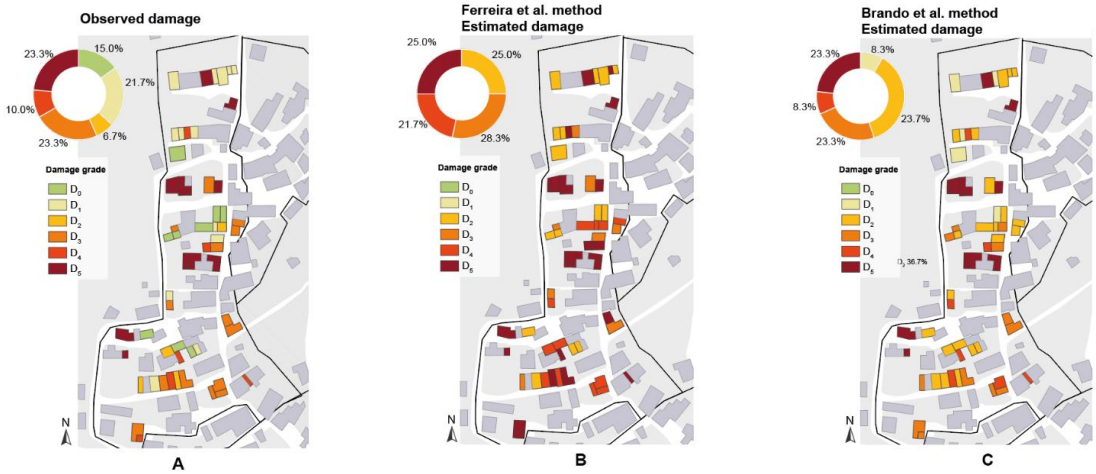

Figure 3 - Comparison between the spatial distribution of the observed discrete damage grades (A) and the estimated discrete damage grade obtained from Ferreira's (B) and Brando's (C) methods.

4. Analysis of uncertainties and sources of error

The effectiveness of vulnerability index-based methods as a decision-support tool in large scale evaluations is nowadays widely recognised (Baquedano Juliá and Ferreira 2021). Nevertheless, these approaches are inherently affected by various sources of error and uncertainty. These mainly arise from the subjective evaluation of building parameters, which depends on data quality and on the expertise of the surveyors, as well as from the use of empirically calibrated weights that may vary depending on the reference dataset. Additional uncertainty is related to the selection of representative building samples in large-scale analyses, which can be difficult to define accurately and may lead to biased assessments of the overall building stock. In this work, particular attention is given to the investigation and discussion of uncertainties associated with the analytical formulations of the methodologies described above (Eqs. 4 and 7). Specifically, the influence of seismic intensity (I), ductility factor (Q) and vulnerability factor (V) is analysed.

4.1 Influence of macroseismic intensity (I) and site effects

Both Ferreira's and Brando's methodologies estimate the mean damage grade (μ_D) as a function of a predefined macroseismic intensity. However, the two approaches rely on different macroseismic scales. Brando's method adopts the Mercalli-Cancani-Sieberg scale (MCS), widely used, particularly in Italy, for the assessment of historical earthquake effects, whereas Ferreira's method employs the more recent EMS-98 scale. Unlike the MCS scale, which was primarily developed for masonry buildings and does not explicitly distinguish between structural typologies, the EMS-98 introduces a classification based on building vulnerability, including also structures designed according to modern codes and categorising them into six vulnerability classes. Despite these differences, a previous study (Del Mese, et al. 2023) showed good agreement between the MCS and EMS-98 scales for buildings featuring a vulnerability class A, which includes structures made of rubble stone and fieldstone masonry. Since the building stock in Campotosto is predominantly composed of such typologies, it can be reasonably assumed to fall within class A, allowing the two macroseismic scales to be considered compatible for the purposes of this study.

Nevertheless, the assumed compatibility between the MCS and EMS-98 scales still represents a potential source of uncertainty, particularly considering the simplified correspondence adopted between the two intensity measures and the conversion of observed discrete damage levels into mean damage grades. These aspects may contribute to discrepancies between observed and predicted damage and should therefore be considered when interpreting the results.

To investigate further the influence of seismic intensity on damage estimation, the damage function of either method (Eqs 4 and 7) is plotted for both intensity levels VII and IX (Figure 4), i.e. for the macroseismic intensities closest to those recorded during the 2017 Campotosto earthquake.

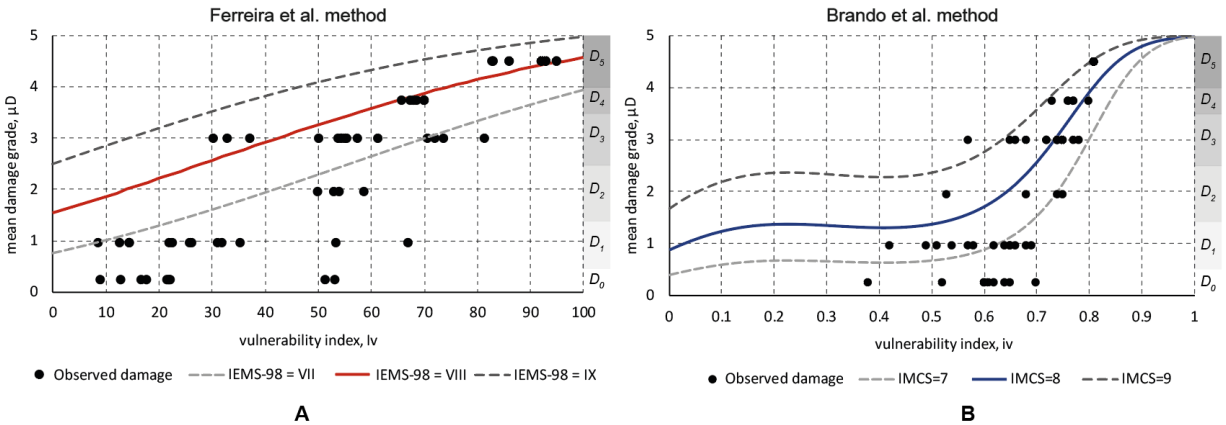

Figure 4 - Vulnerability curves according to Ferreira's (A) and Brando's (B) methods as a function of the macroseismic intensity.

The plots highlight several relevant trends related to the influence of seismic intensity on damage estimation.

- None of the considered formulations adequately capture damage level D0.
- Damage level D1 is better reproduced for intensity VII than for higher intensity values in both approaches, due to the downward shift of the curves, which results in lower μ_D values. However, Ferreira's method tends to overestimate D1 for $I_v > 25$.
- As for D2, Ferreira's formulation provides good agreement with observations for intensity VII, whereas Brando's method distributes predictions between intensities VII and VIII.
- Damage D3 is best captured by Brando's method with intensity VIII, while predictions with I=VII require i_v values greater than 0.75. In Ferreira's approach, D3 is reproduced across a wider range of vulnerability values, reflecting a greater dispersion in the dataset.
- Concerning D4, intensity VIII yields the most accurate predictions in both methods. In contrast, intensity VII generally leads to an underestimation of damage.
- Finally, with regard to damage level D5, Ferreira's method shows a better overall agreement with observed data, accurately capturing all corresponding damage cases.

As highlighted by the previous results, the adoption of a single seismic intensity value may constrain the accurate prediction of damage scenarios, due to uncertainties affecting this parameter, particularly local site effects. As noted by (Brando, et al. 2020), different zones within Campotosto exhibit varying amplification levels related to soil conditions. To underline the consequences of this phenomenon, two structurally similar buildings located in areas with different amplification factors (AFs) are selected for comparison: building 140 located in a low-amplification zone (AF=1.1–1.5) and building 215 sited in a high-amplification zone (AF=1.5–2.0) (Figure 5). Both are three-storey rubble stone masonry structures with comparable geometric and structural features, leading to similar damage grade values in the two approaches ($\mu_{D_215} = 2.06$; $\mu_{D_140} = 2.15$ with Brando's formulation and $\mu_{D_215} = 2.82$; $\mu_{D_140} = 2.43$ with Ferreira's formulation).

However, observed damage differs significantly: building 140 shows almost no damage (D_1), while building 215 is classified as D3. This discrepancy is likely due to different local amplification conditions, highlighting the critical role of site effects and the limitations of assuming uniform seismic intensity.

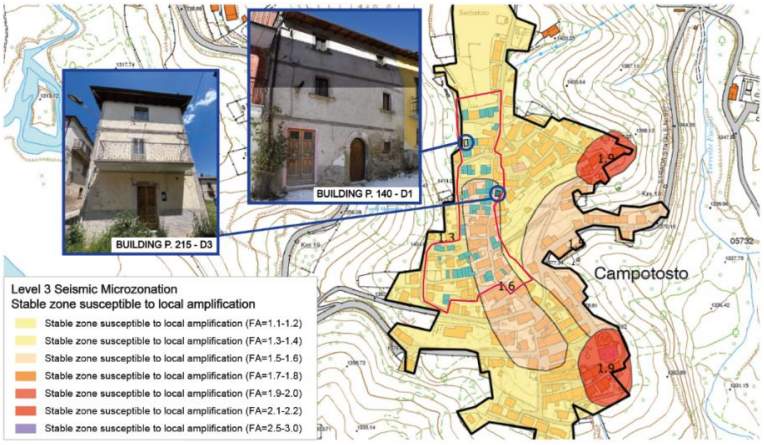

Figure 5 - Selection of two structurally similar buildings located in areas with different amplification factors, according to Level III microzonation studies.

4.2 Epistemic uncertainties associated with the ductility factor (Q)

Another source of uncertainty in the analytical formulation of analysed methods lies in the ductility factor (Q). With values ranging from 1 to 4, this parameter represents the capacity of the structure to undergo inelastic deformation while maintaining its load bearing capacity.

The two selected methodologies adopt different reference values: Brando's method assumes $Q = 2.3$, representative of masonry buildings not designed for ductile behaviour – according to (Lagomarsino and Giovinazzi 2006), whereas Ferreira's method adopts $Q = 3.0$, following the original formulation calibrated by (Bernardini, et al. 2007), which is associated with moderately ductile masonry structures. These values are derived from different calibration processes and case studies, highlighting the influence of methodological assumptions on the results.

To further investigate this source of uncertainty, a parametric analysis is conducted by varying Q from 1.5 to 4.0, revealing how this factor significantly affects the shape of the vulnerability curves (Figure 6).

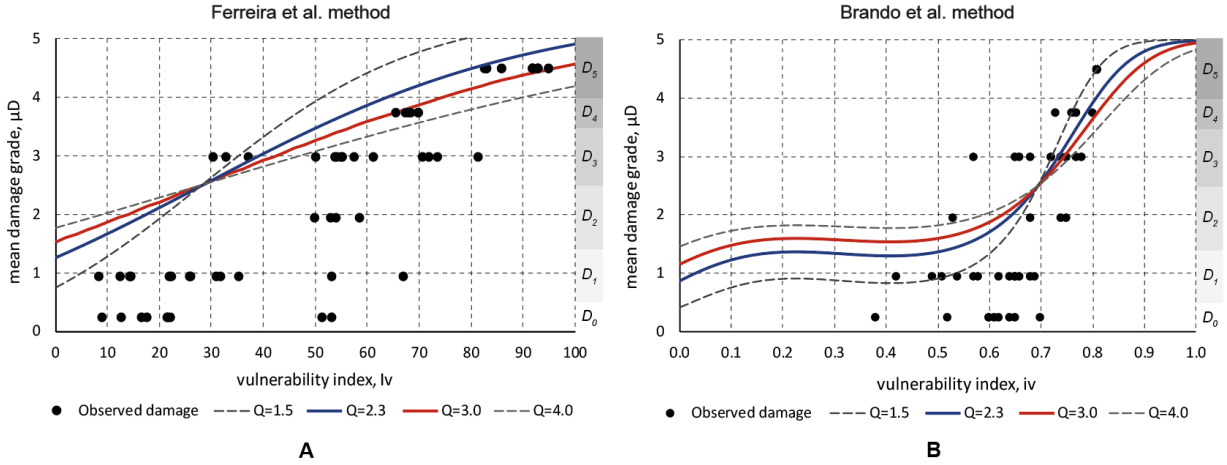

Figure 6 - Vulnerability curves according to Ferreira's (A) and Brando's (B) methods, as a function of the ductility factor.

In both methods, increasing ductility factors produce a rotation of the curves, altering the predicted damage levels. This results into different responses: in Brando's method, the variability is more pronounced for low vulnerability values, allowing a partial capture of lower damage levels, but reducing accuracy for higher damage grades. In contrast, Ferreira's method shows limited sensitivity for low damage levels and improved predictive capability for higher damage grades.

This behaviour reflects the different calibration strategies of the two methods. Since Q is intrinsically building-dependent, assigning a single representative value for an entire building stock introduces epistemic uncertainty. While this uncertainty can be reduced through detailed structural knowledge, such refinement is generally not feasible in large-scale analyses, making it an inherent limitation of VI-based approaches.

4.3 Influence of the vulnerability factor (V)

The vulnerability factor (V) represents another critical source of uncertainty, as it directly governs the relationship between the vulnerability index and the expected damage. The two methods compared in this study adopt different formulations for this parameter: a linear function in Ferreira's approach (Eq. 3) and a cubic function in Brando's (Eq. 6). These formulations were originally calibrated using distinct datasets and structural typologies, thus leading to different shapes of the resulting vulnerability curves and, consequently, to different damage predictions. In both cases, the availability of additional information could be used to refine the analytical formulations by modifying the respective coefficients. For example, (Mosoarca, et al. 2019) used a linear equation for the vulnerability factor, but with coefficients different than those proposed by (Ferreira, et al. 2013).

To better analyse the influence of V, a comparative analysis is performed between the original curves, derived from the equations presented in Section 2, and the modified curves obtained by reversing Eq. 3 and Eq. 6 (Figure 7). For comparative purposes, the following relationship is assumed: $I_v = 100 i_v$.

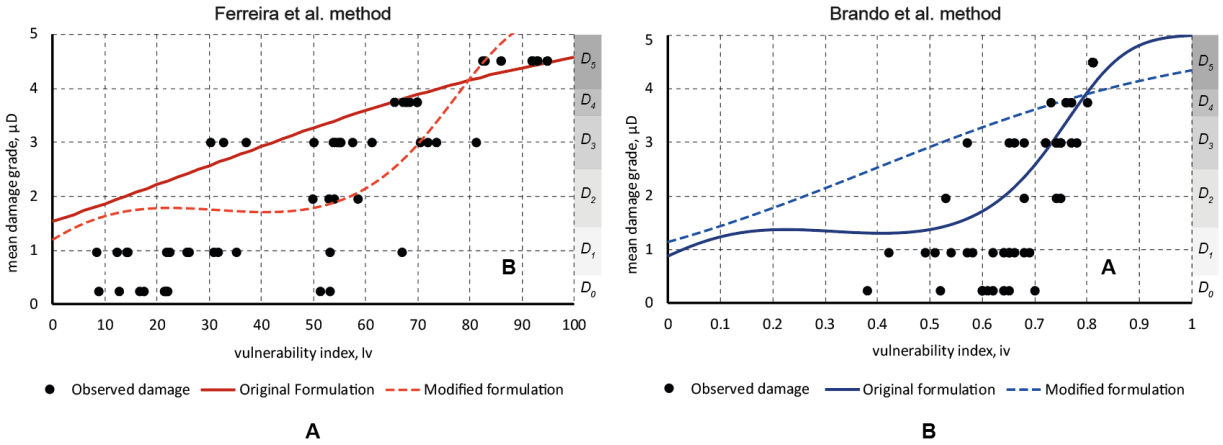

Figure 7 - Vulnerability curves according to the Ferreira's (A) and Brando's method (B), as a function of vulnerability factor.

The analysis shows that modifying the V functions alone does not improve the accuracy of the results. Indeed, the modified formulations lead to increased discrepancies between observed and predicted damage. This confirms that the calibration process plays a fundamental role: the reliability of the results strongly depends on the similarity between the analysed building stock and the one used to derive the original vulnerability functions. Therefore, the vulnerability factor introduces uncertainties not only due to its analytical formulation but also due to its dependence on the representativeness of the calibration dataset.

To provide a quantitative comparison between the predictive performance of the investigated methods, Figure 8 summarises the distribution of coherent (C), overestimated (O), and underestimated (U) damage predictions obtained for all the analysed cases associated with the investigated uncertainty sources, namely the macroseismic intensity (I), the ductility factor (Q), and the vulnerability factor (V).

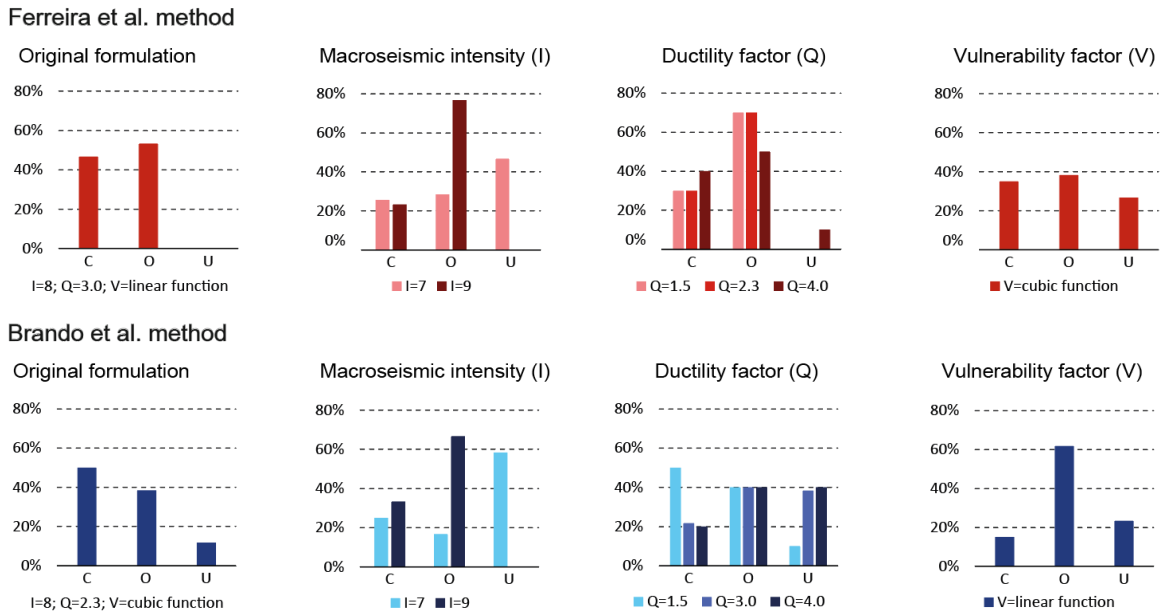

Figure 8 - Distribution of coherent (C), overestimated (O), and underestimated (U) damage predictions obtained with Ferreira's and Brando's methods for the different uncertainty sources analysed, namely macroseismic intensity (I), ductility factor (Q), and vulnerability factor (V).

5. Conclusions

This paper investigates and compares two widely used seismic vulnerability index methods. By applying both approaches to a sample of 60 buildings in the historic centre of Campotosto (AQ), Central Italy, the main sources of error and uncertainty affecting large-scale methods are identified and discussed.

The results show that the choice of the methodology itself represents a primary source of uncertainty. The two approaches, although conceptually similar, produce different damage distributions: Brando's method provides a more balanced prediction across damage levels, while Ferreira's method tends to overestimate damage but performs better for higher damage grades.

Particular attention is given to the analytical formulations adopted in the two methods for estimating the mean damage grade, focusing on the impact of macroseismic intensity (I), vulnerability factor (V) and ductility factor (Q), on the results.

The analyses highlighted that:

- The assumption of uniform seismic intensity (I) over a large area neglects local effects, such as soil amplification, which can potentially lead to significantly different damage scenarios even for structurally similar buildings
- The ductility factor (Q) influences the shape of the damage curves but is typically assigned as an average value for the building stock. Its variability at the building level introduces epistemic uncertainty that is difficult to reduce in large-scale applications
- The analytical formulation of the vulnerability factor (V) strongly depends on the reference dataset used for calibration. When applied to building stocks with different structural features, this may lead to inconsistencies in damage prediction.

Overall, the study confirms that large-scale vulnerability assessment methods, while efficient and widely applicable, are inherently affected by multiple sources of uncertainty. These should be explicitly acknowledged and carefully considered when interpreting results and supporting decision-making processes.

Abstract: This work presents preliminary insights into an ongoing research project that aims to identify, represent, and analyze the retrofitting techniques applied to masonry towers following the 8.0 Mw Algarrobo (1985) and 8.8 Mw Maule (2010) earthquakes in Chile. In this work, four towers are qualitatively analyzed in detail, demonstrating the heterogeneity of the criteria and the types of retrofitting techniques applied, including rigid frames, walls, tie rods, and diaphragms, across reinforced concrete, steel, and mixed systems. The latter is cross-referenced with the typological analysis of the temple (basilica, Latin cross, single-nave, and three-nave layouts), and the categorization of the towers by location, number of bodies, and architectural style. The preliminary conclusions point the study towards an integrated architectural and qualitative structural analysis, which allows for the identification of criteria and methods for retrofitting techniques that balance seismic performance with respect for heritage values and attributes, in accordance with contemporary criteria on the matter.

Keywords: Masonry tower, unreinforced masonry, earthquake damage, retrofitting techniques.

1. Introduction

Unreinforced masonry (URM) bells and clock towers represent a key component of architectural heritage worldwide. However, due to typological features such as geometrical configuration, slenderness, regularity, and mechanical properties, among others, they are extremely prone to suffering damage and local or global collapses under seismic demands (Augenti et al. 2013; Di Tommaso and Casacci 2013; Preciado et al. 2015; Valente and Milani, 2016; Palazzi et al., 2020; Nuzzo and Faella 2021; Valente and Milani 2016; Masciotta and Lourenço 2022). In fact, URM towers rank among the most seismically vulnerable macro-elements in the well-known 28 collapse mechanisms catalog of URM historic churches (Dipartimento della Protezione Civile 2006). Therefore, conducting research in this field is essential not only for a better understanding of these complex structural issues but also for the preservation of these valuable constructions. Several works have addressed this matter, primarily to investigate structural stability and crack patterns associated with specific morphological features. However, few studies have focused on the seismic retrofit interventions, criteria, and techniques used in existing URM towers.

In this regard, Sepe (2008) proposed a large-scale vulnerability assessment method for ancient towers and 4 possible tower positions within a building: isolated, corner, included, and projecting. In line with the damage mechanisms of the abacus, Di Tomasso and Casacci (2013) identified 8 local-specific seismic damage mechanisms for isolated towers, related to crack patterns and out-of-plane collapse. In addition, different analytical models and/or numerical analysis techniques have been applied, such as the work by Bartoli et al. (2017) and linear static analysis using a simple finite element model (Ceroni et al., 2007; Montoya and Barrero, 2017). The studies on historic tower retrofitting interventions are limited. De la Torre et al. (2004) analyzed a set of cases in Mexico and concluded that the local steel-stressed strengthening technique has

demonstrated satisfactory seismic performance. Di Tomasso and Cassaci (2013) analyzed cases of FRP- and steel-rigid-frame strengthening techniques in Italy. Binda et al. (2010) conducted a case study in which a brick-repair, replacement, and mortar-joint-repair retrofitting technique was found to be efficient for a specific case in Monza, Italy. Foti et al. (2016) suggested, for a specific case study, the introduction of a wood structure in the tower's upper area and a system of rods and/or reinforced perforations in the lower area, in addition to grouting and sealing interventions on uneven mortar joints. Milani et al. (2017) investigated a specific case in northern Italy and proposed using the mortar-and-steel-frame technique to improve seismic performance. Despite the brief overview of different research approaches presented here, historic URM towers must be studied on a case-by-case basis due to the numerous variables.

The seismic strengthening of masonry towers remains one of the most challenging tasks in earthquake engineering and heritage preservation. These structures exhibit significant variability in their seismic response due to the inherent heterogeneity of their constituent materials, including different types of masonry units, mortars, main structural elements, and materials introduced during previous repair campaigns. In addition, masonry towers display a broad range of geometric configurations, including variations in height-to-width ratios, wall thicknesses, internal arrangements, openings, and connections between structural components, all of which strongly influence their dynamic behavior and collapse mechanisms under seismic loading. In this scenario, selecting strengthening strategies is further complicated by the need to reconcile seismic safety objectives with conservation requirements. While modern seismic design principles often favor interventions that maximize structural performance and mitigate damage, conservation-oriented approaches seek to preserve historical authenticity through minimal, reversible, and compatible interventions (Palazzi et al., 2026). As a result, the seismic assessment and retrofit of masonry towers require case-specific solutions that account for structural vulnerability, expected seismic demand, material degradation, and compliance with contemporary conservation principles, thereby limiting the applicability of standardized strengthening methodologies.

This work describes and qualitatively analyzes strengthening interventions carried out in four Chilean masonry towers. The study demonstrates the heterogeneity of the criteria and the types of retrofitting techniques applied, including rigid frames, walls, tie rods, and diaphragms, across reinforced concrete, steel, and mixed systems.

2. Cases of study

This work presents 4 case studies of unreinforced masonry (URM) buildings with single towers (Figure 1): 1 civil building and 3 historic churches. The cases are the Historic National Museum (HNM) clock tower and the bell towers of the San José (SJ), Santísimo Sacramento (SS), and San Francisco de Barón (SFB) churches. The NHM is a 2-story, continuous neoclassical façade, secular building arranged around an interior central patio, with a tower over the main façade. SJ and SS have a Latin cross and single-nave layout, with the tower centered in front of the main façade, aligned with the central axis and over the narthex. Both churches are eclectic in the neo-Romanesque and neo-Gothic styles. SFB is a Neobaroque 3-nave church with an apse and a lateral chapel, and the bell and clock tower are over the narthex, aligned with the central axis. NHM, SJ, and SS cases are constructed with URM firebrick box walls, while SFB has an adobe-and-wood system around the box walls, except for the narthex and the tower, which are URM firebrick masonry structures.

As will be seen, the retrofitting techniques employed vary in the materials and structural criteria they use. Some solutions can be described as invasive and irreversible, while others could be considered more in line with modern conservation criteria. In some cases, the reinforcement elements are anchored at specific points in the existing masonry structure, while in others, they are partially embedded within the masonry. The latter highlights the great heterogeneity of the solutions adopted and the lack of guidelines to address this problem.

2.1 National Historic Museum (ex Real Audiencia Palace), Santiago

The NHM is in the middle of Santiago's downtown historic core, the capital city of Chile, and is surrounded by the Central Chilean Postal Office building on the west and Santiago's Municipal Headquarters on the east. The MHN building, also known as the Real Audiencia Palace due to its colonial-era construction and functions, was designed by the Chilean architect Juan José de Goycoolea. It was built between 1804 and 1808, before the Republic of 1818's independence from the Spanish Empire, and is one of the few colonial buildings currently conserved in Santiago. It was declared a Historic National Monument in 1969 (Decreto N° 12392 1969). It has historic, urban, architectural, social, artistic, technical, and cultural heritage values. 8 modules compose the 2-story main façade (22 m long side and 12 m in height), where the access and the clock tower are in the fifth west-to-east module, forming an anomalously asymmetrical neoclassical architectural composition.

The clock tower has 3 free-standing bodies with progressively diminishing story heights and is settled across the 5th front-side module and the transverse façade width. From the ground floor to the top of the wall of the last module, it is 32 m high, with 7 interior levels of variable height. From the ground floor to the 5th interior level, the tower's layout is 5.5 m on the front and back sides and 7.85 m on the lateral sides. The next-to-the-last body is inscribed in a 5.2 m square, and the top free-standing body has a 4.0m square layout. The 3 free-standing bodies are 21 m high. The main façade and the lower tower's body were built in 1808, while the other 2 upper bodies were built between c. 1865 and 1875. Except for specific interventions (such as architectural transformations to the front windows), the tower's exterior architectural features have been preserved. In contrast, at least 2 main structural strengthening interventions were carried out after the 1985 (8.0 Mw) Algarrobo and 2010 (8.8 Mw) Maule earthquakes.

2.1.1 1978-1982 phase

Due to the setting up of the National Historic Museum, an architectural project was carried out between 1978 and 1982, consisting, among some new extensions, of the main façade, clock tower, central patio, and roof architectural restoration, which also included the wooden second-floor structure replacement for a reinforced concrete (RC) slab along the south and main façade's building side. This intervention changed its original structure and increased its horizontal rigidity.

2.1.2 1982-2010 phase

The clock tower sustained serious damage during the 1985 Algarrobo earthquake (8.0 Mw). A critical assessment was carried out, which identified extended crack pattern damage along the interior tower's east and west façades in the lower and middle stages. The upper body registered crack patterns around the 4 exterior façades. Based on it, a retrofitting project was carried out in 1986. The main structural criteria and techniques considered were internal and continuous reinforced concrete (RC) columns, and beam-strengthening insertions within URM walls. Figure 2 shows the retrofit project carried out in the NHM.

The columns and beams inserted into masonry walls have variable sections and are shown from the ground floor to the upper body of the tower. A column-and-beam semi-embedded structure inside the interior was also displayed on the ground-floor access walls, with isolated foundations. A continuous RC rigid frame rises from this level up to the 6th interior floor. Except for the 7th level, which has a steel-structured floor, the others are wooden-structured. The free-standing upper tower's 2 bodies focus on major RC retrofit elements, including short walls and beams. It is important to underline the increasingly diminishing dimensions observed in the 3 free-standing body layouts, which consequently imply variations in the walls' width and axial axes, and thus in the geometrical RC retrofitting elements as well. Between the 5th and 6th floors, the rigid RC frames have been fitted with in-plane RC struts in the interior façades, increasing their vertical rigidity.

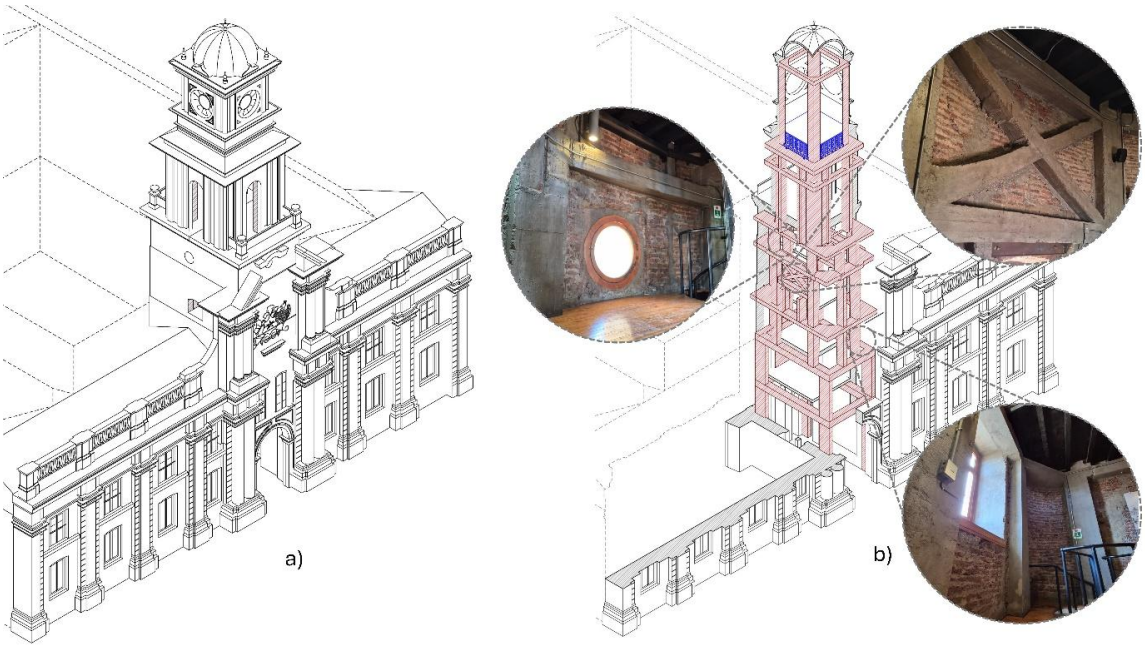

Figure 2 – Strengthening intervention applied to NHM tower: a) exterior view; b) axonometric section with internal RC retrofitting elements (red: RC structure; blue: steel structure).

2.2 San José church, Santiago

The San José church was designed by the French architect Eugène Joannon and built between 1903 and 1909. It is located in the historic Yungay neighborhood, near Santiago's downtown, and is a key building in a historic urban complex block. The church is legally protected as a heritage building by the local Pinteresque Zone (Decreto N°43 2009; Decreto N°13 2019) and as a Historic Conservation Building under the Historic Conservation Building ordinances (Ficha 30, 2005-6). Historic, urban, architectural, artistic, social, and religious values highlight their relevance to heritage. The main façade is preceded by the narthex and the bell tower, which rises 26.5 m to the top's masonry walls, has 4 interior wooden structure floors, and is a 12

m free-standing body high with a 5.5 m front side to 6.4 m lateral sides layout. Two main recent intervention stages have been identified.

2.2.1 1985 - ~2010 phase

After the 1985 Algarrobo earthquake, the bell tower sustained concentrated seismic damage to the upper free-standing body. After a visual on-site inspection, ring RC embedded beams around the inner top masonry walls were identified. Due to the lack of historical information and difficult access, its dimensions and execution data are unknown.

2.2.2 ~2010 – 2026 phase

After the 2010 Maule earthquake, shear damage was identified in the masonry walls' bodies from the ground floor to the middle bell tower. A mixed rigid RC and steel column-and-beam frames within interior walls retrofitting intervention was carried out between 2012 and 2013. The ground and second floors were strengthened with RC columns and beams, and the upper levels were strengthened with steel frames, as shown in Figure 3. The intermediate floors and the spire are wood-structured. An on-site visual inspection identified a lack of continuity in structural retrofitting. However, due to limited access, some areas could not be assessed, specifically at the RC and steel frame connections. The RC columns and beams have an average section of 0.3x0.3 m and are embedded in most masonry walls. The columns, beams, and strut steel elements have a 150x150mm regular section with welding unions. The steel structure is connected to the masonry walls via a plate-and-bolt connection, likely crossing the exterior façade. As shown in Figure 3, the intermediate heights of the steel frame structure vary from level to level.

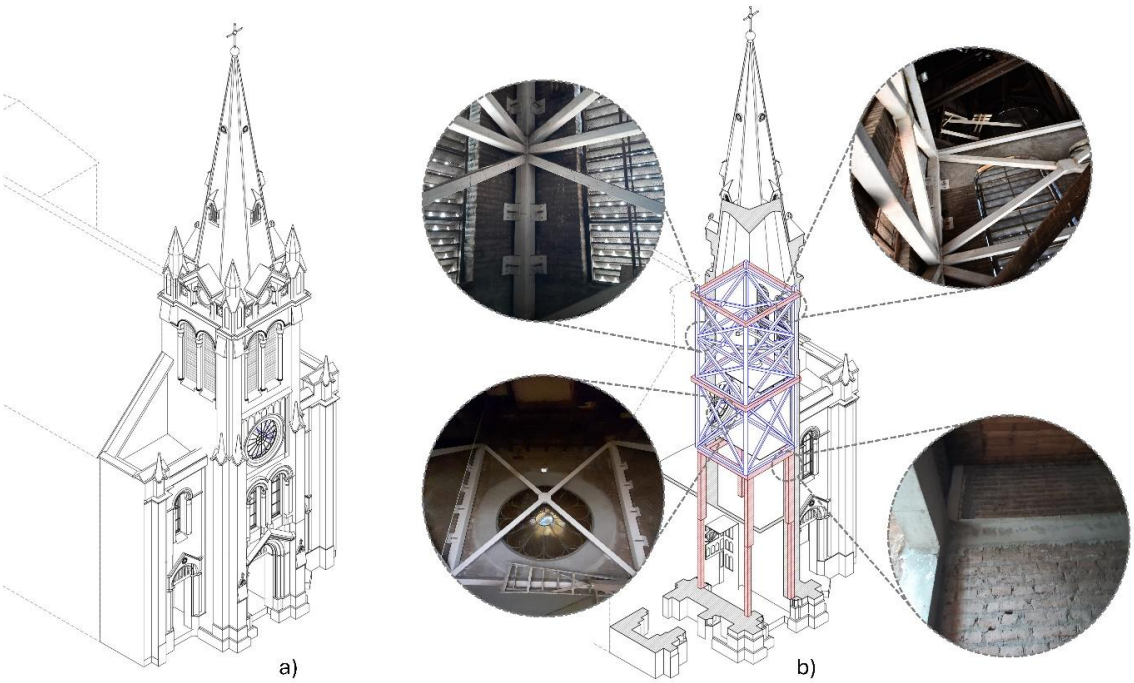

Figure 3 – Strengthening intervention applied to the tower of the San José church: a) exterior view; b) axonometric section view of internal retrofitting internal skeleton (red: RC structure; blue: steel structure).

2.3 Santísimo Sacramento church, Santiago

This church was designed by the French architect Emilio Doyère and built between 1891 and 1896. It was declared a Historic Monument in 1986 (Decreto 132 1986). Its heritage values are historic, architectural, artistic, religious, and technical. The bell tower is centered in front of the main façade, over the prominent 3-

arch narthex, which has 2 lateral semi-octagonal turrets. The entire façade of the building is of exposed brick masonry, including the narthex and bell tower, which facilitated identification of previous structural exterior repair interventions. Its slenderness underlines a particular feature of this case. The tower's average dimensions are inscribed within a 4.7 m square section, and the masonry structure rises 25 m from the base of the spire, which is steel-structured. The tower has 10 wooden structures that make up the interior floors. The study identified 4 retrofitting intervention phases:

2.3.1 1965-1979 phase

Although there is no historical evidence about probable seismic damages after the 1965 La Ligua (7.4Ms) and the 1971 Illapel (7.5Ms) (Servicio Sismológico Nacional) earthquakes, a retrofitting project (1979) with RC columns and beams strengthening elements around the whole masonry structure -including the bell tower- led to supposed eventual local and/or global seismic damages. This project was not executed.

2.3.2 1979-1996 phase

Due to the likely accumulation of damage, in addition to that from the 1985 Algarrobo earthquake, a retrofitting project was carried out in 1996. The structural execution considered an inner steel frame as a mesh that overlapped across the interior bell tower's walls, extending from the choir floor to the top of the masonry wall structure. The ground floor has RC columns and beams, with soil foundations inserted within the columns and arcs. The RC elements are connected to the steel retrofitting internal skeleton and receive the axial vertical loads. The steel frame is connected to the masonry walls by double interior and exterior plates and bolts, probably extending to the exterior façade.

2.3.3 1996-2012 phase

After the 2010 Maule earthquake, seismic damage around the church's box URM walls was repaired in 2012. There is no historical evidence of the details of the retrofitting intervention. However, based on on-site visual inspection and historical photographs, it is possible to identify crack patterns that appear to have been repaired with a concrete technique. In addition, there were no records of local and/or global seismic damage in the bell tower, which the 1996 retrofitting intervention can partially explain. However, for a stronger hypothesis formulation, a major volume of evidence is needed.

2.3.4 2022-2026 phase

The last documented retrofitting intervention was carried out in 2022. The intervention considered external double-tilted columns (Figure 10), connected to the masonry walls by an exterior platen and bolts. Each steel column has soil foundations. The intervention also included interior architectural restoration. However, due to the lack of recent relevant seismic events, it is not yet possible to analyze the church's seismic behavior.

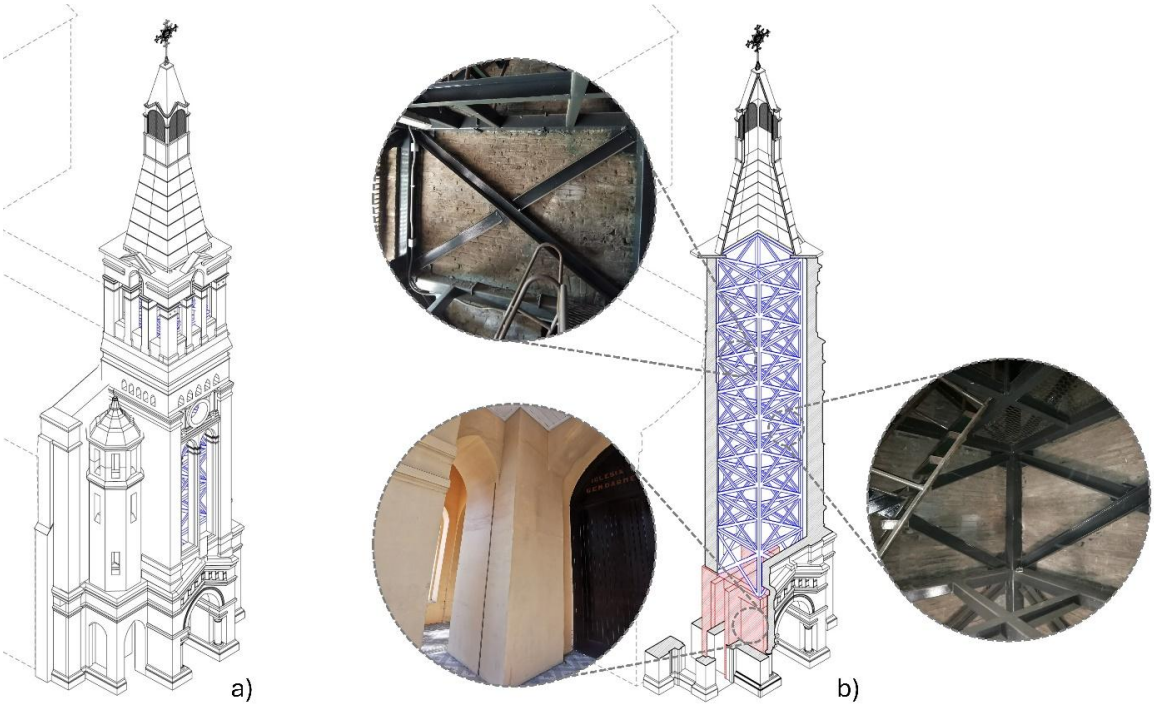

Figure 4 – Strengthening intervention applied to the tower of the Santisimo Sacramento church: a) exterior view; b) axonometric section view of internal retrofitting internal skeleton (red: RC structure; blue: steel structure).

2.4 San Francisco de Barón church, Valparaíso

The SSB temple and monastery are in the seaside city of Valparaíso, 120km from the capital, Santiago. The urban complex is located on the Barón Hill and is a visual landscape icon. The 3-nave (adobe and wooden structure) church was built between 1845 and 1863, and the URM narthex, built between 1890 and 1892, was designed by the Italian architect Eduardo Provasoli in a neo-Baroque style. The complex is a National Monument (Decreto 687, 1983). The church's heritage values are historic, architectural, urban, artistic, religious, social, and technical ones. The current state of the main façade shows a firebrick structure with no stucco finishing, and the bell and clock tower is on the central module's narthex with 2 free-standing bodies and a dome at the top. The church has suffered 3 burning episodes (1983, 2010, and 2013) and several earthquake shocks, such as Valparaíso, 1906 (8.2 Mw); La Ligua, 1965 (7.4 Mw); Illapel, 1971 (7.5 Mw); Algarrobo, 1985 (8.0 Mw); Maule, 2010 (8.8 Mw); and Illapel, 2015 (8.3 Mw) (Servicio Sismológico Nacional). The 3-nave interior structure was rebuilt in 2021, and despite the historic seismic sequence, the church is still standing, which is uncommon. A 3-front-side arcade, URM lateral and rear walls, and dome ceilings structure the URM narthex. The narthex is 21 m long on the side, 9 m wide, and 11.5 m high to the upper cornice of the façade. The wall thickness varies from 0.8 to 1.5 m. The bell and clock tower rises 19.7 m from the cornice base to the dome's top line and 31.2 m from the base ground floor to the top. The tower's average octagonal layout is inscribed on a 7.1 m front-side and 6.6 m lateral-side rectangle. 3 main interventions have been identified.

2.4.1 1984-2009 phase

The 1984 fire destroyed the interior 3-nave wooden structure, arcades, vaults, and roof, and affected the adobe and brick-stone masonry structure. Despite the lack of documentary evidence, it is possible to infer seismic damage after the 1985 Algarrobo earthquake. Between 2007 and 2008, the Mar Vasto study proposed a structural emergency retrofitting intervention using vertical steel tensile bars from the tower's top to the ground floor's narthex, and horizontal steel tensile bars across the perimetral URM-free-standing bodies' walls. However, there is no evidence of the proposed structural design, nor of whether it was finally

executed. In 2009, another non-executed architectural restoration and structural retrofitting project was developed, which included vertical tensile bars in the URM narthex.

2.4.2 2009-2013 phase

2 catastrophes affected the temple in 2010: the Maule earthquake in March, and a fire in September that once again destroyed the 3-nave wooden structure, arcades, vaults, and roof. The masonry structure was affected as well. To repair the church, a restoration initiative was carried out in 2011, during which horizontal steel bar strengthening techniques were applied to the free-standing URM walls, as shown in Figure 5. The steel bars are displayed across the perpendicular walls and extend to the inner wall sides. Outside the URM walls, an RC device was installed as an intermediate connector between the steel reinforcement bars and the masonry structure. To support the steel bells, a set of 2 parallel double-T steel beams per side, anchored to the masonry walls at the interior top of the second free-standing body, was added. In 2013, another fire event burned the building, except for the narthex and the bell and clock tower masonry structure.

2.4.3 2013-2026 phase

In 2021, an integral reconstruction, restoration, and structural strengthening intervention was carried out on the church and the ancient monastery, which are now in their current state. The interior 3-nave was rebuilt with a completely wooden structure and interior finishing. Masonry block repairs and replacement of damaged blocks were performed on the exterior and interior tower façades. Existing steel strengthening elements were repaired, and internal wooden floors were rebuilt.

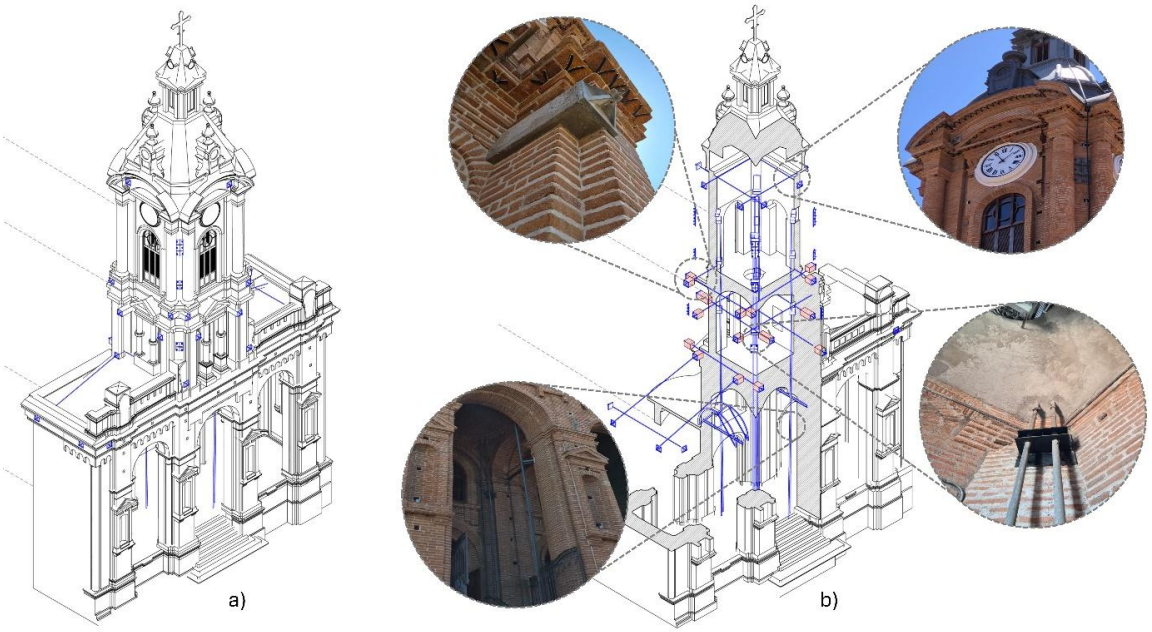

Figure 5 – SFB axonometric southeast view sequence: a) exterior view; b) ~~exploded~~ axonometric section view of internal RC retrofitting internal skeleton. (red: RC structure; blue: steel structure).

The main retrofitting intervention included continuous steel tensile bars from the top of the bell and clock tower to the ground floor along the central narthex module addition (Figure 5b). The bars are anchored to the masonry walls through steel plates and bolts on both the inner and outer sides, and their vertical continuity is provided by steel connectors at intervals. Due to insufficient information, the active tensile strength of the vertical steel bars is uncertain. In addition, horizontal steel bar strengthening techniques

were applied to the walls of the free-standing URM bodies. The steel bars are displayed across the perpendicular walls and extend to the inner wall sides. Outside the URM walls, an RC device was installed as an intermediate connector between the steel reinforcement bars and the masonry structure. Connecting the border sides to the tower's base free-masonry walls, combined with a similar setting at the main façade top to the back longitudinal wall against an out-of-plane mechanism.

3. Conclusions and future research directions

Historic URM towers are valuable architectural structures worldwide. However, they are the most seismically vulnerable structures and may concentrate major seismic damage, local and/or global collapses, impacting society, the economy, and cultural heritage. This study examined 4 architectural-historical bell and clock tower types (3 in Santiago and 1 in Valparaíso), each with different strengthening criteria and techniques, most executed over the past 4 decades following the 1985 Algarrobo and 2010 Maule megathrust earthquakes. From 2010 to the present, no serious seismic events have shaken the area around their location; thus, it is not yet possible to determine their seismic behavior and the effectiveness of the retrofitting interventions. The study identified clear heterogeneity in the variety of architectural bell and clock towers, as well as in the retrofitting and strengthening criteria and techniques used across different chronological periods and circumstances.

3.1 Architectural type diversity

The 4 study cases have 1 single (clock bell and/or clock) tower in front of the main façade. In SJ, SS, and SFB churches, the tower is aligned with the central façade's axis and the narthex of the arcade. SJ and SS temples have a Latin-cross layout, and SFB has a 3-nave layout. Despite its neoclassical style, the HNM clock tower is on the main building's access but in an asymmetrical position on the façade. The towers' height (from the ground floor to the top URM structure) is round, from 25 m (SS) to 32 m (NHM) and 8.5 m (SS) to 21 m (NHM) along the free-standing tower's bodies with a 4.7 m per side averaged layout (SS) to 7.1 m on the front side and 6.6 m on the lateral sides (SFB). Most of the cases registered seismic damage after the 1985 (8.0 Mw) and 2010 (8.8 Mw) earthquakes concentrated on free-standing bodies, as expected according to the literature. Furthermore, the masonry tower's walls have diminishing thickness and vertical-axis variations from the bottom to the top, with vertical load continuity. Finally, all cases have a wooden structure on an intermediate floor, except for the NHM, which has a steel horizontal frame on its upper floor. The total slenderness of the cases is MHN 6,7; SJ 4.8; SS 5.3, and SFB 4.7. Moreover, the slenderness of the free-standing tower is MHN 4.4; SJ 2.2; SS 1.8, and SFB 3.0. Thus, the MHN clock tower represents the slenderest case of study considering the total height and the partial free-standing height.

3.2 Seismic retrofitting intervention criteria and techniques

Despite some geometrical configuration similarities between the cases of study, such as the number of free-standing bodies (2 or 3), morphological regularity, the presence of openings, progressive diminishing width from base walls to the upper ones, and the crack patterns registered after the past 2 earthquakes, the retrofitting techniques applied are all different. Conversely, all interventions were carried out along the inner walls of the masonry structure, thereby diminishing the impact on the heritage attributes. 4 retrofitting intervention types were identified: a) the NHM case has rigid, monolithic, and continuous RC columns and beams embedded and semi-embedded in the masonry structure frames and displayed from the ground floor (with isolated soil foundations) to the top; b) The SJ church has a mixed RC columns and beams embedded frame around the prominent narthex arcades with isolated soil foundations, which acts as the base support for free vertical steel rigid columns, beams, and struts with variable height and connected by platen and bolts to the 4 masonry internal walls' sides; c) The SS church has a mixed RC columns and beams embedded frame around the prominent narthex arcades with isolated soil foundations. Over it, steel

columns, beams, and struts are vertically displayed to the masonry walls' top line. The steel structure is embedded within a double interior and exterior plate and bolt components traversing the masonry width walls; d) the SFB church strengthening technique applied is based mainly on horizontal and vertical steel stress bars. The horizontal ones are freely set along each inner masonry wall, extending to the exterior façades and connected by a RC device on each side of both free-standing towers' bodies. In addition, the longitudinal masonry wall planes (the façade and back wall's narthex) are connected through steel stressed bars set on each lateral side next to the tower. Along with the intrados, narthex arcades were inserted with steel strengthening plates and horizontal bars between the arch's imposts.

The heterogeneous strengthening techniques applied to the examined cases indicate a lack of unified seismic retrofitting criteria, which can be partially explained by differences in execution periods, earthquake shock characteristics, and crack patterns and damage. Except for the SFB church, the strengthening interventions identified in the other cases can be classified as a 'tower in tower' retrofit, with a variety of techniques applied. It is not possible to evaluate their seismic performance at this time. Moreover, to preserve the tower and its valuable heritage and architectural type, the diversity-applied techniques highlight the need for a common set of criteria and an intervention approach.

The research methodology has involved a first stage of on-site data collection to address information gaps arising from historical data on the church construction process, historical seismic performance, executed intervention works, and visual on-site surveys. Then, as in the research carried out by Alvarado et al. (2025), the work will integrate different non-destructive tests (NDT), such as terrestrial laser scanning (TLS), photogrammetry with unmanned aerial vehicles (UAVs), ground penetration radar (GPR), ultrasonic pulse velocity measurement, Schmidt hammer, pendulum hammer, and penetration tests. In addition, an experimental campaign to estimate the modal properties of the masonry towers under study will be conducted using the same method as that used for the Metropolitan Cathedral of Santiago, Chile (Torres et al., 2017).

Abstract:

Structural Health Monitoring (SHM) has become a key tool for the preservation of historical heritage, particularly in medieval constructions. The use of sensors enables real-time acquisition of structural responses, such as accelerations, which can be employed for damage detection. In this context, Operational Modal Analysis (OMA) emerges as a non-destructive technique for identifying the dynamic properties of such structures. This study presents the calibration of the mechanical properties of the Sciri Tower, a medieval masonry structure located in the historic center of Perugia, which has been previously investigated by the University of Perugia. The main objective is to improve the model's geometry based on point cloud data and carry out a new material calibration. An iterative manual calibration procedure was performed by comparing the natural frequencies obtained from numerical simulations with the first four vibration modes identified through OMA. As a result, four distinct material sets were defined and calibrated. This type of analysis represents a fundamental step toward the development of predictive models, including nonlinear analyses for seismic scenarios and pushover analyses.

Keywords: Operational Modal Analysis, Medieval tower, Point cloud, Finite elements method, Structural health monitoring

1. Introduction

Masonry structures constitute a significant portion of the world's architectural heritage, encompassing a large number of historical and medieval buildings that remain in service today. These structures, however are particularly vulnerable to seismic actions due to their low tensile strength, brittle behavior, and often limited structural redundancy. This vulnerability is especially relevant in countries such as Italy, where seismic events frequently threaten the preservation of historic centers and monuments. Among recent examples, the 2012 Emilia earthquake as showed in Tiberti, Acito, and Milani (2016) which highlighted the susceptibility of masonry towers and heritage constructions to earthquake-induced damage, emphasizing the necessity of preventive conservation strategies and reliable assessment methodologies.

The structural assessment of historical masonry buildings, however, presents unique challenges when compared to modern constructions. Centuries of modifications, material degradation, construction irregularities, and the use of vernacular building techniques often result in significant uncertainties regarding both geometry and material properties. Furthermore, the historical value of such structures generally prevents the execution of extensive destructive tests, making the direct characterization of their mechanical properties difficult. Consequently, the development of reliable numerical models capable of predicting structural behavior remains a complex task.

In recent decades, vibration-based Structural Health Monitoring (SHM) has emerged as a valuable tool for the preventive conservation of historic structures. Through the continuous or periodic acquisition of dynamic response data, SHM systems enable the identification of structural changes and provide relevant

information regarding the global behavior of buildings (Alvandi and Cremona 2006; Ubertini et al. 2018; Ramos et al. 2010; Masciotta, Ramos, and Lourenço 2017). In this context, Operational Modal Analysis (OMA) has gained considerable attention due to its ability to extract modal parameters under ambient excitation conditions, eliminating the need for artificial loading systems that may be impractical in heritage structures.

Beyond structural monitoring purposes, experimentally identified modal parameters can be employed in finite element model updating procedures, allowing the indirect estimation of mechanical properties through the calibration of numerical models. Such approaches have been successfully applied to several historical masonry structures and are currently recognized as effective non-destructive techniques for reducing uncertainties associated with material characterization (Salachoris et al. 2024; C. Gentile and Saisi 2006; Carmelo Gentile, Saisi, and Cabboi 2015). Nevertheless, the reliability of the updated mechanical parameters strongly depends on the accuracy of the numerical model adopted. Since modal properties are governed by both mass and stiffness distributions, inaccuracies in the geometric representation of the structure may significantly affect the stiffness matrix and consequently the calibration process, potentially leading to non-unique or physically inconsistent solutions.

Recent advances in terrestrial laser scanning and digital photogrammetry have enabled the generation of highly detailed three-dimensional geometric surveys, allowing the accurate reconstruction of complex historical structures. These technologies provide dense point clouds capable of capturing geometric irregularities, deformations, and construction details that are often neglected in conventional survey techniques. Therefore, integrating high-fidelity geometric acquisition methods with finite element model updating procedures represents a promising strategy for improving the reliability of structural assessment methodologies for heritage masonry buildings.

Previous studies have investigated the dynamic behavior of the Sciri tower through Operational Modal Analysis and finite element model updating. However, the influence of high-fidelity geometric reconstruction obtained from terrestrial laser scanning and aerial photogrammetry on the calibration of the mechanical properties has not yet been thoroughly investigated. Considering that the accuracy of numerical model updating procedures strongly depends on the quality of the geometric representation, this study aims to develop a finite element model of the Sciri tower based on an integrated point-cloud survey and to calibrate its mechanical properties using experimentally identified modal parameters. The results are compared with those available in the literature to assess the influence of geometric fidelity on the estimation of masonry mechanical properties.

1.1 Sciri tower

The Sciri tower is a historic masonry structure located along Via dei Priori in the historic center of Perugia, Italy. The tower was constructed during the 13th century and reaches a height of approximately 41 m. It is surrounded on three sides by adjacent masonry buildings approximately 17 m high, while its front façade remains fully exposed. The tower belonged to the noble Oddi family until 1488, when ownership was transferred to the Sciri family following violent conflicts between rival noble clans that forced the Oddi family into exile. In 1680, the tower and the adjacent building were donated to the Third Franciscan Order, which remained the owner until 2011, when the entire complex was transferred to the Municipality of Perugia.

Regarding its construction materials, the masonry is homogeneous and regular, consisting of squared white limestone blocks (García-Macías and Ubertini 2020). The tower has an approximately rectangular cross-section measuring 7.15 × 7.35 m and can be ideally divided into two structural portions: a lower section and an upper section. The lower section, extending up to a height of 8.4 m, is characterized by masonry walls approximately 2.1 m thick, containing a limited number of small openings, and by a stone masonry vaulted slab located above the rooms of a former chapel (Vaiano et al. 2019). The upper section, extending to the full height of 41 m, consists of slender continuous masonry walls with thicknesses varying between 1.6 m and 1.4 m. Four brick masonry vaulted floors, each approximately 1.5 m wide, are located at different elevations throughout the tower. In addition, a brick masonry roof vault closes the structure at the top. Figure 1a

presents an aerial view of the tower and the surrounding building complex, while Figure 1b shows the ground-floor plan of the tower-house complex.

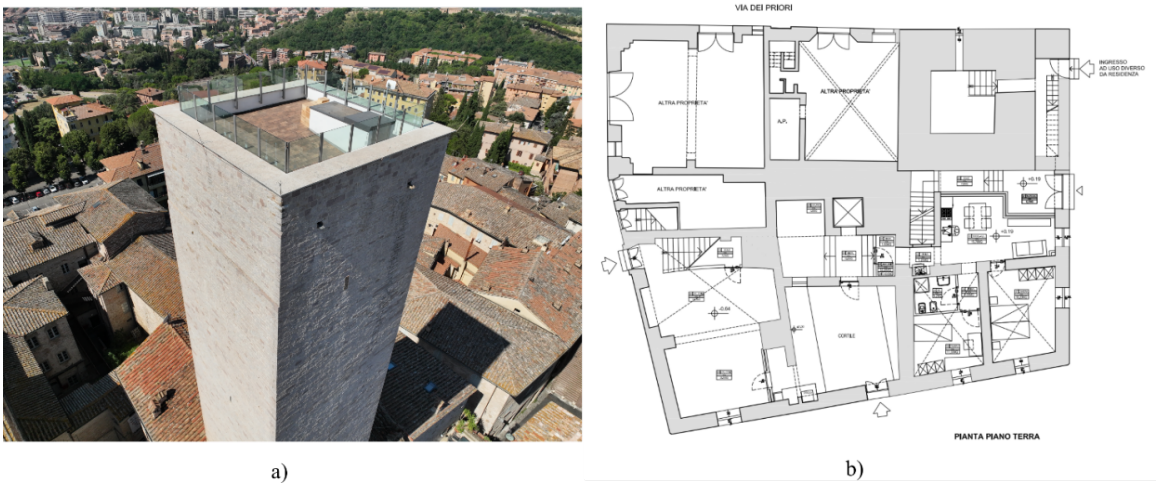

Figure 1 – Sciri tower: (a) aerial view; (b) ground-floor plan.

1.2 Operational Modal Analysis

The Sciri tower was previously investigated by researchers from the University of Perugia through an Ambient Vibration Test (AVT) conducted in May 2017. Details of the experimental campaign can be found in (García-Macías e Ubertini 2020; Venanzi et al. 2020). A total of twelve high-sensitivity uniaxial accelerometers (10 V/g), model PCB 393B12, were installed throughout the tower to measure ambient vibrations induced by environmental actions such as wind and traffic. The sensor layout is shown in Figure 2**Error! Reference source not found.**. The accelerometers, identified as A1 to A12, were installed at Levels 1, 3, 4, and 5 of the tower, while the data acquisition unit was positioned at Level 2. Following signal processing, seven vibration modes were identified within the frequency range between 0 and 11 Hz (Table 1). The identified modes consisted of two bending modes in the northwest direction (x-direction), denoted as Fx1 and Fx2, two bending modes in the southwest direction (y-direction), denoted as Fy1 and Fy2, one torsional mode (Tz1), and two higher-order bending modes (Fx3 and Fy3). The first four identified mode shapes are presented in Figure 3.

Table 1 – Natural frequencies and vibration modes. Adapted from Venanzi et al. (2020).

Vibration mode	1	2	3	4	5	6	7
Mode type	Fx1	Fy1	Fx2	Fy2	Tz1	Fx3	Fy3
Natural Frequency [Hz]	1.722	1.925	5.615	6.006	8.399	9.896	10.928

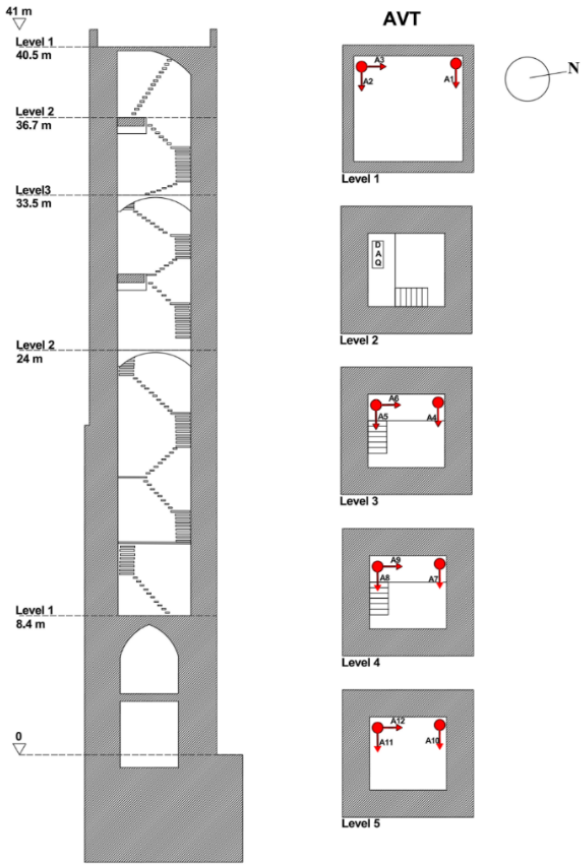

Figure 2 – Sensors layout for AVT Adapted from Venanzi et al. (2020).

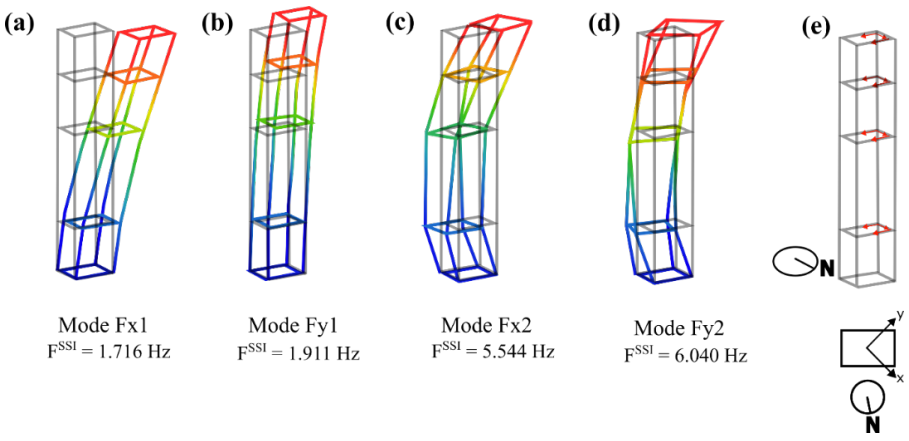

Figure 3 - First four experimentally identified mode shapes Adapted from Venanzi et al. (2020).

The modal parameters identified through the Operational Modal Analysis constitute the experimental benchmark adopted for the calibration of the finite element model developed in this study. To evaluate the structural behavior of the Sciri tower, a three-dimensional finite element model was developed in ABAQUS. The modeling procedure included point-cloud-based geometric reconstruction, geometry simplification,

material definition, loadings, boundary conditions and mesh convergence analysis. The methodology adopted for the generation and calibration of the numerical model is described in the following sections.

2. Metodology

2.1.1 Point cloud and 3D geometry

The geometric representation of the Sciri tower was obtained through an integrated survey combining terrestrial laser scanning and aerial photogrammetry. A Leica RTC360 laser scanner (Figure 4a) was employed to capture the inner parts and construction details of the structure at ground level in exterior areas. To ensure complete coverage of regions inaccessible from terrestrial viewpoints, the survey was complemented by an aerial photogrammetry campaign using a DJI Mavic 3 Enterprise drone (Figure 4b). The point clouds generated from both acquisition techniques were merged and registered in CloudCompare®, producing a unified high-density three-dimensional dataset. The combined point cloud was subsequently exported in .RCP format and imported into Revit® software, where the geometric model of the structure was reconstructed. The integration of terrestrial laser scanning and photogrammetry enabled the generation of a high-fidelity geometric representation, reducing uncertainties associated with geometric idealization and providing a reliable basis for numerical analyses.

Figure 4 - Point cloud data acquisition process: a) Terrestrial laser scanner RTC360; b) Drone DJI Mavic 3 Enterprise.

To improve computational efficiency while preserving the global structural response, secondary architectural features such as ornamental elements, roof components, and the roof slab were excluded from the numerical model and replaced by equivalent boundary conditions when appropriate. The resulting geometry was exported in .SAT format and imported into ABAQUS®, where it was discretized as a single homogeneous deformable solid. Additional geometric partitions were introduced to separate the tower from the adjacent buildings, allowing independent material calibration during the model updating procedure. Figure 4 summarizes the adopted workflow, from point cloud acquisition and processing to the generation of the finite element model used in the subsequent analyses. The Figure 5 summarizes the workflow adopted for the generation of the finite element model, from point cloud acquisition and processing to geometric reconstruction and finite element discretization.

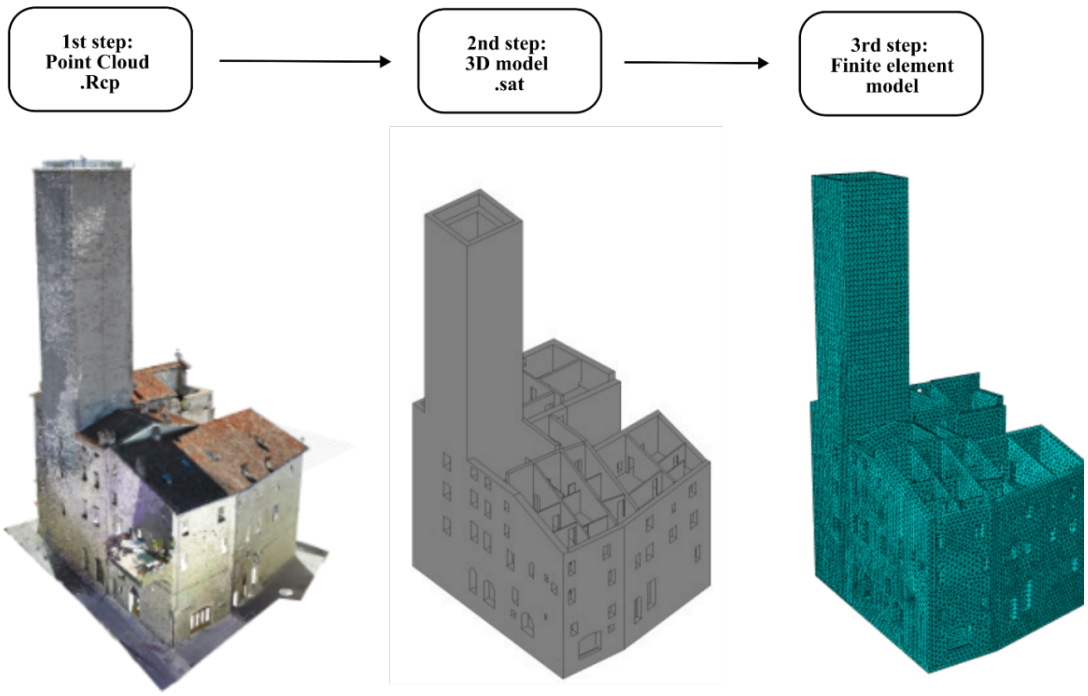

Figure 5 - Geometric modeling workflow of the Sciri tower: (a) acquired point cloud; (b) three-dimensional model developed in Revit®; (c) finite element model.

2.1.2 Material Properties

The initial mechanical properties adopted in the numerical model were selected according to the ranges recommended by the Italian Building Code (*Ministero delle Infrastrutture e dei Trasporti, 2009)*, as summarized in Table 2. Two masonry typologies were considered: squared stone masonry, representing the tower, and solid brick masonry with lime mortar, representing portions of the surrounding buildings.

The tower and the adjacent structures were assigned independent material definitions. Furthermore, the surrounding buildings were subdivided into two distinct regions, initially assigned identical mechanical properties but allowed to vary independently during the calibration process as described by Figure 6. This strategy was adopted to better capture possible differences in stiffness distribution and structural interaction between the tower and its surrounding environment.

The calibration procedure was performed manually through successive adjustments of the elastic modulus, material density and Poisson's ratio. The objective was to minimize the discrepancies between the numerical and experimental modal properties obtained from the Operational Modal Analysis, particularly the first four natural frequencies, which were adopted as calibration targets due to their relevance to the global dynamic behavior of the structure.

Table 2 – Inicial material mechanical parameters

Type of masonry	Fm (N/cm^2)	τ0 (N/cm^2)	E (N/mm^2)	G (N/mm^2)	W (KN/m^3)
Masonry of squared stone blocks	800	12	3200	940	22
Masonry of solid bricks with lime mortar	400	9.2	1800	600	18

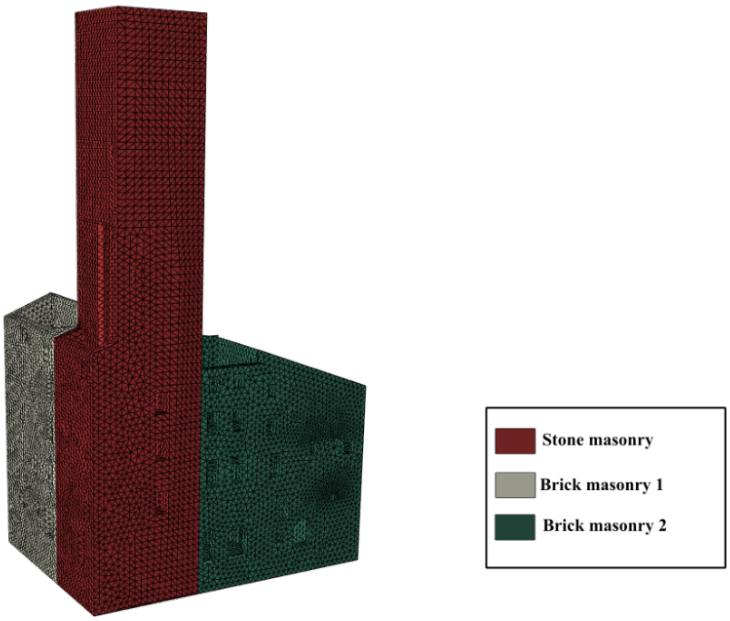

Figure 6 - Material configuration.

2.1.3 Loadings and boundary conditions

Regarding the loading conditions, the self-weight of the structure was automatically considered through the gravity load. Since the roof systems were not explicitly included in the numerical model, their contribution was represented through equivalent external loads applied to the corresponding supporting walls. Based on the estimated weight of the omitted structural components, equivalent loads of 350 kN, 112 kN, and 330 kN were assigned to Roofs 1, 2, and 3, respectively, as represented in Figure 7. Concerning the boundary conditions, the base of the model was assumed to be fully fixed.

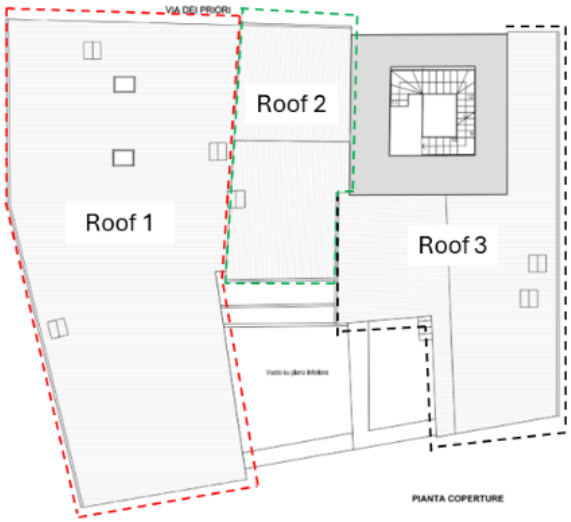

Figure 7 – Roof load distribution.

2.1.4 Mesh and element type

Before the material calibration, a mesh convergence study was conducted to evaluate the influence of mesh refinement on the estimated natural frequencies of the structure. The finite element model was discretized using second-order tetrahedral elements (C3D10), and four characteristic element sizes were investigated, which are 0.8 m, 0.6 m, 0.5 m, and 0.4 m. The corresponding results are presented in Table 3.

For the present model, mesh refinement resulted in a gradual increase in the estimated natural frequencies, indicating convergence of the numerical solution. The variation between successive mesh refinements progressively decreased, particularly for the first four natural frequencies, which were selected as the primary targets of the subsequent model updating procedure.

The final mesh size was selected by balancing computational efficiency and numerical accuracy. Based on the results obtained for the first four natural frequencies, the 0.5 m mesh provided a better result between solution accuracy and computational cost and was therefore adopted for all subsequent analyses. The resulting finite element model consisted of 495,523 nodes and 291,872 C3D10 tetrahedral elements.

Table 3 - Mesh Convergence Study

Mesh size	Natural frequencies [Hz]			
	1st	2nd	3rd	4th
0.8 m	1.209	1.286	4.193	4.339
0.5 m	1.211	1.289	4.202	4.349
0.4 m	1.215	1.291	4.211	4.359
0.3 m	1.224	1.299	4.243	4.392

Table 4 presents the results obtained from the initial numerical model prior to calibration, compared with the experimental modal properties identified through the Operational Modal Analysis. It can be observed that the first two natural frequencies presented errors exceeding 40%, indicating a significant discrepancy between the stiffness of the numerical model and the actual structural behavior of the tower.

Table 4 – Natural frequencies comparison before calibration

Vibration mode	1	2	3	4
Natural Frequency F^{SSI} [Hz]	1.722	1.925	5.615	6.006
Natural Frequency $F^{FEM}{}_0$ [Hz]	1.211	1.289	4.202	4.349
Error %	-42.20	-49.34	-33.63	-38.10

3. Results and discussion

As a result of the manual calibration procedure, after approximately 15 iterations, the material properties presented in Table 5 were obtained. It can be observed that the Young's modulus assigned to the stone masonry increased from 2400 MPa to 4200 MPa. For the surrounding brick masonry, the calibrated Young's modulus values increased from 1200 MPa to 3500 MPa and 4800 MPa for regions 1 and 2, respectively. In particular, the value obtained for Brick Masonry 2 exceeded that assigned to stone masonry. This result likely reflects the need to compensate for structural stiffness contributions that were not explicitly represented in the numerical model, such as local connections. Consequently, higher elastic modulus values were required to reproduce the experimentally identified dynamic behavior.

Table 5 – Material Properties after calibration

Material		Young's Modulus [MPa]	Poisson's Ratio	Mass density [kg/m³]
Before tuning	Stone masonry	2,400	0.25	2,200
	Brick masonry	1,200	0.25	1,800
After tuning	Stone masonry	4,200	0.25	2,000
	Brick masonry 1	3,500	0.2	2,000
	Brick masonry 2	4,800	0.2	2,000

Despite these adjustments, the calibrated parameters produced satisfactory agreement with the experimental modal data, as shown in Table 6. The first two natural frequencies presented relative errors of 4.56% and -1.27%, respectively, indicating that the adopted material properties can reproduce the fundamental dynamic behavior of the structure with good accuracy. The third and fourth vibration modes also presented relatively small frequency discrepancies, with errors of -2.42% and -5.76%, respectively.

Table 6 - Comparison between experimental and numerical modal parameters after calibration

Vibration mode	1	2	3	4
Natural Frequency F^{SSI} [Hz]	1.722	1.925	5.615	6.006
Natural Frequency F^{FEM} [Hz]	1.801	1.901	5.479	5.660
Error	4.56%	-1.27%	-2.42%	-5.76%

According to the modal analysis results, the first two vibration modes exhibited the same deformation patterns identified through the Operational Modal Analysis conducted by the University of Perugia, corresponding to bending in the x- and y-directions, respectively. For the third and fourth modes, however, although the natural frequencies remained close to the experimental values, differences were observed in the associated mode shapes. In the numerical model, the third mode corresponded to bending in the y-direction and the fourth mode to bending in the x-direction, whereas the opposite sequence was identified experimentally during the OMA campaign.

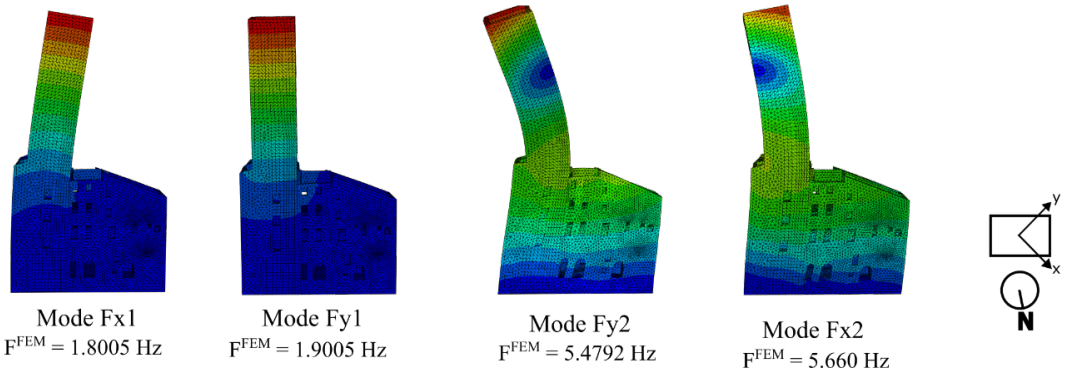

Figure 8 – Natural frequencies and modal shapes FEM model.

4. Conclusions

This study presented the development and calibration of a finite element model of the Sciri tower, a 13th-century masonry tower located in the historic center of Perugia, Italy. The proposed methodology combined a geometric model obtained through terrestrial laser scanning and aerial photogrammetry with an Operational Modal Analysis (OMA)-based model updating procedure. The geometric survey data was processed in Revit® and subsequently imported into ABAQUS®, where the numerical model was generated and discretized using second-order tetrahedral elements (C3D10).

The dynamic characterization of the structure was based on experimental modal parameters previously identified by the University of Perugia. These data served as reference values for the calibration of the elastic mechanical properties of the masonry. The updated model showed good agreement with the experimental results for the first two natural frequencies and their associated mode shapes, with relative errors of 4.56% and −1.27%, respectively. These results indicate that the proposed model was able to reproduce the global dynamic behavior of the tower with satisfactory accuracy. For the subsequent vibration modes, although the discrepancies in natural frequencies remained relatively small, differences were observed between the numerical and experimental mode shapes.

Despite these limitations, the study demonstrates the potential of integrating point-cloud-based geometric reconstruction with vibration-based identification techniques for the structural assessment of heritage masonry buildings. The methodology provides a robust framework for the calibration of numerical models and contributes to the development of more reliable tools for conservation, monitoring, and seismic vulnerability assessment of historic structures. Future developments should focus on creating more partitions and try more different materials in the analysis to better represent the global stiffness of the tower.

Furthermore, automated model updating strategies based on optimization algorithms or surrogate models could be employed to improve parameter identification.

5. Acknowledgments

The authors gratefully acknowledge the support from the Italian Ministry of University and Research (MUR) through the FIS-2021 Advanced Grant project “Smart Masonry enabling SAFEty-assessing STructures after earthquakes (SMS SAFEST)” (Project code FIS00001797).

The present work was carried out with the support of CNPq, National Council for Scientific and Technological Development – Brazil.

Resumo: Na presente investigação é apresentada uma metodologia digital integrada inovadora para o restauro de elementos do património construído, combinando reconstrução digital e fabrico aditivo. Num primeiro momento estabelece um fluxo de trabalho otimizado de reconstrução digital, incorporando digitalização 3D através de fotogrametria, modelação e reconstrução computacional de elementos ornamentais danificados. Foram produzidas próteses através de impressão 3D em polímero (PLA) – para prototipagem rápida e validação geométrica – e impressão 3D com pastas à base de cal otimizadas (NHL) – para uma compatibilidade melhorada com os substratos históricos. A fidelidade dos elementos reproduzidos utilizando PLA e formulações de pasta NHL foram avaliadas através de um método de comparativo dos modelos digitais das peças impressas. Foram ainda incorporados sensores de temperatura, humidade relativa e CO_2 para monitorização de condições ambientais locais. Os processos de reconstrução digital, materiais de impressão, tecnologias de fabrico e métodos de monitorização propostos foram validados num estudo de caso localizado num monumento com classificação de Património Mundial da UNESCO, demonstrando um fluxo de trabalho inovador para a conservação de edifícios patrimoniais.

Palavras-chave: Património construído; Reconstrução digital; Fabrico aditivo; Monitorização

1. Introdução

Os edifícios patrimoniais requerem frequentemente ações extensivas de conservação e reabilitação devido a uma ampla variedade de patologias, que podem resultar da passagem do tempo, de danos induzidos pela ação humana, de condições ambientais a que estão sujeitos, ou, ainda, de efeitos meteorológicos extremos. Os métodos tradicionais de conservação e reabilitação são morosos e dependem fortemente de trabalho manual altamente especializado; contudo, o setor enfrenta atualmente sérias dificuldades na contratação de mão de obra qualificada, o que provoca atrasos nos projetos e aumenta os custos.

Nos últimos anos, as tecnologias digitais têm vindo a ser introduzidas na conservação de edifícios patrimoniais, sobretudo para o levantamento e a documentação digital de estruturas e elementos construtivos com relevância histórica e cultural. Entre as tecnologias digitais, a fotogrametria tem-se destacado como uma ferramenta altamente eficaz e economicamente eficiente para documentar com precisão espaços e objetos tridimensionais (De Fino et al., 2023; Sugiyama et al., 2025). Esta permite recolher informação geométrica e textural, possibilitando a criação de modelos digitais de alta resolução para análise detalhada e avaliação do estado de conservação. Deste modo, permite uma análise geométrica eficaz e o planeamento de ações de conservação a longo prazo. Além disso, através dos modelos digitais obtidos com

esta tecnologia, é possível aplicar processos de reconstrução virtual de elementos danificados ou perdidos (Bourgeois, Ascensão, et al., 2024; Bourgeois et al., 2025); baseando-se quer em elementos de referência bem preservados com características semelhantes, quer recorrendo a evidências historicamente documentadas. Em paralelo, desenvolvimentos recentes das tecnologias de fabrico aditivo (ou impressão 3D) têm vindo a demonstrar as possibilidades de aplicação para a recuperação de elementos patrimoniais, ao permitirem a produção de réplicas físicas precisas de artefactos e ornamentos arquitetónicos. Até ao momento, a impressão 3D tem sido utilizada sobretudo para enriquecer experiências educativas e interpretativas destinadas a visitantes e educadores em contextos de património cultural (Arapakopoulos et al., 2022; Balletti et al., 2018; Balletti & Ballarin, 2019). Ainda assim, a sinergia entre a documentação digital precisa e o fabrico digital oferece novas perspetivas para a reabilitação patrimonial, particularmente na criação de próteses para elementos ornamentais danificados de elevado valor artístico e cultural, nos quais a autenticidade e compatibilidade são princípios de base (Bourgeois, Ascensão, et al., 2024). Neste sentido, a técnica de fotogrametria tem um papel fundamental, ao fornecer a estrutura de aquisição digital necessária para a documentação de geometria e de texturas de alta resolução – permitindo a obtenção de *digital twins* que podem ser eficazmente utilizados para orientar processos precisos de impressão 3D e o fabrico de próteses de alta resolução. Avanços adicionais podem incluir sensores embutidos nas próteses arquitetónicas – nomeadamente sensores de temperatura, humidade e CO_2 – os quais tem demonstrado ser uma mais-valia, ao permitir a monitorização em tempo real de condições ambientais e as suas consequências (Bansal et al., 2022; Blanco et al., 2018; Bourgeois, Pereira, et al., 2024; Parida et al., 2024; Pereira et al., 2024).

Através do caso de estudo aplicado no Mosteiro da Batalha, classificado como Património Mundial da UNESCO, foram examinadas preliminarmente a execução prática e os desafios associados à implementação de um fluxo de trabalho integrado de reconstrução digital e fabrico aditivo, sendo os resultados aqui discutidos. O fluxo de trabalho e as potenciais linhas de investigação a explorar em futuros desenvolvimentos deste trabalho são ilustrados na Figura 1. Os avanços futuros poderão incluir a integração em ambiente BIM, a adoção de automação e de fabrico orientado por inteligência artificial, bem como o desenvolvimento de materiais inovadores imprimíveis em 3D e de tecnologias de fabrico, todos com o objetivo de agilizar a tomada de decisão, otimizar os processos de fabrico e melhorar a qualidade e a relação custo-eficácia das próteses arquitetónicas funcionalizadas, contribuindo para melhores práticas de conservação e reabilitação.

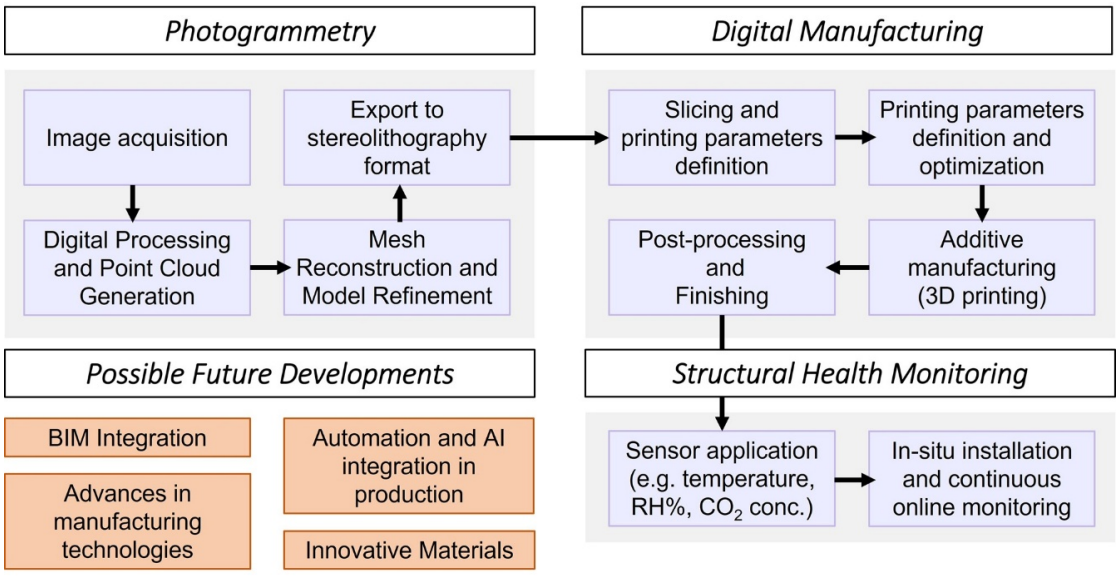

Figura 1 – Fluxo de trabalho

2. Caso de Estudo

O Mosteiro da Batalha (ver Figura 2) é um dos exemplos mais notáveis da arquitetura gótica em Portugal, estando classificado como Património Mundial da UNESCO desde 1983. A sua construção foi requisitada pelo rei D. João I, após a vitória portuguesa na Batalha de Aljubarrota, que garantiu a independência do país.

Ao longo dos séculos, o mosteiro resistiu a dois grandes sismos, em 1755 e 1962, e às invasões francesas, entre 1807 e 1810, acontecimentos que aumentaram drasticamente as necessidades de conservação do mosteiro e aceleraram a degradação natural de muitos dos seus elementos estruturais e ornamentais. Há registos de trabalhos de conservação desde o século XIX; contudo, o complexo monástico é vasto e rico em elementos de elevado valor estético e cultural que ainda necessitam de restauro, bem como em muitos elementos decorativos em falta que faziam parte da ornamentação original.

Em trabalhos anteriores, os autores reportaram levantamentos detalhados que identificaram vários elementos ornamentais como potenciais candidatos à aplicação experimental da metodologia de restauro digital aqui proposta (Bourgeois, Ascensão, et al., 2024; Bourgeois et al., 2025; Sugiyama et al., 2025). Neste trabalho, foram selecionados como caso de estudo os pináculos – elementos muito presentes nas zonas de cobertura – uma vez que se identificou danos locais em diversos elementos que necessitam de intervenção. A Figura 2 apresenta um exemplo do elemento num bom estado de conservação, destacando um elemento que constitui o pináculo e que foi selecionado para reprodução.

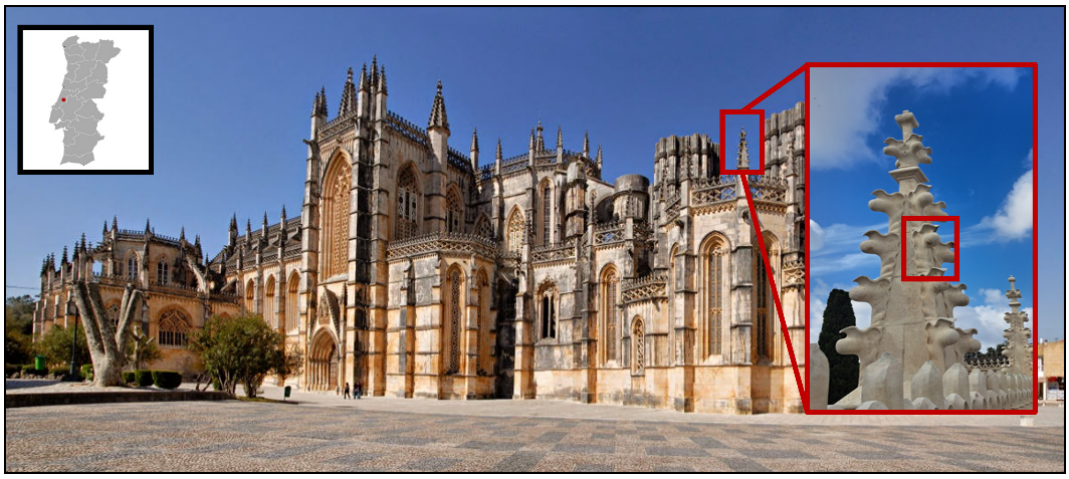

Figura 2 – Fachada principal do Mosteiro de Batalha. A imagem inserida no canto superior esquerdo mostra a localização geográfica do Mosteiro de Batalha em Portugal e, à direita, uma imagem em grande plano de um pináculo e do elemento ornamental a reproduzir.

3. Materiais e Métodos

Foram utilizadas técnicas de fotogrametria, modelação paramétrica e reconstrução computacional para criar modelos digitais do elemento ornamental a reproduzir. Para o levantamento de imagem, foi utilizada uma câmara digital Sony A6100 para captar fotografias de ambos elementos deteriorados e elementos bem conservados. O software Agisoft Metashape foi utilizado para realizar o processo de fotogrametria e obter nuvens de pontos dos mesmos. Com a informação digital destes elementos, foi realizada a modelação computacional recorrendo ao software Blender. Durante o processo de modelação, foram aplicados processos para garantir a compatibilidade entre os modelos e os respetivos suportes do elemento danificado. Uma vez assegurada a compatibilidade adequada, os modelos finais foram convertidos para o

formato de estereolitografia (.stl), para processamento em software de fatiamento e geração de ficheiros G-code para impressão.

Para a prototipagem rápida e o refinamento dos modelos, foram produzidas próteses poliméricas utilizando filamento de ácido polilático (Polylite PLA Pro, Polymaker). Neste caso, o software Bambu Studio foi utilizado como plataforma de fatiamento, e a impressora Bambu Lab X1E foi utilizada para a impressão. A impressão foi realizada a velocidades entre 50 e 150 mm/s para a camada inicial e para a parede interior, respetivamente. Foi definida uma altura de camada de 0,12 mm para melhorar a precisão e a resolução. Foi utilizado um padrão de enchimento com 10% de densidade, bem como suportes do tipo árvore para sustentar cavidades internas (3,0 cm x 5,0 cm x 2,5 cm) concebidas durante a fase de modelação para a colocação de sensores (ver

Figura **3** e Figura 4). Após a impressão, os suportes temporários foram facilmente removidos manualmente, sem provocar quaisquer defeitos nas próteses impressas. Não foi necessário qualquer pós-processamento adicional.

Foi desenvolvido, validado e embutido um sensor Arduino SCD40 nas próteses para monitorizar as condições ambientais, incluindo temperatura, humidade relativa e níveis de CO_2. A funcionalização das próteses impressas em 3D visa estabelecer correlações entre as condições ambientais e a progressão de determinadas patologias construtivas, perspetivando o desenvolvimento futuro de um sistema de sensorização simples, não intrusivo e contínuo, suportado por próteses inteligentes de elevada fidelidade. Antes da colocação do sensor, foram perfurados pequenos orifícios nas próteses para permitir a circulação de ar e possibilitar a medição precisa dos dados ambientais (ver Figura 5).

Para uma maior compatibilidade estética com os substratos históricos, foram desenvolvidas pastas de cal hidráulica natural (NHL) para *robocasting*. O fatiamento para *robocasting* foi realizado utilizando o software Simplify3D. Foi utilizada uma impressora 3D Delta Wasp 40100 equipada com um extrusor WASP 3.0 e um bocal circular com 2 mm de diâmetro, operando a 1250 mm/min e com uma altura de camada de 1,8 mm. Neste caso, foi utilizado um padrão de enchimento retilíneo, embora com uma densidade de enchimento superior, de 50%, em comparação com as impressões em PLA.

As pastas de NHL utilizadas para impressão foram previamente desenvolvidas pelos autores, sendo compostas por cal hidráulica natural comercial NHL 3.5, de acordo com a norma EN 459–1 (Secil®, Pataias, Portugal), argila caulinítica (A130S, MotaCeramic Solutions®, Oiã, Portugal) e água destilada. Nanoclay (Myta, Zaragoza, Espanha), um agente modificador de viscosidade à base de celulose (Walocel, DOW, Estarreja, Portugal) e um superplastificante de elevado desempenho (Master Ease 3530, BASF Portugal, Porto, Portugal) foram utilizados como aditivos modificadores da reologia, de modo a tornar as pastas compatíveis com os requisitos reológicos das tecnologias de impressão 3D. Uma descrição detalhada das formulações das pastas, das proporções de mistura, dos aditivos utilizados e do método de preparação é apresentada noutro trabalho (Bourgeois, Ascensão, et al., 2024; Bourgeois et al., 2025).

Todas as próteses foram impressas em condições ambiente (20 °C ± 5 °C e HR 65% ± 5%). Após a impressão, as próteses em PLA foram armazenadas em condições ambiente, enquanto as próteses à base de NHL foram curadas em ambiente controlado (20 °C ± 5 °C e HR 95% ± 5%) durante 7 dias, de modo a minimizar a retração, sendo posteriormente também armazenadas em condições ambiente.

4. Resultados e Discussão

A metodologia aplicada permitiu demonstrar a viabilidade da reconstrução digital de elementos ornamentais danificados com base na tecnologia da fotogrametria. A aplicação desta técnica possibilitou a

obtenção de uma representação tridimensional suficientemente detalhada dos elementos existentes, evidenciando que a qualidade do modelo final depende fortemente da resolução, quantidade e consistência das imagens recolhidas, bem como do desempenho do software utilizado no processamento fotogramétrico. A aquisição de um conjunto alargado de imagens de alta resolução, com elevado grau de sobreposição, revelou-se essencial para gerar uma nuvem de pontos robusta e um modelo preliminar coerente do pináculo (Bourgeois, Ascensão, et al., 2024). A justaposição da nuvem de pontos do elemento danificado com o modelo reconstruído permitiu avaliar e ajustar a compatibilidade geométrica entre a prótese digital e a estrutura existente, assegurando um encaixe mais adequado no suporte original. Este processo evidenciou a relevância da integração entre levantamento digital e modelação computacional para minimizar discrepâncias geométricas antes da fase de fabrico. Além disso, a incorporação de uma cavidade interna para alojamento do possibilitou compatibilizar os requisitos estéticos da reconstrução ornamental com funcionalidades adicionais de monitorização. A

Figura **3** apresenta uma vista lateral do modelo 3D otimizado, bem como a cavidade concebida para a colocação do sensor.

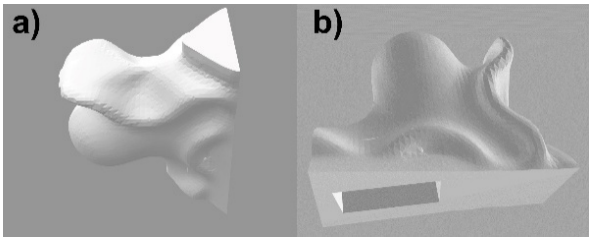

Figura 3 – Modelo do elemento ornamental: a) vista lateral e b) cavidade para a instalação do sensor.

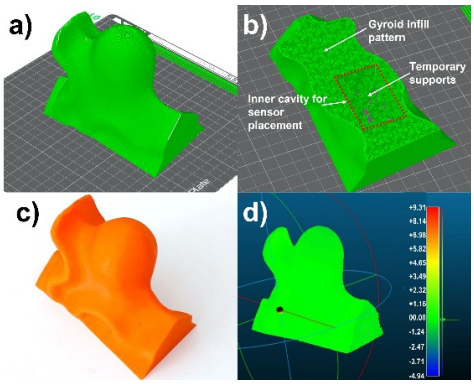
Para prototipagem rápida, foram inicialmente produzidas próteses em PLA. A Figura 4 a) ilustra o processo de fatiamento e o percurso de impressão, enquanto a Figura 4 b) mostra a cavidade interna e as estruturas de suporte temporárias utilizadas durante a impressão. Dada a natureza termoplástica do PLA, o processo de impressão revelou-se altamente fiável, decorrendo sem constrangimentos ou dificuldades técnicas. Não foi necessário qualquer pós-processamento além da remoção manual dos materiais de suporte. A Figura 4 c) mostra a prótese impressa final, enquanto a Figura 4 d) apresenta a sua fidelidade ao modelo digital gerado por fotogrametria. Como se pode observar, as próteses impressas foram capazes de replicar com precisão o modelo digital, com desvios inferiores a -0,2%. A distribuição gráfica da exatidão geométrica não revela áreas críticas, indicando uma distribuição homogénea de erros mínimos de impressão. Assim, as próteses em PLA demonstram um potencial significativo para aplicações em edifícios patrimoniais, nomeadamente ao permitirem a prototipagem rápida, o ajuste de modelos e a criação de réplicas manuseáveis de baixo custo para experiências culturais e educativas imersivas.



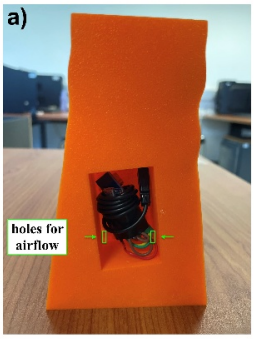


Figura 4 – a) Visualização do percurso de corte e impressão, b) pré-visualização do padrão interno e do preenchimento, c) prótese em PLA impressa, e d) análise da fidelidade do modelo e distribuição gráfica da precisão geométrica. Escala de cores — verde-azulado escuro: redução de volume > 2%; verde-claro: desvio de volume < 2%, e laranja-avermelhado: aumento de volume > 5%.

A Figura 5 a) mostra a integração do sensor nas próteses em PLA e destaca as localizações específicas das aberturas para circulação de ar. As leituras ambientais do sensor SCD40 foram recolhidas ao longo de um período de 12 dias, num ambiente laboratorial controlado, para validação do sistema. As medições de temperatura, humidade relativa e CO_2 foram realizadas em intervalos regulares de 1 hora, sendo os dados transmitidos para uma base de dados online. Os resultados de temperatura refletiram com precisão a temperatura média no interior da sala de ensaio, sendo também capazes de acompanhar as variações dia-noite (ver Figura 5 b). As medições de humidade relativa permaneceram estáveis ao longo do período de monitorização e em boa concordância com as condições ambientais (ver Figura 5 c). Por sua vez, as medições dos níveis de concentração de CO_2 mostraram-se capaz de captar picos de concentração coincidentes com períodos de maior ocupação da sala (Figura 5 d), nunca excedendo o limiar recomendado de 1000 ppm, prescrito pela maioria das normas europeias para espaços públicos interiores. Em conjunto, estes resultados preliminares demonstram que o sistema de sensorização desenvolvido, incorporado em próteses inteligentes, pode ser eficazmente utilizado para monitorizar dados ambientais em edifícios patrimoniais e, por conseguinte, poderá ser explorado para otimizar o planeamento da manutenção e a conservação a longo prazo.

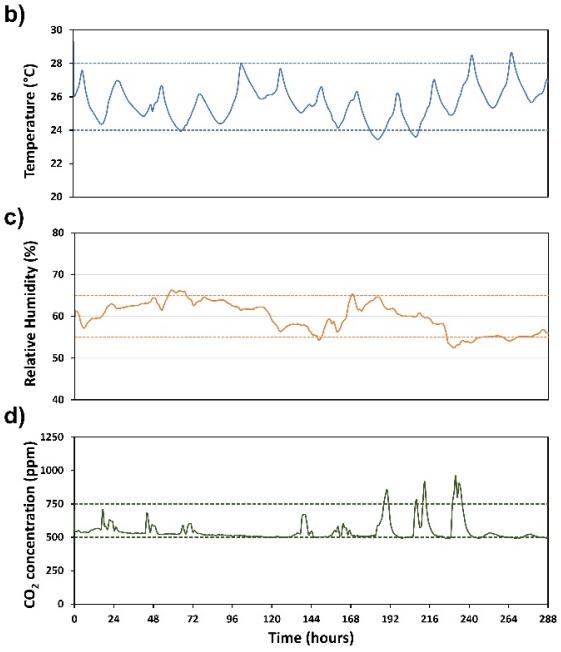

Figura 5 – Localização do sensor no interior da prótese de PLA a) e dados ambientais recolhidos: b) temperatura (°C), c) humidade relativa (%) e d) concentração de CO_2 (ppm).

A Figura 6 a) mostra o processo de fatiamento e o percurso de impressão das próteses em NHL. Embora tenha sido utilizado software diferente, a modelação digital nesta fase foi muito semelhante ao processo descrito para as próteses em PLA. As pastas de NHL foram previamente desenvolvidas e otimizadas para impressão em estudos anteriores (Bourgeois, Ascensão, et al., 2024; Bourgeois et al., 2025), não tendo ocorrido entupimentos nem bolhas de ar significativas que comprometessem o processo de impressão. Foi alcançada uma extrusão bastante consistente, sendo apenas necessários ajustes mínimos de pressão e de velocidade de impressão durante o processo. A Figura 6 b) apresenta uma amostra de uma prótese de pináculo produzida com pastas de NHL, evidenciando a consistência do produto impresso.

Figura 6 – a) Visualização do percurso de corte e impressão, b) prótese NHL impressa e c) análise da fidelidade do modelo e distribuição gráfica da precisão geométrica. Escala de cores: verde-azulado escuro:

redução de volume > 10%; amarelo-verde claro: desvio de volume < 10% e laranja-vermelho: aumento de volume > 10%.

À semelhança da metodologia seguida para as próteses em PLA, as próteses produzidas com pastas de NHL foram digitalizadas após a impressão e cura, e justapostas ao modelo digital para avaliar a sua exatidão e fidelidade. Os resultados mostram que, embora as próteses impressas em 3D com NHL tenham, de um modo geral, replicado a geometria original, apresentaram desvios significativamente superiores aos das suas congéneres em PLA, variando aproximadamente entre -5% e +25% (ver Figura 6 c). A análise volumétrica indica que tais desvios se caracterizaram predominantemente por aumentos de volume, e não por reduções, estando muito provavelmente associados à deformação plástica do filamento no estado fresco, mais do que à redução dimensional decorrente de fenómenos de retração durante a cura.

As próteses em PLA demonstraram uma fidelidade geométrica visivelmente superior relativamente aos modelos digitais, beneficiando de um comportamento térmico mais previsível durante a impressão e de uma deformação plástica e retração pós-impressão mínimas. Em resultado da sua maior capacidade para reproduzir características complexas dos elementos ornamentais, as próteses em PLA parecem vantajosas quando é exigida uma correspondência geométrica rigorosa. Contudo, embora as próteses poliméricas possam destacar-se na reprodução de detalhes morfológicos finos, a sua compatibilidade química e física com substratos históricos é limitada, levantando questões de compatibilidade mecânica e química com o suporte original, bem como à durabilidade a longo prazo. Neste contexto, as próteses em NHL, embora ainda apresentem desafios em termos de fidelidade dimensional – que poderão ser ultrapassados através do refinamento dos parâmetros de impressão, do ajuste das formulações dos materiais, da compensação por escala ou da exploração de estratégias de fabrico híbridas – demonstraram potencial para futura otimização e aplicação em projetos de conservação e reabilitação.

5. Conclusões

Este trabalho apresenta um fluxo de trabalho digital inovador para a reabilitação do património contruído, integrando reconstrução virtual e fabrico aditivo avançado. Através do caso de estudo de um elemento ornamental de um monumento classificado como Património Mundial da UNESCO, o Mosteiro da Batalha, foi demonstrado o valor da tecnologia de fotogrametria no levantamento digital detalhado que permite uma base sólida para a reconstrução digital de ornamentos patrimoniais danificados e perdidos, sendo posteriormente explorado para produzir próteses de reabilitação precisas.

As próteses de reabilitação foram produzidas utilizando materiais poliméricos, nomeadamente PLA, e materiais de base mineral, nomeadamente NHL, tendo a sua qualidade de impressão e fidelidade geométrica sido avaliadas. Os resultados mostram que as próteses em PLA oferecem maior controlo sobre o processo de fabrico e superior estabilidade dimensional, enquanto as próteses à base de NHL apresentam níveis mais baixos de fidelidade geométrica e precisão de impressão. Ainda assim, as próteses em NHL foram produzidas com uma precisão razoável, demonstrando um valor promissor para futura otimização e aplicação em projetos de reabilitação que priorizem a autenticidade cultural e a compatibilidade material.

Assim, verificou-se que a seleção do material depende das prioridades de conservação e dos requisitos específicos de utilização pós-impressão de cada projeto, devendo considerar fatores como a eficiência de impressão, o desempenho físico e a compatibilidade a longo prazo com a estrutura original. A integração bem-sucedida de sensores incorporados nas próteses impressas revelou-se também viável, evidenciando um potencial valor acrescentado para a monitorização em tempo real e in situ do estado de conservação estrutural. Com desenvolvimentos futuros deste trabalho, poderão ser concebidas soluções de

monitorização economicamente eficientes e não intrusivas, visando contribuir para o desenvolvimento de práticas de conservação preventiva baseadas em dados.

Agradecimentos

Esta investigação foi financiada pela Fundação para a Ciência e a Tecnologia (FCT), ao abrigo do financiamento UID/6438/2025 (https://doi.org/10.54499/UID/06438/2025) da unidade de investigação CERIS. Este trabalho foi também apoiado pela FCT no âmbito do projeto de investigação 2024.14274.PEX – 3D Printing for the Conservation and Recovery of Built Heritage Elements – PRINTHERITAGE (https://doi.org/10.54499/2024.14274.PEX).

Abstract: The Metro of Porto (MdP) service, in Porto, Portugal, is presently expanding its network. Part of that expansion, namely the new Pink Line, which will connect “Casa da Música” (Music Hall in Boavista zone) to the São Bento train station, is fully underground and at least half of its extension runs underneath important built historical heritage assets in Porto downtown.

Following a risk analysis of all buildings within the project's influence area, the MdP administration requested that the Faculty of Engineering of the University of Porto (FEUP) support the structural assessment and survey of a set of historical landmarks to identify potential issues and effects arising from underground excavation works. This includes iconic Porto monuments, namely the Clérigos Church-Museum-Tower, the São Bento train station, the adjacent Congregados Church and the Boavista Obelisk, where possible settlements, rotations, vibrations, and crack openings are continuously measured by installed sensors and data acquisition systems.

This paper describes the development and implementation of digital twins of monuments that have been subjected to continuous monitoring of structural response during the construction works. The monitoring system is briefly described, followed by a summary of the architecture of the computational framework responsible for data collection and transformation. The paper continues with the presentation of the BIM models of the historical buildings. The implementation of the digital twins in a web-based framework is then discussed, with a focus on the developed interface that enables the dynamic exchange and contextualized visualization of data between the monitoring system and the geometric layer of the digital twin.

Keywords: Digital Twins, Historical buildings. Structural monitoring, Underground excavation effects

1. Introduction

The integration of emerging technologies across various professional sectors has accelerated remarkably in recent decades, driven by significant advances in computing, automation, and data management. In the field of civil engineering, the incorporation of these innovations represents a strategic opportunity to enhance the efficiency, safety, and sustainability of built structures. However, this transition also poses a considerable challenge due to the traditionally conservative nature of the sector and the high degree of responsibility associated with structural integrity, where potential failures can have severe consequences.

In this context, Structural Health Monitoring (SHM) has established itself as a multidisciplinary technology, serving as a powerful tool to raise the standards of maintenance and intelligent infrastructure management. Supported by mathematical analysis techniques, SHM systems enable engineers to track structural conditions, detect anomalies, and assess safety based on long-term data acquired through a strategic sensor network (Farrar and Worden, 2007; Cunha, Caetano and Magalhães, 2007). These non-destructive and non-invasive methodologies allow for the collection of vast volumes of data concerning accelerations, velocities, displacements, rotations, settlements, as well as environmental variables such as temperature. However, as infrastructure complexity increases, the autonomous, accurate, and robust processing of these monitoring data has become a primary concern for the SHM technical community.

The rapid development of simulation, data acquisition, and communication technologies has fostered unprecedented interactions between the physical and virtual spaces. To bridge the gap between raw data collection and intuitive interpretation, the concept of the Digital Twin (DT) has emerged as a transformative solution. A DT is developed by combining real-time data with a virtual representation of the structure, functioning as a dynamic digital mirror that integrates physical and virtual data throughout the entire lifecycle of the asset. This synergy generates a massive volume of data that can be processed by advanced analytics, providing a cyber-physical system with precise insights into the operational state and real-world structural response.

Beyond the capabilities of traditional monitoring methods, a DT can combine real-time sensor data with historical datasets, enabling the analysis of trends, patterns, and correlations that might otherwise go undetected. Despite these benefits, implementing DTs in infrastructure monitoring faces challenges related to scalability and computational demands. The complex nature of civil structures frequently requires high processing capacity, which can limit the efficiency of real-time monitoring.

Typically developed within a Building Information Modeling (BIM) environment and linked to physical sensors, the Digital Twin (DT) architecture developed in this study facilitates real-time remote monitoring and lifecycle management. This approach is particularly vital in complex urban environments, where the preservation of architectural heritage must be balanced with the expansion of modern infrastructure. By ensuring automated synchronization and spatial contextualization of monitoring data, this paper presents a functional framework designed to enhance the decision-making process, contributing to the mitigation of potential damage and the preservation of structural integrity in critical projects, such as the Metro of Porto infrastructure works.

2. Brief state of art overview

2.1 SHM and Damage in Built Heritage

Safeguarding structures of high heritage value within consolidated urban environments constitutes a complex challenge in contemporary structural engineering, exacerbated by the need for underground transportation infrastructure. The preventive conservation of these assets is governed by the principles of minimum intervention and the preservation of material authenticity (Flah *et al.*, 2021). Consequently, SHM systems have established themselves as indispensable non-destructive methodologies for the continuous diagnosis and behavioral prognosis of structures (Bao and Li, 2021).

Throughout its lifecycle, historical built heritage accumulates damage resulting from material degradation/fatigue phenomena, cyclic actions, and successive rehabilitation interventions that introduce mechanical heterogeneity and modify the original load paths (Cimino *et al.*, 2022; Clementi *et al.*, 2021). In terms of structural mechanics, damage manifests as alterations in the geometric or constitutive properties of the system that adversely affect structural stiffness and/or load-bearing capacity. SHM systems operate by detecting these anomalies through continuous comparative analysis between the baseline state and subsequent states, aiming at mitigating catastrophic risks and optimizing lifecycle costs through condition-based predictive maintenance strategies (Farrar and Worden, 2007; Magalhães, Cunha and Caetano, 2012).

2.2 Data Streams, IoT, and Sampling Rates

The effectiveness of a SHM system critically depends on the data acquisition architecture and the topology of the sensor network within the Internet of Things (IoT) ecosystem. Contemporary smart sensors integrate analog transducers, local microprocessors for preliminary signal processing, and wireless communication modules (Pinto, 2023). From an analytical perspective, the collected data support four levels of diagnostic maturity: descriptive (statistical characterization), exploratory (identification of correlations and outlier filtering), predictive (stochastic trend modeling), and prescriptive (direct decision-making support in risk management).

A fundamental design parameter in monitoring engineering is the sampling rate. Excessively high sampling rates introduce high-frequency noise and overburden storage layers, whereas undersampled frequencies may prevent the detection of critical kinematic features (da Silva, 2022).

To manage the high volume of generated data, the architecture can implement gateways as edge computing nodes. These devices act in the local aggregation and pre-processing of the signal, performing a preliminary downsampling prior to remote transmission. This approach reduces system latency and optimizes network bandwidth.

2.3 Digital Twin Paradigm and Semantic Modeling Challenges

The concept of the Digital Twin (DT) represents the evolution of static information models into dynamic, synchronous representations characterized by a continuous, bidirectional flow of information between the physical asset and its virtual counterpart (Grieves and Vickers, 2016). In civil engineering, and particularly within historical heritage, creating a DT faces severe constraints due to morphological asymmetry, geometric irregularities, and the lack of standardization among ancient constructive elements.

Different taxonomies have been proposed to classify virtual representations of infrastructure. In particular, models have been classified as Digital Shadows rather than Digital Twins when they simply transfer data from the physical asset to its digital representation via a one-way, automated data flow. This taxonomy has been widely accepted by industry and academia, but the current standard, EN 18162, for DTs applied to the built environment does not explicitly include these categories as steps towards a fully compliant DT.

Although Heritage BIM (HBIM) methodologies, supported by photogrammetric surveys and Laser Scanning, offer high geometric fidelity through point clouds, scientific practice validates the adoption of simplified modeling strategies when developing DTs oriented towards risk management. By removing or neglecting non-critical building components (such as roof structures), processing efficiency and graphical rendering of the three-dimensional model are optimized. This controlled geometric simplification preserves the rigor of the structural domain while ensuring the responsiveness required for real-time simulation and visualization of physical interactions.

2.4 Time Series Management and Dedicated Storage Architecture

The continuous nature of SHM systems dictates the generation of massive data streams structured chronologically, where each record is strictly linked to a timestamp. Conventional relational databases

demonstrate computational inefficiency and horizontal scalability issues when subjected to this type of load. For this reason, advanced SHM systems utilize time series databases.

InfluxDB (InfluxData, 2026a) stands out in this category as a storage engine optimized for write-intensive operations and concurrent analytical reads. Structuring data into *measurements* (physical variables), *fields*, and *tags* provides high efficiency for historical data querying and compression. Through the Flux analytical query language (InfluxData, 2026b), the system executes automated aggregation routines and retention policies directly within the data layer. This technical infrastructure enables the dynamic feeding of interactive dashboards seamlessly integrated into the three-dimensional environment of the DT. Consequently, the end user benefits from a unified platform where time series are spatially contextualized within the geometry of the monument, allowing short-term deformation peaks to be correlated with the physical progress of adjacent infrastructure works.

3. Case study: Porto Historical Buildings and the Metro of Porto expansion works

3.1 Framework

The application of the developed methodology is based on a SHM campaign of high-value heritage assets integrated within the direct zone of influence of the Porto Metro network expansion works. The project focuses on the construction of the Pink Line (Line G), an underground infrastructure approximately 3 km in length with double tracks, connecting the São Bento intermodal hub to the Boavista Roundabout. Given that the alignment is executed entirely in a tunnel and within a dense urban environment, the Faculty of Engineering of the University of Porto (FEUP) was requested to program, implement, and monitor a strategic plan for continuous observation to mitigate risks associated with ground stress relief and potential settlements induced by the advancing excavation fronts.

The core of this analysis focused on four highly vulnerable monuments: the São Bento Railway Station, the Church of Santo António dos Congregados, the Clérigos Church and Museum, and the Monument to the Peninsular War Heroes (also called Boavista Obelisk), three of which are identified and located in an aerial plan view shown in Fig. 1.

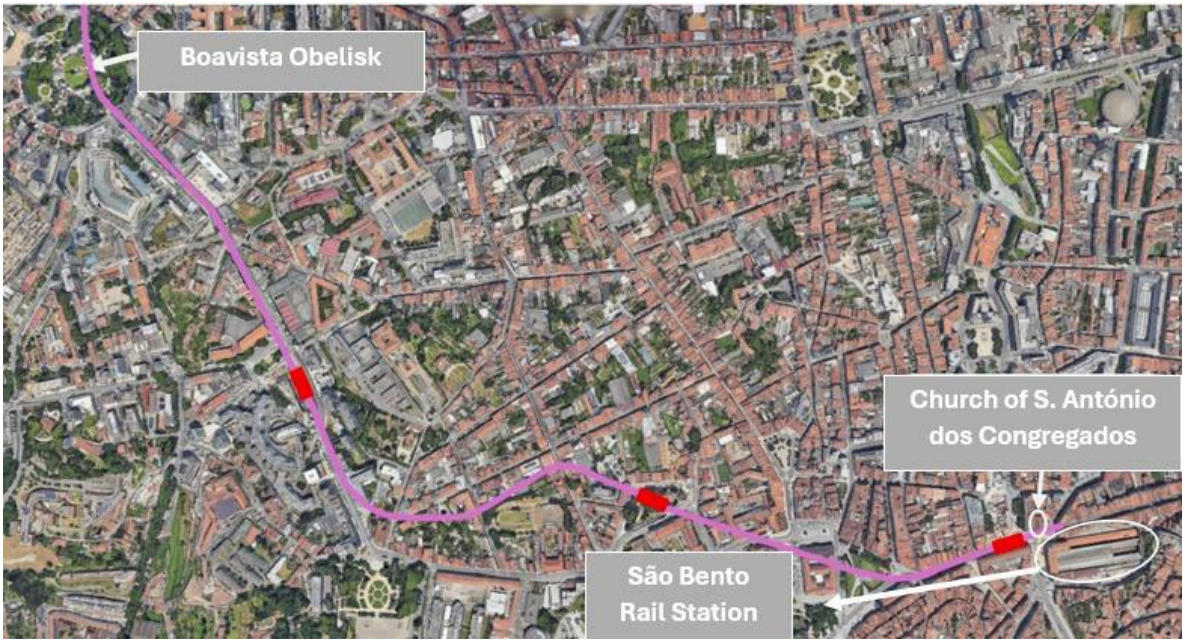

Figure 1 – Alignment of the new Pink Line (in the final construction stages), highlighting the three monuments considered in the case study: the Boavista Obelisk, the Church of Santo António dos Congregados and the São Bento Railway Station

3.2 Structural Characterization and Sensor Network Configuration

Each of the monuments highlighted in Fig. 1 was object of study, under which a monitoring sensor system was installed to characterize its structural behavior during the construction works in the surrounding area. The instrumentation was spatially distributed across critical zones and levels, utilizing five sensor typologies parameterized by standardized coding: crack meters (FS) for monitoring the opening and closing of cracks, clinometers (CL) for recording in-plane and out-of-plane wall rotations, temperature sensors (T) for monitoring temperature variations, level sensors (SN) for settlement control, and accelerometers (VB) for dynamic recording.

4. Prototype Architecture and System Development

4.1 System Architecture and Data Engineering

The developed prototype consists of a web-based Digital Twin (DT) platform designed for real-time Structural Health Monitoring (SHM) of heritage monuments within the influence zone of the Porto Metro expansion works. The system integrates three-dimensional geometric models, IoT sensor networks, and time-series databases into a unified, browser-accessible environment, aimed at providing a robust decision-support tool.

The solution adopts a decoupled client-server topology modularized via Docker containers, ensuring portability, operational stability, and the elimination of software dependency conflicts. Within the storage core, InfluxDB was selected for its native support of the Flux query language, executing filtering, aggregation, and downsampling processes directly within the data layer, thereby mitigating frontend latency when querying extensive historical datasets.

Communication is mediated by an Express.js (Node.js) proxy server. Data is hierarchically organized into isolated repositories (*buckets*) assigned to each monument. Inside each bucket, measurements are segmented by tagged fields (*tags* and *fields*), mapping each physical transducer to its respective engineering quantity (rotation, displacement, temperature, or acceleration). This modeling approach, based on JSON metadata, provides system scalability since accommodating new monuments or expanding the sensor network requires no source-code modifications or database migrations.

4.2 Automated Querying and Adaptive Processing

The automated query engine is based on an intelligent mapping logic structured across three functional dimensions:

- **Configuration Management:** The system automatically identifies the location of each sensor within the database, eliminating the need for rigid, hard-coded programming for newly deployed equipment.
- **Adaptive Processing:** Queries are dynamically adjusted based on the time frame selected by the user (e.g., minute-by-minute data for daily analyses or daily averages for monthly trends), optimizing both graphical clarity and computational effort.
- **Data Abstraction:** The strict separation between the interface logic and the database layer ensures system scalability, enabling the seamless integration of new monuments or sensors in the future without modifying the core codebase.

4.3 Semantic Interoperability via IFC Standard

The conversion of static geometric models into dynamic representations leverages the neutral IFC 4.3 format. Crucially, this updated standard provides significantly enhanced semantic definitions for sensor entities and dynamic property sets compared to legacy versions, natively streamlining the logical

connection between real-time IoT time-series streams and specific structural components of each monument (Jiang *et al.*, 2022). To link time-series data to the IFC geometry, a layer of interactive markers (*digital anchors*) was implemented with two relevant properties:

- **Selective Visibility:** A dedicated rendering technique based on 2D markers implemented with Three.js was developed to ensure that sensor references remain visible even when located behind opaque structural components such as walls, columns, slabs, and roofs. This capability enables the instantaneous localization of sensors installed in concealed zones or embedded deep within the structure.
- **Semantic Identification:** Each marker is bound to a unique ID that establishes a direct mapping to the corresponding tags and fields within the database (InfluxDB), encompassing spatial coordinate properties (X, Y, Z) and the respective physical metric being monitored.

4.4 User interface and result browsing

4.4.1 General layout and features

The primary value of this Digital Twin is to grant the user immediate access to monitoring data directly within the spatial context of the 3D model. The interface was engineered to bridge the abstraction gap typical of conventional technical reports. As shown in the platform's homepage (Figure 2), the user is greeted with an integrated visualization environment that structurally contextualizes each asset, establishing an intuitive gateway for real-time remote inspection.

Figure 2 – Homepage interface of the digital twin platform for historical structures

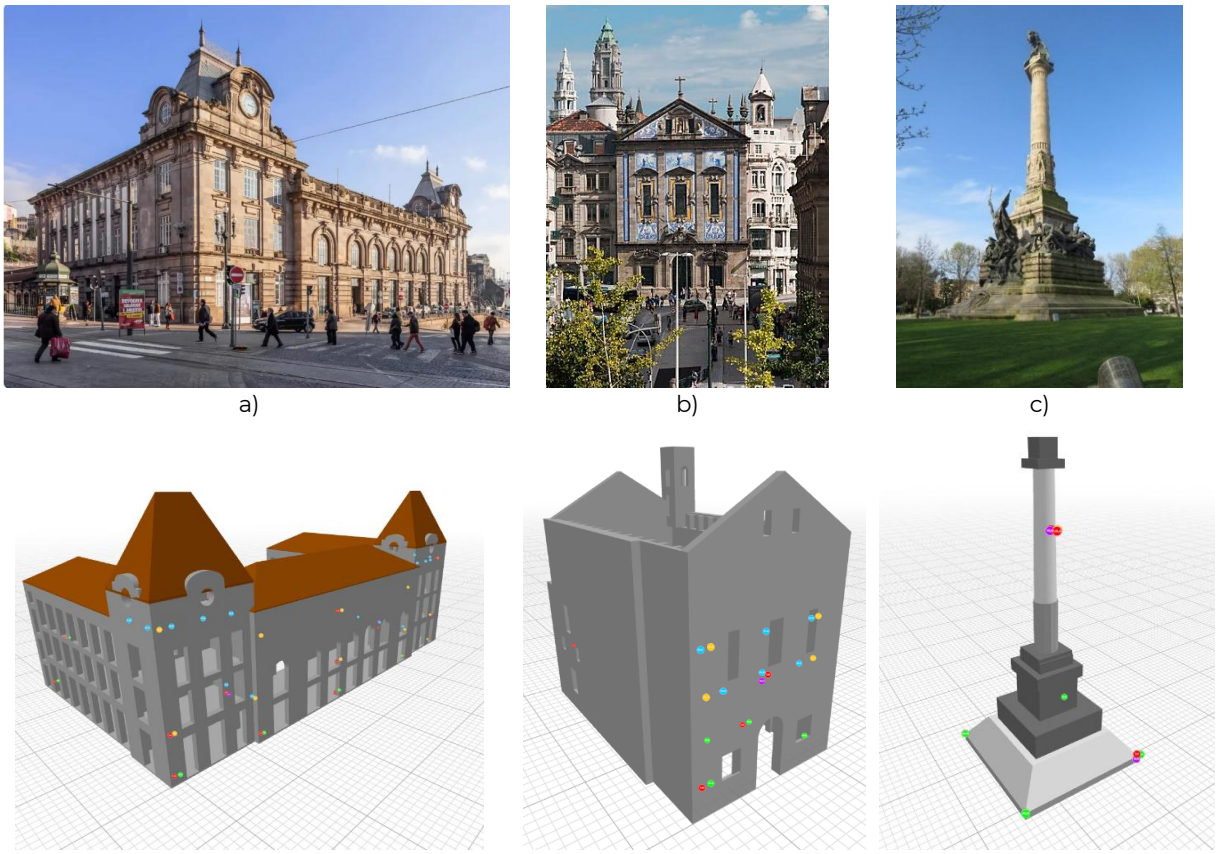

Figure 3 – Views of the three historical buildings and corresponding digital twin models: a) and d) São Bento Railway Station, b) and e) Church of Santo António dos Congregados, c) and f) Boavista Obelisk

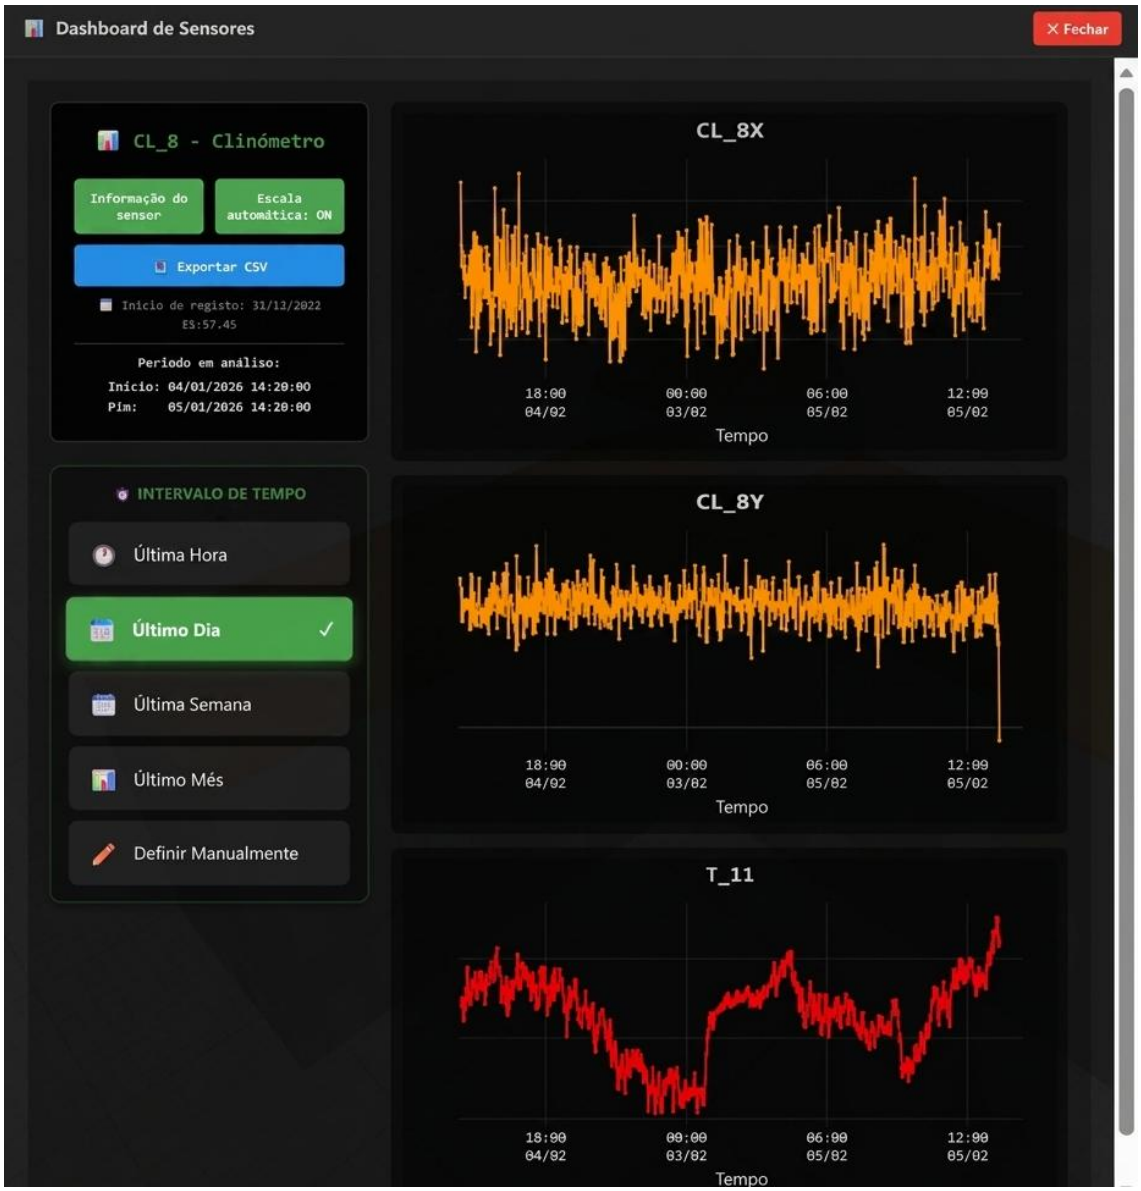
Upon clicking a 2D marker, the system recognizes the sensor ID, extracts its historical dataset from InfluxDB, and automatically identifies the geometrically closest temperature sensor via a proximity algorithm (Fig. 4). By concurrently rendering both mechanical and temperature parameters within a floating panel, the platform enables the user to analyze the influence of cyclic environmental effects from any baseline shifts potentially induced by the adjacent construction works.



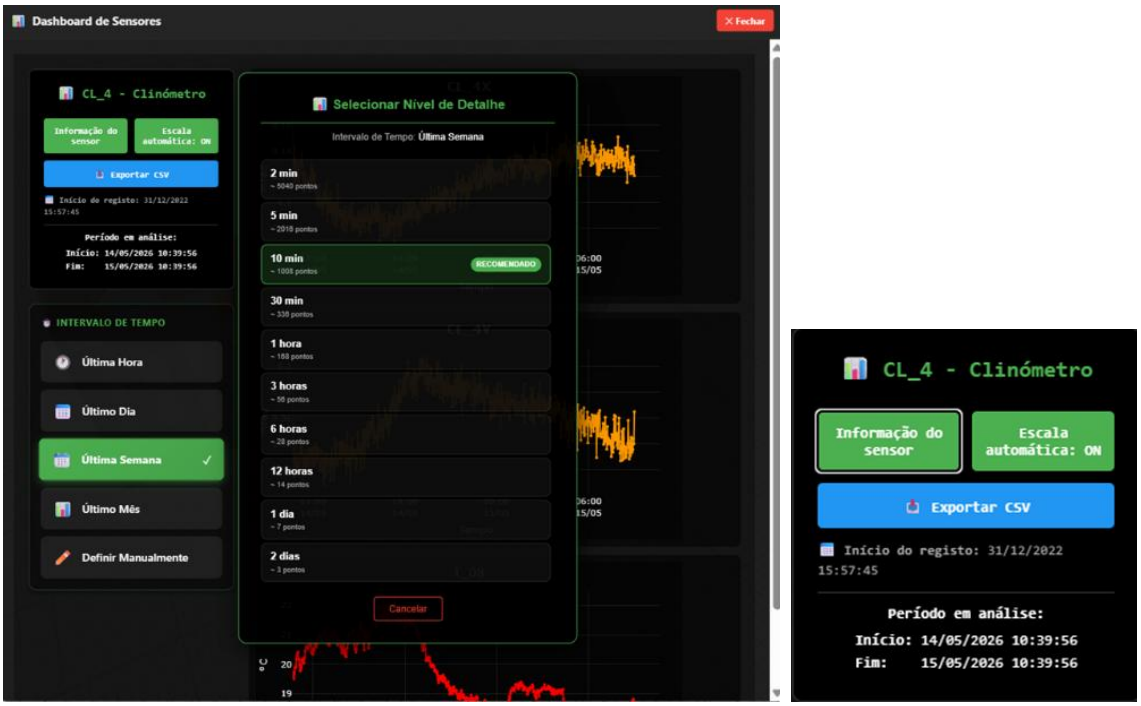


Figure 4 – Clinometer CL_8 with its respective associated temperature sensor, T_11

4.4.2 Temporal filtering and results' management

To streamline the analytical process, some filtering mechanisms were integrated:

- **Specific Period Selection:** Users can choose predefined intervals or specify dates on a dynamic calendar, allowing monitoring data to be analyzed during relevant construction phases or specific operational milestones of the project (Fig. 5a). In addition, the interface provides an estimate of the number of data points and the corresponding data volume associated with each aggregation period, enabling users to anticipate query complexity and facilitating more efficient data retrieval.
- **Data Export:** All queried data can be exported in .csv format, enabling users to extract clean datasets tailored to the selected analysis and aggregation window for further use in external specialized software (Fig. 5b).

a) b)

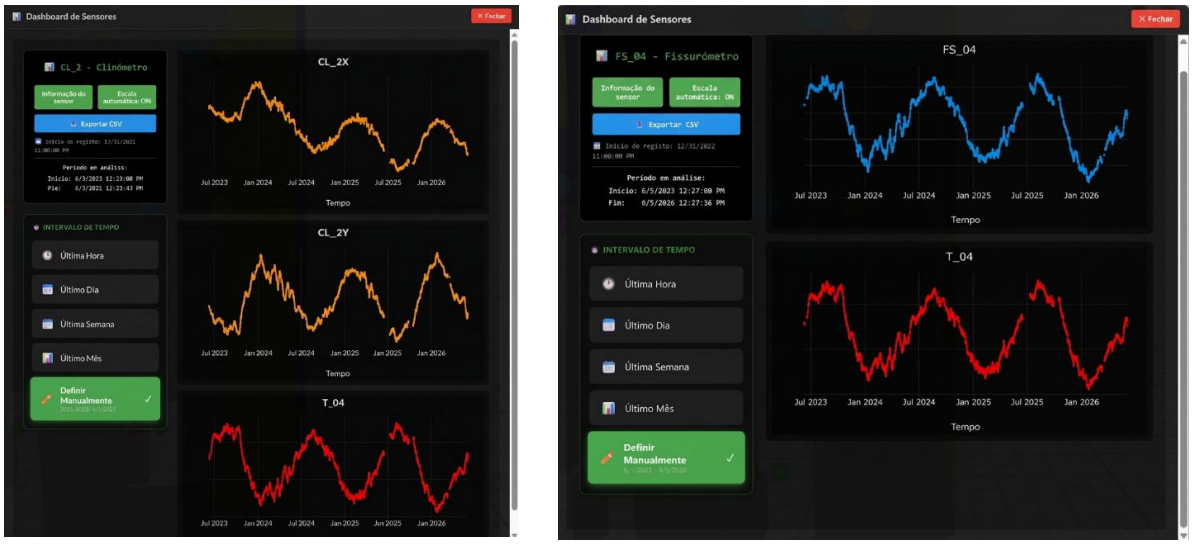

Figure 5 – a) Selection window for the data aggregation period; b) Export window for the .csv format file

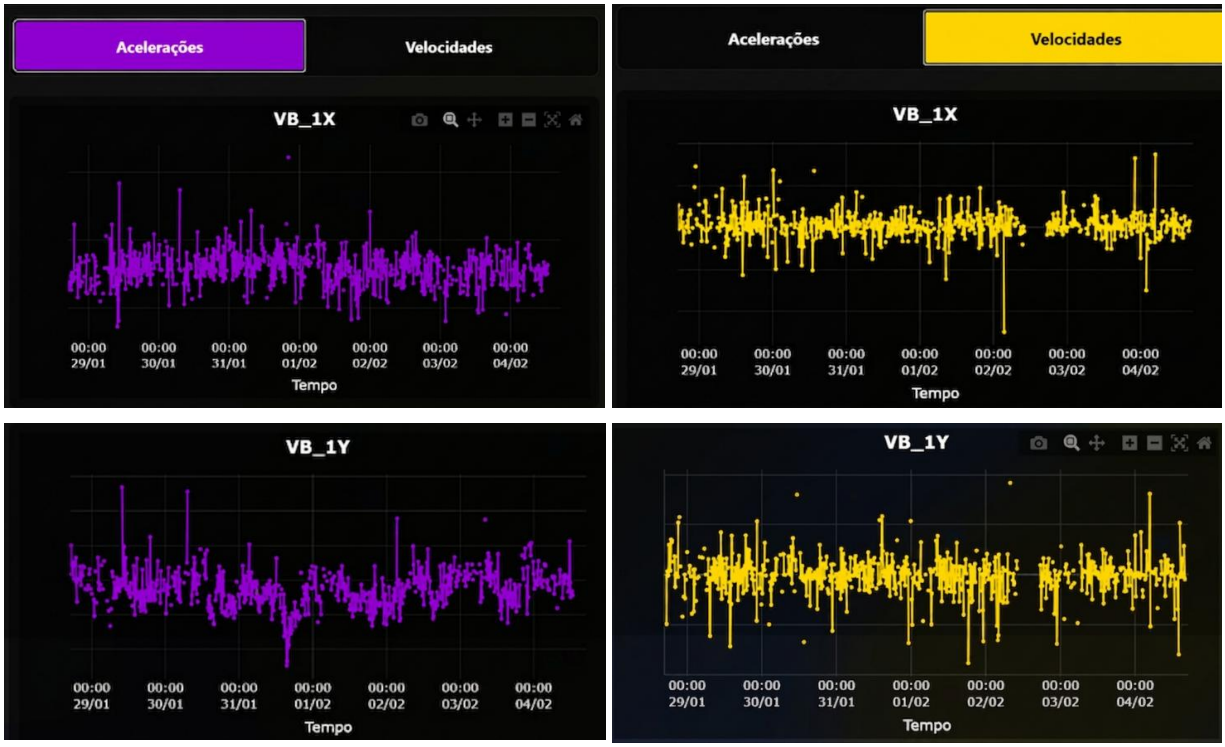
4.4.3 Exemplification of results

The primary objective of this section is to show practical results obtained from the multi-sensor network installed across the historical monuments, focusing on the datasets retrieved from one clinometer and one crackmeter shown in Fig. 6. To evaluate the long-term structural behavior and validate the data handling capacity of the platform, a comprehensive dataset spanning an extended period of approximately three years was selected for analysis.



As illustrated in the retrieved records, the structural variations and displacements closely follow the cyclical patterns of ambient temperature fluctuations. This high correlation between the physical deformations and thermal actions indicates that these structural responses are directly related to ambient temperature variations. Thus, the visualization of these continuous, long-term trends suggests that the structural integrity of the monitored assets has not been adversely affected by the adjacent underground excavation works. Furthermore, the seamless rendering of this massive three-year time-series underscores the efficiency of the developed Digital Twin framework in transforming raw, continuous sensor readings into clear, actionable structural health indicators.

Additionally, Figures 7 and 8 present the experimental records captured by one sensor of the accelerometer network. These datasets illustrate the acceleration and velocity profiles over time, serving as continuous indicators of the structural vibration levels and providing a general baseline to monitor the overall dynamic behavior of the monument during the construction works.

a) b)

Figure 6 – Long-term structural health monitoring data spanning a three-year monitoring period: (a) clinometer CL_2 results for X and Y components correlated with temperature sensor T_04; (b) crackmeter FS_04 displacement results correlated with temperature sensor T_04.

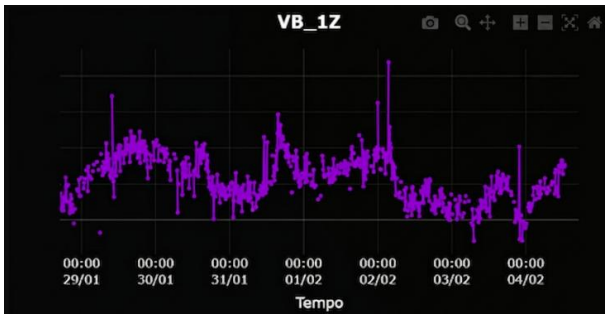


Figure 7 – Layout of the acceleration records (m/s^2), highlighted in purple, across the three components X, Y, and Z

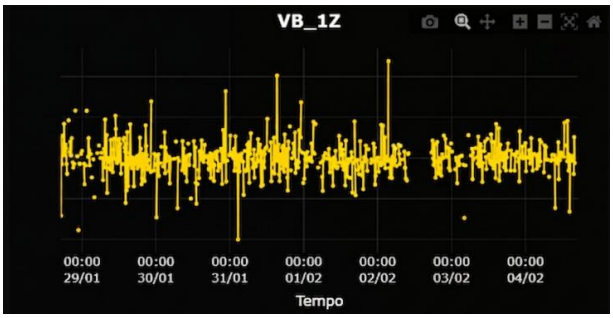

Figure 8 – Layout of the velocity records (mm/s), highlighted in yellow, across the three components X, Y, and Z

5. Conclusions

This paper sought to briefly describe the development process of a web-based Digital Twin (DT) platform as a useful and robust tool for real-time Structural Health Monitoring (SHM) of monuments prone to be affected by adjacent construction works or other type of anthropogenic or natural action sources. The transition from static geometric models to a dynamic digital ecosystem resolved critical data engineering challenges, namely the management of massive volumes of readings and the mitigation of latency.

The key developments of the prototype refer to the spatial contextualization of the information, overcoming the paradigm of analyzing readings in abstract graphs or isolated tables, since the automated query engine and the 3D interactive markers eliminate this barrier. Through selective visibility, the user instantaneously localizes sensors installed in concealed zones. Furthermore, the addition of the closest temperature sensor to the sensor under analysis allows the user to perceive the effects of thermal variations in the records, by distinguishing reversible cyclic deformations from eventual anomalous movements caused by other adjacent sources.

The development criteria granted the platform the necessary robustness to support decision-making and monument management. The structuring based on JSON metadata ensures that the inclusion of new sensors or structures can be achieved immediately and autonomously. Moreover, the current architecture provides a straightforward migration path towards relational database solutions, enabling the ecosystem to scale in terms of users, sensors, monitored structures, and data sources and schemas. The ecosystem thus establishes a robust, interoperable, and reproducible methodological framework, useful for the preservation and deformation control of built heritage under the influence of adjacent complex urban infrastructure interventions or other external action sources.

Future developments may further extend the capabilities of the platform beyond monitoring functions. In particular, control and automation mechanisms based on Shelly devices could be integrated into the Digital Twin environment, enabling the remote switching and management of routers and gateways according to their spatial location within the monitored infrastructure. In addition, the capabilities offered by available communication libraries open the possibility of remotely managing sensor configurations directly through the platform, paving the way for adaptive monitoring strategies. Such developments would allow the proposed framework to evolve from a monitoring-oriented system towards a more active and interactive cyber-physical ecosystem.

Unveiling hybrid two-way out-of-plane response of existing unreinforced masonry structures through extensive shake-table testing

Abstract: The 2030 Agenda for Sustainable Development has set the objectives to reduce the risk of disasters. In the context of Sustainable Cities (Goal 11), the promotion of planning and management of human settlements in disaster-prone areas is stressed. Nearly 50% of the global built heritage stock is represented by unreinforced masonry structures (URM), historically built in seismic-active regions. URMs are highly vulnerable to strong ground motions, particularly when they lack wall-to-wall and wall-to-diaphragm connections, which reduce the box-behaviour and increase the likelihood of out-of-plane (OOP) deformations.

Current code-oriented assessments for the OOP response of URMs due to strong ground motions are based on simplified kinematic or pushover analyses. On the one hand, assuming a rigid deformation up to collapse, these methods lead to reasonable estimates of the yielding and ultimate capacity of buildings and monumental structures. On the other hand, these methods do not incorporate the highly non-linear response associated with rocking and non-smooth contacts, as well as the influences of different seismic signals.

This contribution presents two shake-table campaigns addressing these gaps for the upcoming Second Generation of Eurocodes. Using dry-stack masonry to replicate the behaviour of existing URM structures, extensive dynamic testing was conducted on half- and full-scale specimens between the University of Minho (PT) and LNEC, Lisbon (PT). Experimental outcomes revealed complex OOP responses dependent on boundary conditions, as well as varying geometry and input signals. A hybrid two-way bending collapse mechanism was identified, providing the first evidence on a still limited literature topic. Experimental data were post-processed and made publicly available to support the calibration and validation of numerical models. The work was developed within the Stand4Heritage project that, in line with the 2030 Agenda Goals, aims at introducing new standards for safeguarding built cultural heritage.

Keywords: Unreinforced masonry, out-of-plane, shake-table test, dry-stack, hybrid two-way bending.

1. Background and motivation

On September 25, 2015, 193 United Nations Member States adopted the 2030 Agenda for Sustainable Development through the implementation of 17 Sustainable Development Goals (UN (2015)). Among all, Goal 11 promotes sustainable urban development and the resilience of human settlements to the threat of natural hazards. In this context, particular attention should be paid to unreinforced masonry structures (URMs), which account for more than 50% of the existing built heritage and are highly present in earthquake-prone areas. Despite extensive research in recent times, full comprehension of the URMs' capacity when subjected to ground motions (GMs) excitation is still limited due to uncertainties in material and boundary conditions (Parisi and Augenti (2012), Roca *et al.* (2010), Rota *et al.* (2014)). URMs are known to withstand horizontal actions if the so-called box-behaviour is available (Lourenço *et al.* (2010)). During a seismic event, two stiffnesses are activated: the in-plane (IP) and the out-of-plane (OOP). While the former is higher and usually associated with damage accumulation and crack openings (Inzunza Araya *et al.* (2024)), the latter is lower due to limited tensile and shear strength-to-mass ratio (Ferreira *et al.* (2015)) and poor wall-to-wall and wall-to-diaphragm connections.

The current version of the Eurocodes provides guidelines regarding the OOP response for newly designed and existing URMs. The former is based on global ductility (capacity-design approach) and prescriptive rules to prevent any OOP mechanism (European Committee for Standardization (2005, a)). The latter acknowledges that existing URMs may not meet the prescriptive rules (European Committee for Standardization (2005, b)) and suggests the estimation of design flexural strength and overburden values, while limiting vertical slenderness (height-to-thickness ratio). However, Griffith *et al.* (2007) provided evidence in their campaign that, if an adequate degree of connections is met, URM walls may sustain displacements above their flexural capacity. The upcoming Second Generation of the Eurocode has markedly improved the assessment of the OOP response, suggesting the use of an equivalent Single-Degree-of-Freedom (SDOF) system and pushover analyses (CEN/TC 250 (2004)). Nevertheless, dynamic effects have not been accounted for. In fact, due to rocking and non-smooth contacts in extremely narrow events, URMs might dissipate internal energy differently than what is assumed in rigid-body deformations (Lagomarsino (2015)). In addition, interactions between IP-OOP mechanisms may arise, forming hybrid two-way bending (Vaculik *et al.* (2014)), which was observed in a static campaign (Restrepo Vélez *et al.* (2014)).

To address these gaps, this paper details the design and presents preliminary outcomes from two extensive shake-table testing campaigns conducted between the University of Minho (PT) and LNEC, Lisbon (PT). The dynamic OOP response of URM assemblies was investigated by testing reduced-scale and full-scale specimens. Because mortar usually ages in existing URMs, the specimens were built using dry-stack configurations. All the specimens featured a U-shaped configuration, tested under varying geometries, input signals and wall-to-diaphragm connections. Several tests and repetitions demonstrated hybrid two-way bending, the non-linear behaviour of rocking structures, and the role of the wall-to-diaphragm connection in the OOP collapse mechanisms. Experimental data were collected into an open-access dataset (Vecchio *et al.* (2026)) for future validations of refined numerical models and probabilistic analyses targeting adequate Intensity Measures (IMs) and the construction of Fragility Curves (FCs). Both experimental campaigns were conducted within the Stand4Heritage project (STAND4HERITAGE (2020)) funded by the EU through the European Research Council (Advanced Grant No. 833123), with the ambitious goal of improving the next generation of code-based guidelines for the preservation of the existing built heritage.

2. Shake-table campaigns

This section describes the design, including material and specimens' geometry, instrumentation, choice of the input signals, and loading protocol of both experimental campaigns. While the reduced-scale specimens were tested at the University of Minho, a full-scale specimen was tested at LNEC.

2.1 Reduced-scale specimens

The reduced-scale campaign was conducted on the 1-Degree-of-Freedom (DoF) shake table of the University of Minho, having operational ranges: (i) ± 5 g in acceleration, (ii) ± 85 cm/s in velocity, (iii) ± 125 mm in displacement, (iv) 0-50 Hz in frequency, and (v) 3 tons as maximum payload. Two specimens were constructed using hard granite blocks typical of the *Iberian Peninsula* built heritage stock, with the following dimensions: (i) 300 mm x 150 mm x 150 mm and (ii) 150 mm x 150 mm x 150 mm (length, height, and width). The material characterisation, including density ρ, compressive strength f_c, elastic modulus E, normal k_n and tangential interface stiffness k_n, friction coefficient μ, and hysteretic damping ξ, were available prior to the start of the campaign (Colombo (2025)). The values are listed in **Table 1**.

Table 1 – Material and interface properties adopted in the experimental program

ρ	f_c	E	k_n	μ	k_s	ξ
(kg/m^3)	(MPa)	(GPa)	(MPa/mm)	(MPa/mm)	(-)	(%)
2580	139	73.9	10^1-10^4	10^1-10^2	0.48	2.0-5.5

The U-shaped configuration featured a central façade (orthogonal to the direction of the loading), and two sidewalls (in the direction of the loading). The geometry was based on constant height and length of the sidewalls, with an aspect ratio (façade span-to-height ratio) of 0.8 for Specimen A and 1.4 for Specimen B. The total weight of the specimens did not exceed the shake-table maximum payload, with total weights of 2.1 and 2.8 tons, respectively. The reduced-scale campaign focused on the insufficient wall-to-diaphragm connection. Therefore, the design boundary conditions included fixed base support, moment connection due to corner interlocking, and vertical restraint at the end of the sidewalls. The fixed base support was achieved by drilling and anchoring the first masonry course with M18 bolts to base steel plates, which were connected to the shake-table through M27 threaded bolts. Corner interlocking was provided with a typical toothing texture, overlapping half of the blocks' length in each masonry course. Finally, a system of extension springs was used to apply precompression at the end of the sidewalls, to avoid undesired deformation of the sidewalls, leaving the façade free to deform in the OOP direction and the sidewalls to detach.

Unlike conventional shake-table tests, the reduced-scale campaign took advantage of Digital Image Correlation (DIC) techniques. The six cameras installed along the perimeter of the shake table were initially paired and calibrated with speckle patterns glued on the visible blocks. This strategy allowed recording and spatial reconstruction of the specimens' deformation during the dynamic loading. The DIC software Istra4D (Dantec Dynamics (2022)) was used to estimate the coordinate and displacement time histories of any points detected on the visible surfaces. In addition to the DIC cameras, the shake-table accelerometer and Linear Variable Differential Transducer (LVDT) were used to monitor the input acceleration and displacement time histories. The vertical precompression was monitored with four conventional load cells.

A preliminary numerical investigation on a contact-based model (Vecchio *et al.* (2025)) showed collapse due to overturning when the model was subjected to two near-fault ground motions (GMs). These GMs were selected from the European Strong Motion Database (ESM) (Luzi *et al.* (2020)). To avoid disintegration due to high-frequency content (Indirli *et al.* (2013), Vlachakis *et al.* (2020)), Butterworth and Fourier bandpass filters were applied to the original GMs. The original GMs represented the 1998 Fajal (PT) and one of the 2016 Central Italy (IT) seismic events (NRC station). Both events induced in several URMs buildings and monumental structures collapses due to overturning of structural and non-structural elements.

The loading protocol followed an Incremental Dynamic Analysis (IDA) (Vamvatsikos and Cornell (2004, 2005)) protocol through scaling of the input signals from low intensity up to the shake-table limits. Incremental scale factors of 20% and 25% were tuned with dummy masses against the shake table prior to the start of the campaign, resulting in maximum increments of 200% and 320% for Signal 1 (filtered Fajal 1998) and Signal 2 (filtered NRC 2016), respectively. The IDA was performed with multiple repetitions at high-

displacement and collapses areas, to assess the randomness of the response, obtain sufficient data for the fitting of empirical FCs and observe the variability of the OOP collapses. To avoid any biased responses, the specimens were constantly reconstructed upon separation or damage before each seismic test. Four testing batches were conducted, featuring 54 tests for Batch I (Specimen A under Signal I), 54 for Batch II (Specimen A under Signal II), 53 for Batch III (Specimen B under Signal 1), and 50 for Batch IV (Specimen B under Signal II). **Figure 1** shows the specimens, including plan and elevation views, direction of the loading, and details of the boundary conditions. **Table 2** reports the main characteristics of the chosen inputs.

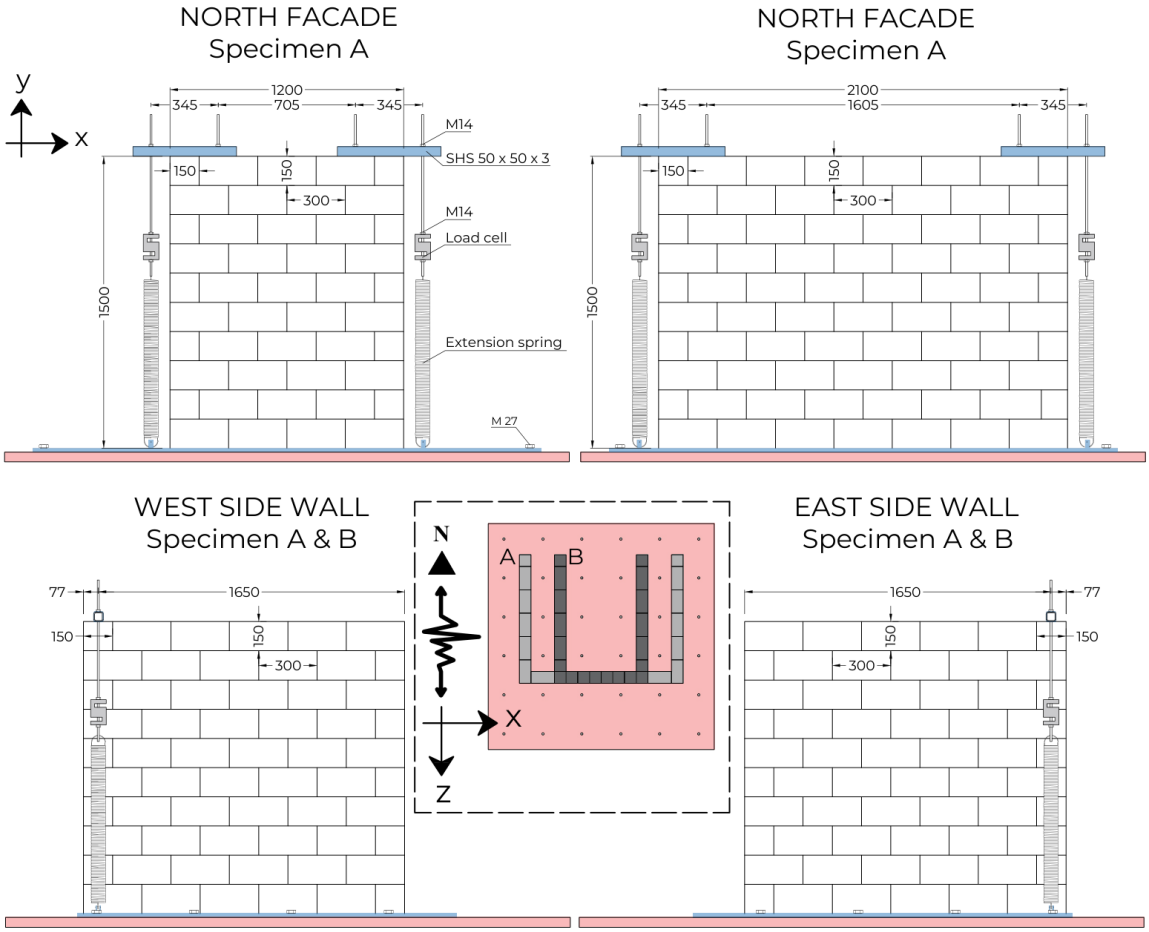

Figure 1 – Plan, elevation views and instrumentation details of the reduced-scale campaign

Table 2 – Characteristics of the input signals of the reduced-scale campaign

Signal	PGA |g|	PGV |cm/s|	PGD |mm|	Incremental scale factors (%)	IDA range (%)
1	0.368	34.7	37	25	0-200
2	0.236	22.7	33	20	0-320

2.2 Full-scale specimen

The full-scale campaign was conducted at LNEC Lisbon, which hosts a 3-DOF platform of with dimensions of 6400 mm x 5600 mm that can operate within the following operational ranges: (i) maximum acceleration of ±1 g, (ii) maximum velocity of 65 cm/s, (iii) maximum displacement of ±200 mm, (iv) frequency range of 0-40 Hz, (v) and maximum payload of 40 tons. The U-shaped specimen was made of granite blocks (see 2.1) with two dimensions: (i) 600 mm x 300 mm x 300 mm and (ii) 300 mm x 300 mm x 300 mm (length, height,

and width). The geometry featured 3000 mm-high walls, 900 mm-long sidewalls, and 4200 mm-long façade, resulting in an aspect ratio of 1.4. The campaign was designed to observe the hybrid two-way bending with a wall-to-diaphragm connection condition. Therefore, the boundary condition system included: (i) fixed base support, (ii) moment connection given by interlocking at the corners, (iii) vertical restraint at the end of the sidewalls, and (iv) rotational restraint on the façade, allowing only uplift. The fixed base support was achieved by encasing the first masonry course in perimetral UPNs 300x100 steel profiles, whose bottom flat flanges were drilled with chemical anchors into the 200-mm thick reinforced concrete base, while the profiles were stiffened at each 500 mm along the perimeter. Corner interlocking was provided with a typical toothing texture (see 2.1) while two steel rods were prestressed up to 10 kN to restrain the ends of each sidewall against undesired deformations. A more complex system was required to implement the rotational restraint. First, an HEB 300 was anchored to the additional top masonry course, which in turn was left unconnected to the bottom course. The HEB 300 was used to distribute uniformly a vertical overburden representing the weight of a parapet with a system of eight extension springs. Next, the web and the top flange of the HEB 300 were connected horizontally to a rear retaining frame, using two horizontal channel profiles to counteract coupled forces. A pair of rollers was provided at the end of each horizontal profile, allowing only sliding on the vertical flange surface of the steel column belonging to the retaining frame.

The instrumentation adopted for the full-scale campaign included: (i) ENDEVCO and PCB accelerometers, (ii) LVDTs, (iii) JX-P420 wire potentiometers, (iv) Hamamatsu C5949 optical potentiometers, and (v) 101BH load cells. The accelerometers were placed to monitor acceleration amplification according to the expected deformation, at the reinforced concrete base, and on the web of the HEB 300. The LVDTs were located at the mid-height and mid-length in the external side of the façade, at 1/3 and 2/3 of the height in the internal side of the façade, and on the sliding connections. Wire potentiometers were used to monitor displacements under the boundary conditions, while Hamamatsu optical displacement transducers measured 2D displacements at the end of the HEB 300. Finally, load cells were employed to monitor the vertical overburden in the extension spring system and the precompression level in the steel rods.

Only one signal (1-DoF) was selected for the present campaign. The GM representing the 1999 Düzce (TK) was employed as it represents a far-field event, and with different characteristics from the signals used in the reduced-scale campaign. Because the peak displacement exceeded the LNEC shake-table capacity, a Butterworth bandpass filter was applied to the GM.

Due to facility and material restrictions, fewer tests were conducted in this campaign. Prior to and after the application of 50% incremental scale factors, dynamic identification tests were conducted to assess the reduction in frequency. This campaign featured a total of 11 seismic tests and 10 dynamic identifications. **Table 3** reports the main characteristics of the selected input. **Figure 2** shows the plan and elevation views for the geometry, direction of the loading, details of the boundary conditions, and the adopted instrumentation.

Table 3 – Characteristics of the input signal of the full-scale campaign

Signal	PGA |g|	PGV |cm/s|	PGD |mm|	Incremental scale factors (%)	IDA range (%)
1999 Düzce	0.16	22.3	39.8	50	0-250

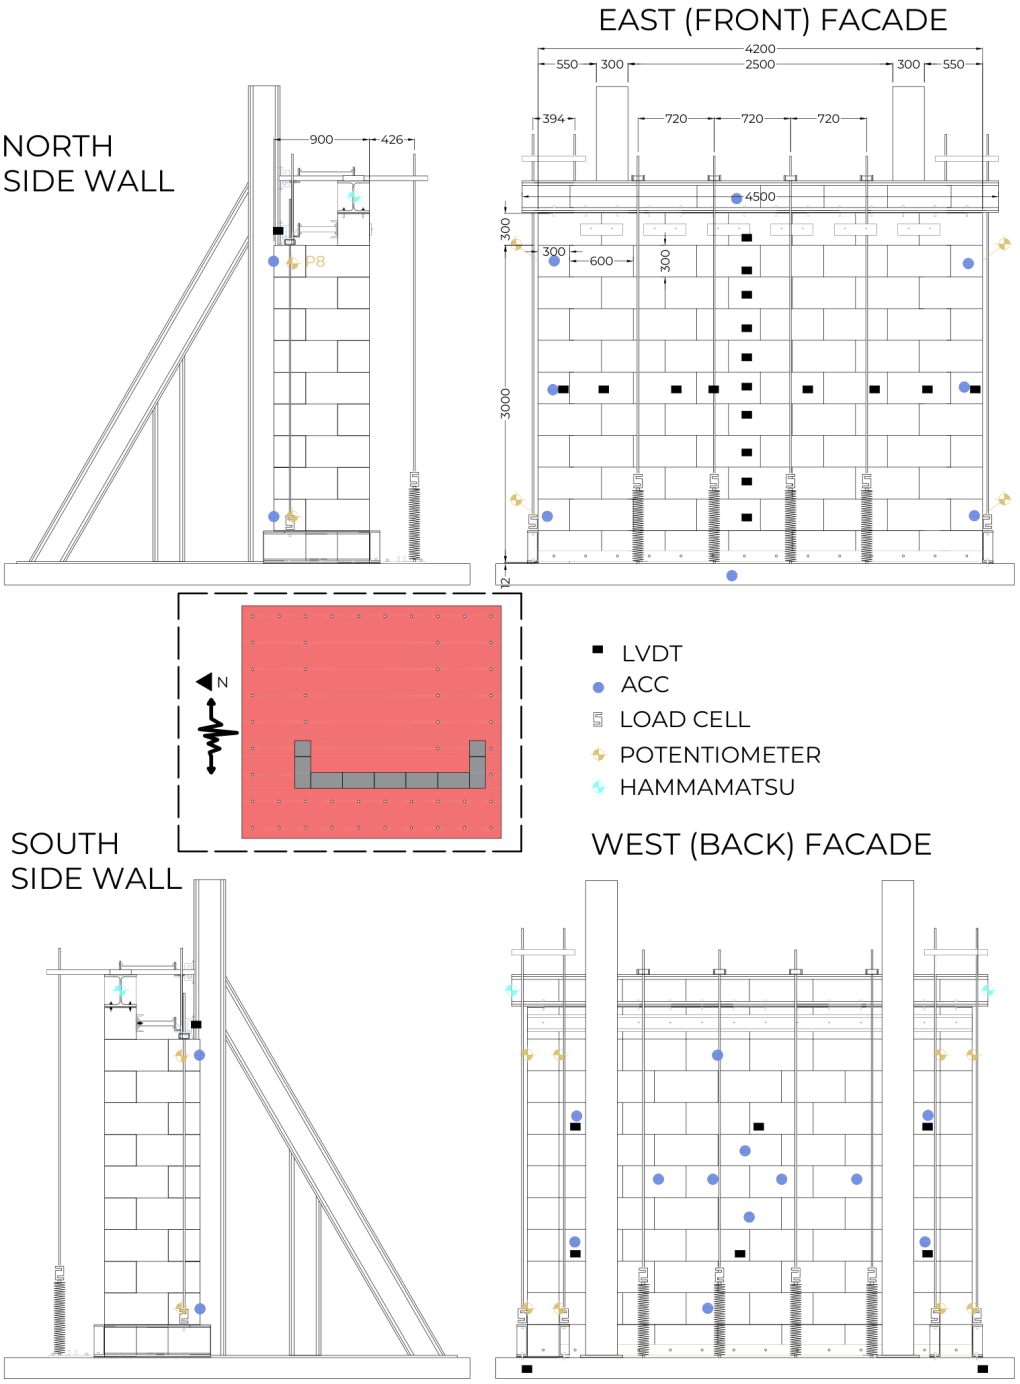

Figure 2 – Plan, elevation views and instrumentation details of the full-scale campaign

3. Experimental results

3.1 Evidence of hybrid two-way bending

Preliminary outcomes showing the presence of hybrid two-way bending can be observed by plotting the experimental IDAs. The adopted Engineering Demand Parameter (EDP) is the maximum Absolute Vector Magnitude computed in the x-z plane between the x- and the z-displacements of the blocks sitting at the top course of the specimens (**Figure 1**), against the Peak Ground Acceleration (PGA) of the seismic input.

While the blocks' numbers and locations, according to the open-access database (Vecchio *et al.* (2026)), are depicted in **Figure 3**, **Figure 4** shows the experimental IDAs for each testing Batch. Note that the red dashed horizontal line at 300 mm is used only to separate collapse from non-collapse events.

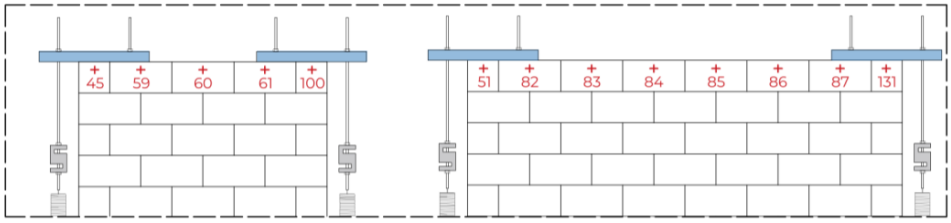

Figure 3 – Location of the points and blocks adopted to compute the absolute vector magnitude

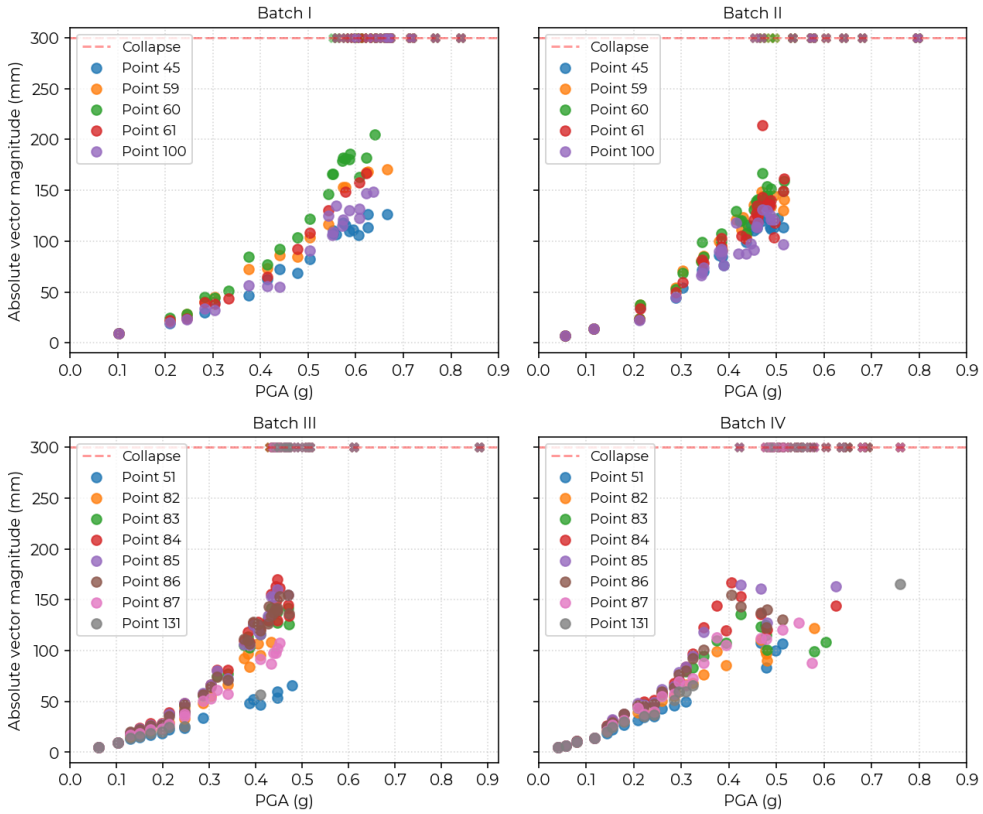

Figure 4 – Experimental Incremental dynamic analyses (IDAs) of the reduced-scale campaign: absolute vector magnitude vs PGA (Peak Ground Acceleration)

Evidence of hybrid two-way bending can be observed in the displacement magnitude exhibited by the central façade when compared to the corners. Excluding the collapse events, the central blocks exhibit larger displacements in the OOP direction, while the corner blocks show significant lateral deformation. The behaviour is attributed to torsional rotation at the corners, while the central façade tends to bend and form a typical arching mechanism (horizontal arching mechanism). Despite a slight asymmetry due to the dry-stack configuration, the corners follow similar trends. The influence of the geometry can be observed in earlier collapse events and pronounced randomness (larger dispersion) for Batch III and Batch IV due to the higher aspect ratio. Also, different signal inputs influence the response. For example, Signal 1 produces higher displacement of the central blocks and steeper IDAs (less dispersion).

The displacements' components for two corner blocks, P41 and P51, for Batches I-II and Batches III-IV, respectively, are compared in **Figure 5** to validate the abovementioned. Note that here, collapse events are

disregarded. The comparison is useful to verify that the specimens are deforming both in the OOP direction (z-axis) and laterally (x-axis). While the OOP direction is linked to rigid overturning, the lateral deformation is converted to torsional rotation of the corner. This response confirms the participation of the sidewalls and the hybrid two-way bending characterised by horizontal arching of the façade and rotation due to frictional behaviour at the interfaces.

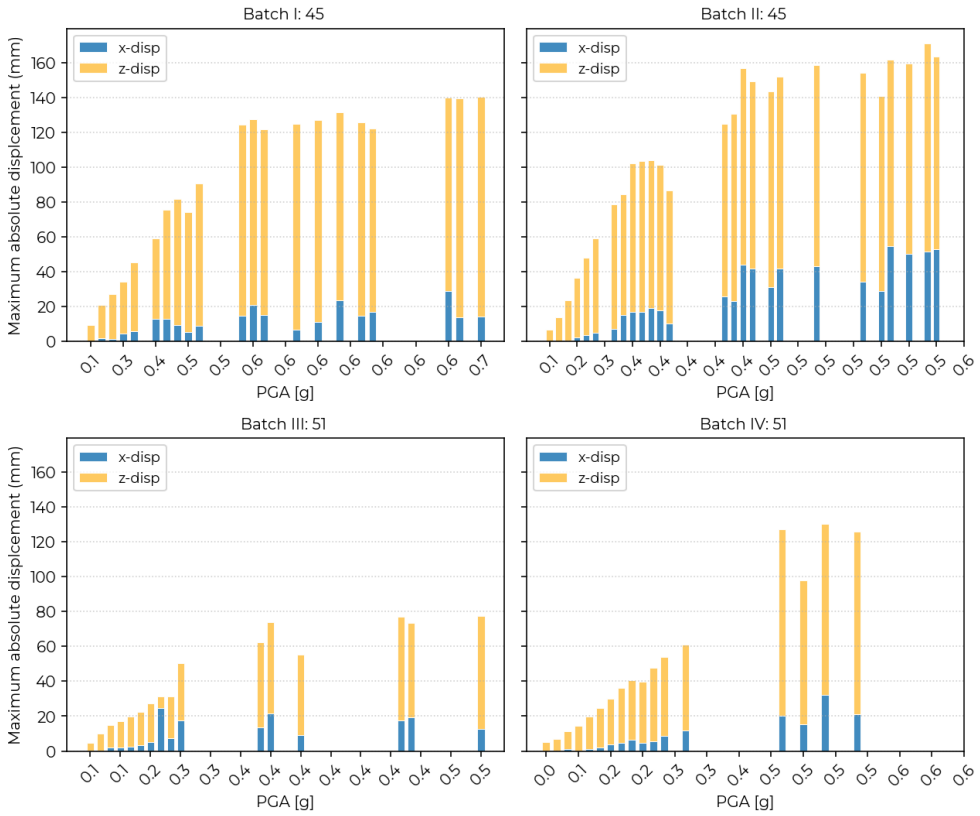

Figure 5 – Maximum absolute displacements and corresponding x- and z-axis components

3.2 The role of the wall-to-diaphragm connection

The importance of the wall-to-diaphragm connection is observed in the comparison between the reduced-scale specimens' and the full-scale specimen's responses. Note that the top boundary condition for the latter (rotational restraint and uplifting) is a possible configuration of existing URMs, in particular for one-way spanning walls (Vlachakis *et al.* (2025)). Due to that and to the presence of corner interlocking, interaction between vertical and horizontal bending was expected, leading to hybrid two-way bending with participation of sidewalls.

Figure 6 shows the OOP collapse mechanism observed in the reduced-scale specimens. The absence of an adequate wall-to-diaphragm connection between the façade and the sidewall led to the overturning of the façade with the participation of the sidewalls. The participation of the sidewalls was observed to increase at larger intensities. The influence of the input signal can be observed by comparing Batches I-III vs Batches II-IV, in particular knowing that Signal 1 is characterised by a dominant velocity pulse in the time history, while Signal 2 resembles more a cyclic behaviour. As a result, greater dispersion is observed in the OOP collapses of Batches II-IV. Not only that, but other OOP collapse mechanisms were also observed throughout the campaign. Nevertheless, the hybrid two-way bending occurred frequently, approximately 65% of the total observed collapse events.

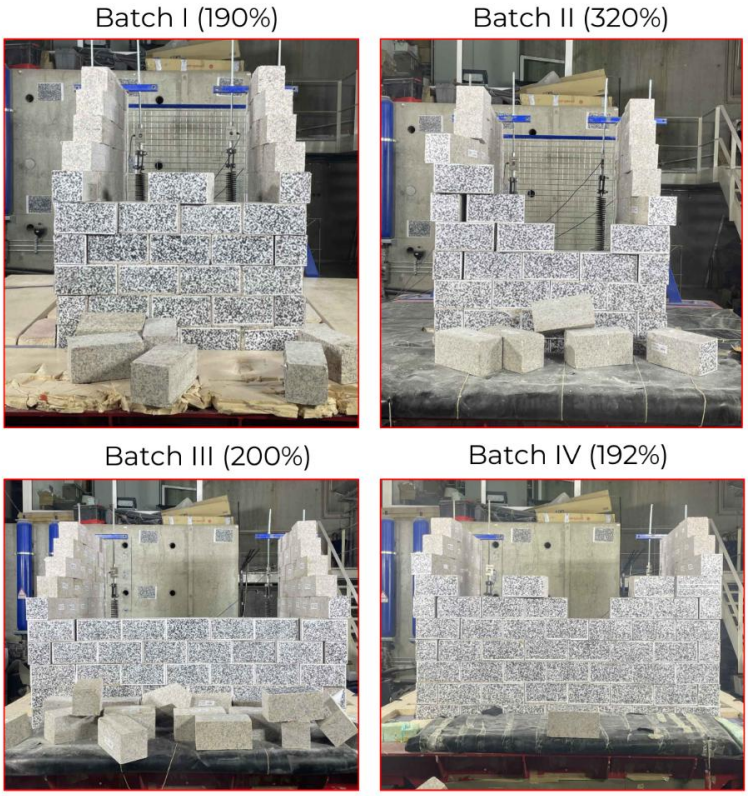

Figure 6 – OOP collapses observed in the reduced-scale campaign due to the insufficient wall-to-diaphragm connection

Figure 7 shows the OOP collapse mechanism experienced by the full-scale specimen. On the left, the picture depicts the expected OOP mechanism composed of horizontal and vertical bending (rigid two-way bending) (Graziotti *et al.* (2019), whereas the right side displays the observed OOP collapse mechanism at the 250% scale factor of the 1999 Düzce GM. In both pictures, the red dashed lines represent the separation of the interfaces, and the arrows indicate the direction of the expected (untested configuration) and observed (tested configuration) rotations. First, the frictional dissipative behaviour at the interfaces (corner interlocking) influenced the response, creating a non-vertically symmetric cracking pattern in both corners. In addition, the applied vertical overburden was not sufficient to prevent the OOP deformation of the façade, which experienced an arching mechanism, with a collapsed block at the mid-length. Nevertheless, the overburden was sufficient in preventing collapse in the sidewalls and in limiting vertical bending of the façade, which behaved as a cantilever. As a result, the test confirmed the hybrid two-way bending composed by horizontal bending of the façade together with the participation of the sidewalls, while providing experimental evidence on the influence of the wall-to-diaphragm connection.

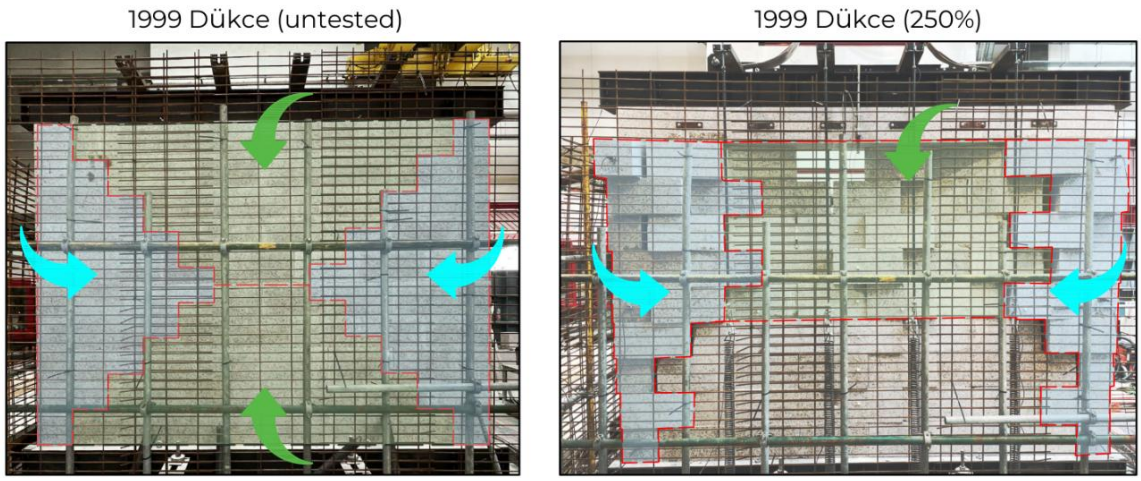

Figure 7 – OOP collapses observed in the full-scale campaign due to insufficient wall-to-diaphragm connection. On the left, the expected response, on the right, the obtained collapse mechanism. Note that the green and light blue colours are used for the rotation over the horizontal and vertical axis, respectively

4. Conclusions and future works

This paper has discussed the preliminary outcomes obtained from two extensive shake-table campaigns on the seismic OOP response of URM specimens. URMs are vulnerable to natural hazards such as earthquakes, and for that, are considered in the objectives defined by Goal 11, Sustainable Cities, which is part of the 2030 Agenda for Sustainable Developments. Research is needed to enhance knowledge of existing URM buildings and monumental structures when subjected to natural hazards such as earthquakes. Dynamics affects the OOP response and the influence of geometry, boundary conditions, and different inputs, but it still lacks adequate comprehension. Also, the next generation of Eurocodes does still not account for complex non-linear behaviour due to rocking, energy dissipation, and mechanisms' coupling leading to mixed collapses. The campaigns described in this paper have taken advantage of dry-stack masonry to conduct several tests and repetitions. One of the major outcomes was the experimental evidence of hybrid two-way bending, featured by simultaneous bending/overturning of the façade together with participation of the sidewalls. The second major objective of collecting the experimental data (reduced-scale specimens) into a reliable and open-access database was also achieved. Based on that, future works will focus on the calibration and validation of refined numerical models to simulate the dynamic response of URMs under varying geometry, input signals and boundary conditions. Also, future research will be carried out in probabilistic frameworks, including analyses on adequate intensity measures and the final construction of fragility curves.

Acknowledgments

This work was financed by national funds through FCT (*Fundação para a Ciência e a Tecnologia*) under agreement 2023.03854.BDANA (first author) and 2024.01310.BD (second author). The experimental campaigns were fully funded by the STAND4HERITAGE project (New STANDard FOR seismic assessment of built cultural HERITAGE) that has received funding from the European Research Council (ERC) under the EU Horizon 2020 research and innovation program through the Advanced Grant No. 833123. This study was also partly funded by FCT/MECI through project 2022.05425.PTDC (RESISTANCE) and project national funds (PIDDAC) under the R&D Unit Institute for Sustainability and Innovation in Structural Engineering (ISISE), under reference UIDB/04029/2020, and under the Associate Laboratory Advanced Production and Intelligent Systems ARISE under reference LA/P/0112/2020.

Conceptual Model of Resilient Decision-Making for PDHR in Critical Zones

Carlos OLIVEIRA CRUZ[1], **Ahmed ASHOUR**[2]

[1] CERIS, Institute of Superior Técnico, University of Lisbon, Portugal, oliveira.cruz@tecnico.ulisboa.pt
[2] CERIS, Institute of Superior Técnico, University of Lisbon, Portugal, ahmed.ashour@tecnico.ulisboa.pt

Abstract: Post-Disaster Housing Reconstruction (PDHR) in critical zones remains insufficiently addressed within existing reconstruction theories and decision-support approaches. Most current frameworks prioritize technical optimization, cost efficiency, and sustainability under relatively stable operational assumptions, while providing limited consideration for contextual feasibility under conditions of uncertainty, instability, and constraints. Consequently, reconstruction alternatives that appear technically optimal in stable conditions may become operationally infeasible in critical zones.

Therefore, this paper proposes a resilience-oriented conceptual framework for PDHR decision-making in critical zones. The framework introduces contextual feasibility as a preliminary screening mechanism prior to technical and economic optimization. The proposed model consists of three sequential analytical layers, starting with feasibility assessment (filter), then goes to the second layer of performance evaluation, and last layer of economic evaluation. The framework integrates hybrid Multi-Criteria Decision-Making (MCDM) approaches and Cost–Benefit Analysis (CBA) to support trade-off analysis between contextual operability, technical performance, sustainability, and long-term economic value in order to enhance the decision-making.

Keywords:

Contextual Feasibility; Critical Zones; Decision-Making; Post-Disaster Housing Reconstruction (PDHR); Resilience.

1. Introduction

Post-disaster housing reconstruction (PDHR) represents a critical phase of disaster recovery that extends beyond rebuilding damaged structures to influencing long-term social recovery, economic stability, institutional legitimacy, and community resilience (Johnson, 2007). Over recent decades, significant progress has been made in developing reconstruction frameworks emphasizing cost efficiency, sustainability, structural resilience, and rapid recovery through approaches such as “Build Back Better” (BBB), Sendai Framework, and resilience-based design methods (Kennedy et al., 2008; Lizarralde et al., 2010). Emerging technologies including modular construction, prefabrication, and 3D-printing systems have further expanded opportunities for accelerating reconstruction while reducing material waste and lifecycle costs.

However, many existing reconstruction frameworks remain implicitly grounded in assumptions of operational stability and predictable recovery conditions. This limitation becomes increasingly problematic in what this paper conceptualizes as “critical zones”: environments characterized by persistent uncertainty, instability, and operational constraints that continue beyond the initial disaster event. Such conditions may emerge from recurring natural or human disasters, political instability, forced displacement, institutional fragility, sanctions, economic collapse, disrupted supply chains, or restricted site accessibility (Tierney, 2023). Unlike conventional recovery environments, reconstruction in critical zones occurs under continuously evolving disruptions that directly affect implementation feasibility and decision-making processes.

In such contexts, reconstruction failure is often linked not to the technical inadequacy of reconstruction systems, but to the inability of decision-making frameworks to adapt to contextual realities. Reconstruction alternatives that appear technically optimal under normal conditions may become operationally infeasible due to governance fragmentation, logistics disruption, insecurity, or resource shortages. Experiences from post-earthquake Haiti and the Middle East conflict-affected regions (Ex, Syria and Yemen) demonstrate how institutional fragility, disrupted logistics, and political instability can fundamentally constrain reconstruction implementation despite substantial technical and financial support (Barakat & Zyck, 2011; Schuller, 2016).

Although existing PDHR literature increasingly recognizes complexity and uncertainty in disaster recovery, resilience is still predominantly conceptualized as a characteristic of reconstruction outcomes rather than of the decision-making process itself. Existing frameworks largely focus on how resilient, sustainable, or cost-effective reconstruction outputs may be, while comparatively limited attention has been given to whether the decision-making architecture itself remains adaptive, feasible, and robust under persistent disruption. In critical zones, the central challenge is often not identifying the theoretically “best” solution, but identifying solutions capable of surviving contextual constraints while maintaining acceptable performance outcomes.

Accordingly, this paper argues that resilience in PDHR should be reconceptualized as a property of the reconstruction decision-making process itself. To address this gap, the study proposes a resilience-oriented conceptual framework for PDHR decision-making in critical zones. The framework introduces contextual feasibility as a preliminary screening mechanism prior to technical and economic optimization. It integrates feasibility assessment, performance evaluation, and economic assessment through the combined application of hybrid MCDM approaches and Cost–Benefit Analysis (CBA). The novelty of the framework lies in integrating contextual feasibility within a sequential resilience-oriented decision architecture where feasibility precedes performance. The study therefore contributes a conceptual foundation for future empirical research and practical application in highly constrained reconstruction environments.

2. Theoretical Grounding

2.1 Defining the Critical Zone Construct: Characteristics and Context

Post-disaster housing reconstruction (PDHR) has traditionally been examined within relatively stable recovery environments, where reconstruction activities are assumed to progress through sequential phases of emergency response, recovery, rebuilding, and eventual normalization (Alexander, 2014). However, an increasing number of contemporary disasters occur within critical zones. The expression of “Critical Zones” in this paper is used as a metaphor to refer to a spatial-operational framework for protracted crisis zones,

where it is mainly characterized by persistent uncertainty, instability, and contextual constraint. This criticality varies in degree depending on the origin. It can originate from natural, human-made or hybrid sources. Furthermore, it usually witnesses one or more of socio-economic fragility, political unrest, governance fragmentation, and repeated disruptions that continuously affect reconstruction processes, making the predictable recovery trajectories no longer reliably apply. Such environments challenge the assumptions embedded in conventional post-disaster recovery models and require a broader conceptualization of reconstruction dynamics that extends beyond traditional recovery conditions (Tierney, 2023).

Examples include conflict-affected regions, politically unstable territories, areas under sanctions, regions experiencing repeated climate-related disasters, displacement environments, economically collapsed states, or territories suffering from long-term infrastructure degradation (Wisner, 2004). In such contexts, reconstruction challenges extend beyond physical damage and involve dynamic socio-political and operational disruptions (Lewis, 1999). Unlike conventional post-disaster settings, where disruption is often temporary and recovery pathways are comparatively linear, critical zones are characterized by recurrent disruptions that alter the assumptions upon which traditional reconstruction models are based (Olshansky et al., 2012). and made the reconstruction decision-making and its implementation in such zones is a challenging task.

2.2 Limitations of Existing Theories and Decision-Support Approaches in PDHR at Critical Zones

Several influential theories and frameworks have shaped PDHR planning and reconstruction policy over recent decades. These include the disaster management cycle, the “Build Back Better” concept, the Sendai Framework for Disaster Risk Reduction, sustainability-oriented reconstruction models, and various optimization-based decision-support tools such as MCDM and the traditional project management “Iron Triangle.” While these frameworks have significantly improved reconstruction planning in many contexts, their isolated applicability within critical zones remains inefficient.

2.2.1 Limitations of the Disaster Management Cycle

The traditional disaster management cycle conceptualizes disasters through sequential stages including mitigation, preparedness, response, recovery, and reconstruction (Alexander, 2014). Although widely adopted, this framework assumes that disasters represent temporary disruptions followed by progressive stabilization.

However, recovery processes in critical zones rarely follow linear trajectories. Olshansky et al. (2012) argue that post-disaster recovery processes are often nonlinear, compressed, and deeply shaped by uncertainty. In conflict-affected or politically unstable environments, reconstruction may occur simultaneously with ongoing crises, making conventional stage-based recovery models insufficient.

The reconstruction experience following Hurricane Katrina illustrates this limitation. Despite extensive technical and financial resources, recovery was significantly complicated by governance fragmentation,

institutional failures, and social inequalities that traditional disaster frameworks failed to adequately address (Comfort, 2006).

2.2.2 Limitations of the "Build Back Better" Approach

The "Build Back Better" (BBB) paradigm emphasizes improving resilience, sustainability, and development outcomes during reconstruction processes (Kennedy et al., 2008). While conceptually valuable, BBB often assumes that institutional systems, governance mechanisms, and reconstruction resources remain sufficiently functional to support long-term rebuilding strategies.

In highly constrained environments, however, immediate operational feasibility may become more critical than optimization-oriented rebuilding objectives. Reconstruction priorities may shift toward adaptability, accessibility, and rapid deployability rather than idealized long-term redevelopment goals.

The post-2010 Haiti reconstruction process demonstrates this limitation. Despite extensive international promotion of sustainable reconstruction principles, implementation was severely constrained by institutional fragmentation, land tenure conflicts, weak governance coordination, and heavy dependence on imported systems and external actors (Schuller, 2016). As a result, many reconstruction initiatives struggled to achieve intended recovery outcomes.

2.2.3 Limitations of the Sendai Framework

The Sendai Framework for Disaster Risk Reduction emphasizes resilience-building, risk governance, preparedness, and sustainable recovery (UNDRR, 2015). However, the framework primarily operates at the strategic policy level and provides limited operational guidance for reconstruction decision-making under persistent instability and constrained implementation conditions.

While Sendai strongly promotes resilience-oriented recovery, it does not sufficiently address how reconstruction decisions should adapt when governance systems are fragmented, logistics are disrupted, or operational feasibility continuously changes.

2.2.4 Limitations of the Short-Term versus Long-Term Approach

PDHR literature frequently distinguishes between short-term emergency shelter and long-term permanent reconstruction. However, this distinction becomes increasingly blurred within critical zones where temporary settlements may persist for years or even decades due to prolonged instability and displacement conditions (Quarantelli, 1995).

In many conflict-affected regions, temporary housing systems have evolved into semi-permanent environments because political and operational conditions prevented transition toward conventional long-term reconstruction. Such realities challenge simplified temporal distinctions embedded within traditional recovery models.

2.3 Limitations of Traditional Decision-Support Tools

2.3.1 The Iron Triangle

The traditional “Iron Triangle” framework evaluates project success primarily through cost by tools such as LCCA and CBA, in addition to time duration, and output quality dimensions. Although useful for conventional project management, this approach inadequately captures contextual uncertainty, institutional fragility, political instability, and operational feasibility challenges present in critical zones.

2.3.2 Multi-Criteria Decision-Making (MCDM)

MCDM approaches have become increasingly popular in reconstruction planning because they allow simultaneous evaluation of multiple criteria. However, many MCDM applications prioritize performance optimization without sufficiently accounting for whether reconstruction alternatives remain feasible under unstable operational conditions.

Therefore, a technologically advanced reconstruction solution may rank highly according to sustainability or cost-efficiency metrics while remaining impossible to implement due to material shortages, border restrictions, security risks, or institutional collapse.

The reconstruction experience in Syria provides an illustrative example. Several technically sophisticated reconstruction proposals were proposed during the conflict period, yet implementation remained severely constrained by political fragmentation, sanctions, infrastructure destruction, restricted logistics, and governance instability (Barakat & Zyck, 2011). Similarly, reconstruction efforts following Hurricane Katrina revealed how social inequality, governance fragmentation, and institutional failures complicated recovery implementation despite substantial technical and financial resources (Vale & Campanella, 2005).

These examples collectively demonstrate that existing PDHR theories and decision-support tools remain insufficient for critical zones because they continue to prioritize reconstruction performance without adequately integrating contextual feasibility into the decision-making process itself.

Accordingly, this paper argues that resilient PDHR decision-making in critical zones requires a conceptual integration of feasibility measures into the performance ones to guarantee the resilience of the decision-making architecture operating under persistent uncertainty and operational disruption.

3. Research Methodology

3.1 Research Design

This study adopts a conceptual research design aimed at developing a theoretically grounded framework for resilient decision-making in Post-Disaster Housing Reconstruction (PDHR) within critical zones. Conceptual research is particularly appropriate for addressing emerging or insufficiently theorized phenomena where existing models fail to adequately explain complex realities (Jaakkola, 2020). In the context of PDHR, existing reconstruction theories and decision-support approaches remain largely grounded in assumptions of operational stability, creating limitations when applied to environments characterized by persistent uncertainty, instability, and/or constraints.

Accordingly, the purpose of this study is not to empirically test a predefined hypothesis, but to construct a new conceptual understanding of resilient decision-making under constrained operational conditions. The research, therefore, focuses on theory synthesis, conceptual integration, and analytical abstraction derived from existing literature.

The methodological process consisted of two sequential phases:

1. Systematic identification and synthesis of relevant decision-making variables from the literature;
2. Conceptual abstraction and framework development based on identified theoretical patterns.

This structure was adopted to ensure methodological transparency and theoretical rigor during the framework development process.

3.2 Literature Review and Knowledge Synthesis

3.2.1 Literature Review Strategy

The first phase of the study involved a structured literature review aimed at identifying the principal concepts, variables, and theoretical gaps associated with PDHR decision-making in unstable and constrained environments.

The review process was informed by Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) principles to improve transparency in article selection and thematic synthesis. Relevant literature was collected from two major academic databases; Scopus, Web of Science. The search strings were developed using Boolean operators and combinations of four core thematic clusters, as explained in "Table 1".

Table 1 - Research Clusters

Cluster	Keywords
Decision-making	Decision-making OR "MCDM" OR "multi-criteria decision analysis" OR "decision framework"
Disaster consequences	Post-disaster OR destruction
Housing reconstruction	"Housing reconstruction" OR "residential rebuilding" OR "Shelter" OR housing
Critical zones	Restriction OR uncertainty OR disruption OR "disaster-prone regions" OR instability

Peer-reviewed journal articles, books, institutional reports, and international policy frameworks were reviewed to ensure interdisciplinary coverage of the topic.

3.2.2 Inclusion and Exclusion Criteria

To improve relevance and conceptual consistency, the review prioritized studies that:

- Addressed PDHR or reconstruction decision-making;

- Discussed resilience, uncertainty, or operational constraints;
- Examined governance, logistics, or implementation challenges;
- Applied evaluation or prioritization approaches in disaster recovery contexts.

Studies focused exclusively on structural engineering performance without decision-making relevance were excluded. Similarly, purely technical construction optimization studies without contextual constraints, instability, uncertainty, or disruptions were not prioritized.

3.3 Analytical Approach

The collected literature was analyzed using thematic synthesis and conceptual categorization techniques. The objective of this phase was to identify recurring patterns, relationships, and gaps within existing PDHR decision-making approaches.

Particular attention was given to:

- Variables influencing reconstruction implementation;
- Criteria used in reconstruction evaluation;
- Limitations of existing decision-support frameworks;
- Operational causes of reconstruction failure in unstable contexts.

Through iterative comparison and abstraction, the analysis revealed that existing PDHR literature often prioritizes performance-related evaluation criteria, while contextual feasibility-related conditions are less presented without sufficient integration between them under persistent disruption. This observation became central to the conceptual development process. Figures 1 and Table 2 represent this review.

4. The Proposed Conceptual Model

This study proposes a resilience-oriented conceptual framework for Post-Disaster Housing Reconstruction (PDHR) decision-making in critical zones characterized by uncertainty, instability, governance fragility, supply-chain disruption, and operational constraints. Unlike conventional reconstruction approaches that primarily focus on technical optimization and performance efficiency, the proposed framework argues that reconstruction suitability in critical zones must first satisfy contextual feasibility conditions before technical and economic evaluation can be meaningfully conducted.

The framework begins with identifying potential reconstruction alternatives such as traditional construction systems, modular housing, prefabricated structures, hybrid systems, and emerging technologies including 3D printing. Rather than assuming all reconstruction systems are equally deployable across different contexts, the model recognizes that reconstruction feasibility depends heavily on environmental, institutional, logistical, political, and socio-economic conditions.

The first analytical layer consists of a contextual feasibility filter, representing the primary conceptual contribution of the framework. This layer evaluates whether reconstruction alternatives can realistically operate under critical-zone constraints. Feasibility criteria include institutional capacity, supply-chain stability, labor accessibility, political conditions, financing availability, and social acceptance. The framework proposes the use of Multi-Criteria Decision-Making (MCDM) methods to evaluate alternatives according to weighted contextual criteria. Alternatives that fail to satisfy minimum feasibility conditions are excluded from subsequent evaluation stages.

Reconstruction alternatives that pass the feasibility stage proceed to the second analytical layer: performance evaluation. This stage assesses technical and operational performance using criteria such as construction speed, structural resilience, flexibility, sustainability, and long-term adaptability. Because reconstruction priorities may vary significantly across disaster contexts, the framework allows adaptive weighting of performance criteria using hybrid MCDM approaches.

The third analytical layer consists of economic evaluation through Cost–Benefit Analysis (CBA). This stage evaluates lifecycle implications, affordability, maintenance requirements, and long-term recovery value. The integration of MCDM and CBA enables the framework to balance contextual feasibility, technical performance, and economic sustainability within a unified decision-support structure.

Finally, the framework synthesizes feasibility assessment, performance evaluation, and economic analysis into an integrated trade-off decision process aimed at supporting resilient reconstruction strategies under persistent uncertainty and operational disruption. The novelty of the framework lies not in the isolated use of MCDM or CBA methods, but in integrating them within a sequential resilience-oriented decision architecture where contextual feasibility precedes optimization.

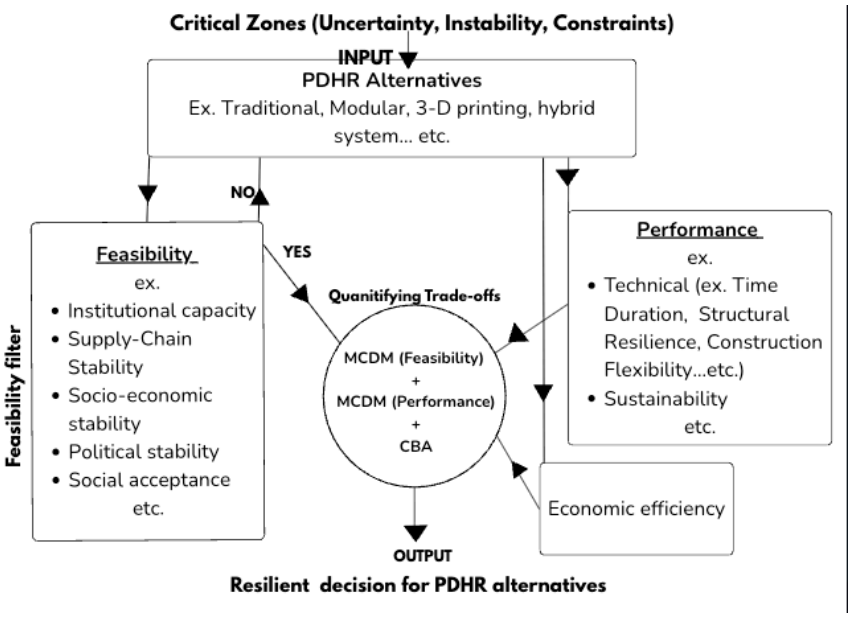

Figure 2 - Model for PDHR decision making in critical zones

5. Discussion

The findings of this study suggest that reconstruction decision-making in critical zones cannot rely solely on conventional performance-oriented approaches. Although criteria such as cost efficiency, sustainability, construction speed, and structural resilience remain important, reconstruction success in unstable environments is often determined by contextual feasibility rather than technical superiority alone. In such conditions, reconstruction systems that appear optimal theoretically may become impractical due to disrupted supply chains, governance fragility, labor shortages, financing limitations, or political instability.

The proposed framework therefore emphasizes that resilient PDHR decision-making requires integrating contextual feasibility alongside technical and economic evaluation. Existing reconstruction models frequently prioritize optimization-based performance criteria while underrepresenting operational constraints that directly affect implementation capability. However, experiences from conflict-affected and disaster-prone regions demonstrate that institutional capacity, logistics continuity, material accessibility, and social acceptance can fundamentally determine reconstruction success or failure in practice.

The study further argues that reconstruction priorities are not universally fixed across all disaster contexts. Different critical zones may require different evaluation priorities depending on operational realities. Consequently, the integration of hybrid Multi-Criteria Decision-Making (MCDM) approaches and Cost–Benefit Analysis (CBA) provides greater flexibility for balancing contextual feasibility, technical performance, and long-term economic sustainability.

The primary theoretical contribution of this study lies in reframing resilience from an outcome-oriented concept toward a process-oriented perspective. The framework shifts reconstruction logic from identifying the theoretically optimal solution toward identifying the most contextually survivable and operationally adaptable solution under persistent uncertainty and disruption.

6. Conclusion and Future Research

This paper proposed a resilience-oriented conceptual framework for Post-Disaster Housing Reconstruction (PDHR) decision-making in critical zones characterized by instability, uncertainty, and operational disruption. Unlike conventional approaches that primarily emphasize technical optimization, the framework introduces contextual feasibility as a preliminary filter prior to performance and economic evaluation. The study argues that resilient reconstruction depends not only on resilient housing outcomes, but also on resilient decision-making processes capable of adapting to unstable conditions.

The framework integrates feasibility assessment, performance evaluation, and Cost–Benefit Analysis (CBA) through hybrid Multi-Criteria Decision-Making (MCDM) approaches to support adaptive reconstruction planning under constrained environments.

However, the framework remains conceptual and requires empirical validation. Future research should test the model through case studies, expert evaluation, simulation modelling, or Delphi methods in conflict-affected and disaster-prone regions. Further studies may also explore the integration of digital technologies and real-time data systems to improve operational decision support in critical zones.

Abstract: The conservation of earthen masonry heritage is conditioned by technical considerations as well as by administrative procedures and regulatory frameworks that govern intervention practices. This study is motivated by the need to understand how management decisions can either mitigate or accelerate structural vulnerability in earthen buildings. The research focuses on a rare and culturally significant earthen *troje* located in the dense urban context of Mexico City, within the former Hacienda de San Nicolás Tolentino Buenavista. By correlating archival records (1970–2009) with fieldwork documentation, the study establishes a direct link between institutional processes and physical decay. The analysis shows that cumulative management failures contributed to the progressive structural weakening of the *troje*, ultimately leading to severe deterioration. Rather than resulting from a single technical failure, the case demonstrates how management practices can themselves present systemic threats to earthen heritage. Three key patterns are identified: delayed responses to documented structural threats, the use of incompatible materials, and external interventions that altered the building's structural and spatial integrity. Additionally, the case exposes limitations in current regulatory frameworks, particularly their insufficient consideration of earthen construction systems and challenges in enforcement. Consequently, the study highlights the need for integrated approaches that align technical knowledge, clear regulatory instruments, and effective institutional coordination to prevent administrative processes from becoming drivers of earthen heritage deterioration in urban contexts.

Keywords: earthen masonry heritage, heritage management, administrative decision-making, structural deterioration, urban heritage.

1. Introduction

Earthen architectural heritage represents a specialized and increasingly rare category of the built environment, particularly within dense urban contexts such as Mexico City. While traditional construction techniques such as adobe and rammed earth remain widely represented in rural areas of Latin America, their presence in large metropolitan environments is exceptional, making their conservation a matter of urgent cultural priority. While environmental factors are commonly recognized as primary agents of decay, the survival of these rare urban earthen structures is increasingly threatened by human and institutional actions. Recent research has significantly advanced the technical understanding of earthen materials, including their structural behavior and conservation needs, as illustrated by Sánchez-Calvillo *et al.* (2024).

However, comparatively less attention has been paid to how administrative processes fail to address the specific complexities of earthen architecture, particularly within urban systems. In many cases, unclear intervention protocols, lack of coordination between institutions or insufficient technical knowledge among stakeholders contribute significantly to the progressive deterioration of heritage structures, as noted by Abad Rodas and Idrovo Carpio (2016), Guerrero Baca and Esteba Ávalos (2022), and Robles García and Corbett (2017).

In Mexico, the conservation of architectural heritage is regulated under the Federal Law on Archaeological, Artistic and Historical Monuments and Zones (1972, latest amendment April 1, 2024) and its Regulations (1975, latest amendment January 5, 2024) (DOF, 1972; DOF, 1975; Rotondaro *et al.,* 2024, 56). This legal framework establishes institutional responsibilities and authorization procedures, through the National Institute of Anthropology and History (INAH). Although it provides a formal basis for protection, its application often reveals limitations when addressing the specific complexities of earthen architecture. Despite international efforts to standardize earthen construction since the early 2000s, as documented by Rotondaro *et al.* (2024), most notably through the PROTERRA network and technical standards such as Mexico's NMX-C-508-ONNCCE-2015 regarding Compressed Earth Blocks, regulatory frameworks specifically tailored for the intervention of historic earthen structures remain insufficient. While these efforts have transitioned from academic initiatives into formal technical documents, their application within heritage conservation practice, particularly under institutional frameworks, continues to face significant challenges.

This paper examines the case of an earthen *troje* located within the former Hacienda de San Nicolás Tolentino Buenavista in Iztapalapa, Mexico City. The building, originally constructed between the 18th and early 19th centuries, has undergone a series of administrative processes, interventions, and periods of neglect that have significantly altered its structural condition over time. The availability of archival documentation makes this case particularly relevant for analyzing the relationship between management decisions and material deterioration. In light of this, the aim of this study is to identify how administrative actions, authorization processes, and institutional coordination have influenced the progressive deterioration of this historically significant building. By highlighting the interaction between regulatory frameworks, technical practices, and material performance, this study contributes to a broader understanding of heritage management as a critical factor in the conservation, or deterioration, of earthen architecture.

2. Methodology

The methodology is based on three complementary components. First, an archival research process was conducted in the INAH historical archives, *Archivo Histórico y Planoteca Jorge Enciso (AHP-JE)* of the *Coordinación Nacional de Monumentos Históricos (CNMH)*, where administrative records, technical reports, or official letters (1970–2009) related to the case study were identified and analyzed. Second, fieldwork was carried out with authorization from the local authorities, including photographic documentation, architectural survey, and on-site identification of construction systems, materials, and deterioration patterns. Finally, a comparative analytical approach was developed, consisting of the chronological correlation between documented administrative actions and the current physical condition of the building. This allowed the identification of causal relationships between management decisions, intervention practices, and observed deterioration processes.

3. Study Case

This research examines an 18th-century earthen *troje* located within the San Lorenzo Tezonco civil cemetery in Iztapalapa, Mexico City (see Figures 1 and 2). According to INAH (1989; 1990), this structure is officially protected under Mexican heritage law (DOF, 1972) and is registered in the National Catalog of Historic

Monuments (ID: I-0014100021). Its 16th–19th century chronology, specifically identified as the Troje of San Nicolás Tolentino Buenavista, meets the required legal criteria for national protection.

Figure 1 – General (east) view of the *Troje* in 1975. Source: INAH (1989)

Figure 2 – West façade view of the Troje in 1975. Source: INAH (1989)

The building originally belonged to the Hacienda de San Nicolás Tolentino Buenavista, a historic agricultural estate founded in 1580 (Nazario Cruz 2014, 34), and located adjacent to the indigenous town (*pueblo originario*) of San Lorenzo Tezonco. The hacienda's development benefited from its strategic location near streams and the former Lake Xochimilco, where access to essential roads, local ranches, and indigenous labor settlements was further enhanced by its proximity to Mexico City, the primary commercial and demographic center of New Spain. Its main economic activity centered on the cultivation of alfalfa and oats (Gómez and Villasana 2021). Throughout its history, it had several owners, including the Jesuits, who acquired it in 1705 and retained ownership until 1767. This period is considered the hacienda's time of greatest prosperity, as it experienced no economic losses and reached an extension of approximately five thousand hectares. However, in comparison with other Jesuit properties, it remained relatively small.

By 1792, there are records documenting the *troje* as part of the hacienda complex, indicating that, in addition to a masonry house with arches, there was also a two-level *troje* described as large and capable of storing the agricultural production of the hacienda (Nazario Cruz 2014, 39–40). In 1812, another document describes the hacienda as having a *troje* composed of three bays with 20 masonry pilasters supporting 20 wooden columns, with both levels connected by a vaulted staircase (Lara Paredes 2017, 33). The building's current state aligns with these historical descriptions: a two-story structure with adobe walls and stone buttresses. Records indicate that the buttresses were early 20th-century interventions, designed to align with the architectural rhythm and spacing of the original perimeter walls (INAH, 1994b; 1994e). Currently, 16 masonry columns are preserved on the ground floor, with four others documented as collapsed. In 1908, the owners established the *Compañía Agrícola de San Nicolás, Sociedad Anónima* with the aim of draining and irrigating the land to improve productivity. Due to limited economic returns, the property was gradually subdivided and sold in lots during the first half of the 20th century. At the same time, part of the land was granted to the town of San Lorenzo Tezonco, with which there had been longstanding conflicts since the hacienda's foundation over land appropriation. In 1970, the government expropriated the remaining hectares to establish what is now the San Lorenzo Tezonco Civil Cemetery (Gómez and Villasana 2021).

The *troje* currently features a foundation of irregular stone masonry bonded with lime–sand mortar. Ground-floor walls are constructed of adobe bricks (approximately 40 × 15 × 10 cm) with 5-cm joints. The structural system includes columns with stone masonry bases and fired-clay brick shafts. The floor system is supported by wooden beams resting on capitals atop the columns; this assembly consists of timber joists and wooden

planks embedded into the walls, topped with a layer of earthen fill (*terrado*), a lime–sand leveling bed, and a brick floor finish. Upper-level walls exhibit mixed construction, preserving original adobe masonry in some sections while introducing fired-brick masonry with cement–sand mortar in others. Between these walls, buttresses of mixed stone and fired-brick masonry are bonded with lime–sand mortar. These are topped by reinforced concrete posts that support a roof structure of steel trusses and galvanized metal sheets (see Figure 3).

4. Results: administrative timeline and deterioration processes

This section contextualizes the actions performed on the *troje* by examining the administrative and physical records of the hacienda found in the historical archive AHP-JE of the CNMH-INAH. At the time of this research (2024), these documents were preserved under the original name of the former hacienda (*Ex-Hacienda* de San Nicolás, currently the San Lorenzo Civil Cemetery). The records cover the period from 1970, when the remaining hacienda lands were expropriated by the Department of the Federal District (DDF), to 2009. The earliest documentation from this period corresponds to a formal report submitted to INAH regarding unauthorized restoration works (INAH 1970a). This indicates that the institution became aware of ongoing interventions at that time, which prompted administrative actions through on-site inspections. This early documentation also makes it possible to establish the original condition of the *troje*, which at that time still preserved its traditional materials and structural system (INAH 1970c). Table 1 presents the chronological records of administrative actions during 1970, as well as the associated deterioration processes and their consequences. This initial phase is particularly relevant, as it documents both the original state of the building and the first administrative responses to unauthorized interventions.

Table 1 – Administrative actions and deterioration recorded in 1970

Date / Reference	Administrative action	Type of deterioration
February 11, 1970 (INAH, 1970b)	Site inspection and testimony from the works supervisor regarding structural changes (Reported Nov 24)	Demolition of 15 rooms and stone-and-mud masonry of the formerly Hacienda; replacement with incompatible modern materials (brick/concrete) despite preservation of the chapel's Ex-hacienda (*troje* unaffected at the time of reporting)
February 18, 1970 (INAH, 1970a)	Formal report to INAH regarding arbitrary 'restoration' works	Alteration of architectural integrity of the urban setting by destroying original fabric of historic buildings within the *Ex-hacienda* (*troje* unaffected at the time of reporting)
December 7, 1970 (INAH, 1970c)	Site inspection and formal summons for rehabilitation plans following the detection of unauthorized and incompatible interventions	Assessment of the *troje* as well-preserved stone-and-mud masonry with original timber roofing; potential risk identified due to proposed conversion into a chapel without approved technical drawings
December 14, 1970 (INAH, 1970d)	INAH requested a formal technical briefing with DDF supervisors to address the intervention actions	Although there were institutional attempts to mitigate improper interventions through technical alignment on restoration methods, the resulting preventive mechanisms failed to achieve effective conservation

While the 1970 records document the initial condition of the *troje* and early administrative actions, the following documentation shown in Table 2 reflects the long-term effects of these processes, including structural deterioration, delayed interventions, and increasing risk of collapse. The documents shown in Table 1 and Table 2 provide an overview of the transformations experienced by the *troje* over a period of nearly four decades. Following the expropriation of the hacienda, the site was repurposed as a civil cemetery, and the existing structures began to be modified without prior notification to INAH. As a result, institutional inspections were conducted, confirming that demolition works had already taken place in the *Ex-hacienda*. At the time of the initial inspections in 1970, the *troje* itself had not yet been intervened. However, it was described as having a well-preserved timber roof structure. This contrasts with later documentation from 1989, which reports a metal roof, increased wall heights, and structural instability in the lateral walls (INAH 1989; 1990). Due to the absence of documentation between 1970 and 1989, these modifications were most likely carried out between 1970 and 1975, as supported by photographic evidence from 1975 (see Figure 1 and Figure 2). Despite requests for clarification from those responsible for the works in 1970, there is no record indicating that proper coordination or compliance was achieved. By 1990, technical assessments identified severe deterioration, including diagonal cracks (45°), settlements, and wall tilting, and even included a cost estimate for restoration. However, there is no evidence that any intervention was carried out.

Four years later, according to INAH (1994a), a partial collapse of the *troje* was reported, which is illustrated in Figure 4. Considering this, a new technical assessment was made, which confirmed differential settlements that likely produced the collapse of the south façade. The report concluded that, due to the damage state that can be observed in Figure 5, urgent intervention was required, including structural shoring and the development of an integral restoration project. Although an intervention proposal was prepared shortly after, no action was implemented.

By May 1995, local authorities formally requested authorization for either the demolition or rescue of the building due to the imminent risk of collapse. One year later, in June 1996, the CNMH-INAH denied

authorization for a proposed intervention project submitted by a private company, citing non-compliance with conservation criteria. Beyond this period, there is no record of restorative work. Aside from a 2009 permit for a water treatment plant next to the west façade, the building has not undergone formal intervention, leading to the progressive deterioration shown in Figure 6, Figure 7 and Figure 8.

Table 2 – Chronological record of administrative actions and associated deterioration processes (1989–2009)

Date / Reference	Administrative action	Type of deterioration
April 4, 1989 (INAH, 1989)	Official report documenting spatial alterations and structural instability	Evidence of early structural failure; height increase to accommodate a gabled roof; documented instability in the front and right lateral walls; building's original 16th-century proportions compromised by its conversion into a warehouse
January 30, 1990 (INAH, 1990)	Technical memorandum and restoration cost estimate providing a detailed structural diagnostic	Progressive material degradation; active structural instability including a 20cm stair separation, diagonal cracking (45°), and a wall tilt caused by soil settlement between the 4th and 5th axes; presence of biological growth (lichens) and moisture; despite façade decay and makeshift galvanized roof, the original 18th-century timber mezzanine remained in good condition
September 20-22, 1994 (INAH, 1994a; 1994b)	Urgent decree for structural shoring and integrated restoration planning	Increased risk of total collapse; differential settlements caused by a nearby artesian well (20m distance) resulting in severe fractures (45°), masonry fragmentation, and wall tilts; failure of the metal roof and identification of historical but structurally detached buttresses
October10-21, 1994 (INAH, 1994c; 1994d; 1994e)	Rapid emergency response sequence (commission, inspection, and formal proposal) triggered by a public report of structural collapse (in coordination with local authorities in Iztapalapa)	Confirmation of ongoing differential settlements requiring specialized soil studies; identification of early 20th-century buttresses as insufficient to stabilize the earthen walls; proposal (but not implemented solutions) to consolidate adobe masonry with brick tie-ins and treat timber with pentachlorophenol to combat biological decay
May 12-29, 1995 (INAH, 1995a; 1995b)	Formal petition for demolition authorization issued by the Iztapalapa Delegation to INAH	Advanced structural decay leading to the total restriction of access; local authorities prioritize public safety over heritage value, citing the "danger of collapse" of the earthen masonry walls
June 10, 1996 (INAH, 1996)	Official rejection of the intervention project submitted by a private firm	Prolonged exposure of the compromised structure due to inadequate project proposals; administrative refusal to authorize works that did not comply with conservation principles
March 23-27, 2009 (INAH, 2009a; 2009b)	Conditional feasibility granted for the construction of an adjacent Water Treatment Plant	Partial demolition of historic stone-and-mud boundary walls; transformation of the monument's setting despite "safeguarding" claims by the developers

5. Discussion

This section interprets these findings to identify underlying patterns, systemic issues, and broader implications for heritage management.

5.1 Management-Driven Patterns of Decay

The analysis of archival documentation and field observations reveals that the deterioration of the *troje* cannot be attributed to a single technical failure, but rather to a sequence of administrative decisions, omissions, and interventions carried out over several decades. The chronological correlation between documented actions and the building's physical condition allows for the identification of three main patterns in which management processes directly contributed to structural and material degradation.

5.1.1 Deterioration driven by delayed actions and institutional fragmentation

One of the most significant factors identified is the lack of timely intervention despite clear evidence of structural damage. As early as 1989 and 1990, official documents reported instability in the walls, presence of moisture, cracking, and differential settlement. However, no effective intervention was implemented following these assessments. This delay allowed existing pathologies to evolve into more severe structural problems, ultimately leading to partial collapses reported in 1994. This pattern suggests a disconnection between technical diagnosis and administrative response, likely influenced by fragmented institutional responsibilities and unclear coordination between authorities and stakeholders. The absence of prompt action in response to known risks has transformed manageable deterioration processes into critical structural failures. In this sense, deterioration was not only the result of material vulnerability, but also of inaction within the management system.

5.1.2 Incompatible interventions and lack of technical coherence

A second key factor is the introduction of incompatible materials and construction systems during earlier interventions, particularly those carried out around the 1970s. Archival evidence and current building analysis indicate that original earthen masonry was modified through the addition of reinforced concrete elements, steel roofing systems, and masonry using cement-based mortars. These changes introduced significant differences in stiffness, weight, and mechanical behavior between the original and new materials. In earthen architecture, such incompatibility can lead to stress concentrations, cracking, and loss of structural continuity. The observed fissures and failures in the *troje* are consistent with these phenomena (Pilar Vázquez, 2025). This situation reflects not only a lack of technical knowledge, but also the historical promotion of inadequate intervention criteria. As noted in restoration guidelines from the 1970s and 1980s, cracks in adobe walls were often treated using methods developed for stone materials, such as injections of lime–sand mortars with added cement (SEDUE 1984, quoted in Guerrero Baca and Uviña Contreras 2020, 146-147). Such approaches failed to consider the specific mechanical behavior of earthen systems, introducing material incompatibilities that could accelerate structural deterioration rather than mitigate it. Although contemporary conservation practices have advanced significantly, the case illustrates how earlier decisions, taken without adequate technical criteria, can have long-term negative consequences on structural stability.

5.1.3 External interventions and the loss of cultural and spatial integrity

The construction of new infrastructure in the immediate surroundings of the *troje*, particularly the water treatment plant authorized in 2009, represents a third form of impact linked to management decisions. While the project included certain measures intended to mitigate its effect on the historic structure, documentation indicates that construction activities had already begun prior to full authorization, and that elements of the original site, such as perimeter walls, were partially demolished (INAH, 2009). Beyond

physical damage, this type of intervention alters the spatial configuration, visual perception, and cultural significance of the heritage asset. The insertion of contemporary infrastructure within the historic context compromises the integrity of the architectural ensemble and reflects a prioritization of functional needs over heritage conservation. This highlights the absence of regulatory instruments capable of adequately protecting not only the building itself, but also its surrounding cultural landscape.

5.2 Regulatory and institutional challenges in earthen heritage conservation in Mexico

As noted in Section 3, Mexican heritage legislation (DOF, 1972) primarily bases its cataloging criteria on the time of construction, as well as on location within designated heritage zones or proximity to historically significant contexts, thereby overlooking construction materials and techniques in the legal protection process. This creates a contradiction, as earthen buildings of exceptional value may be legally protected due to their historical classification, yet receive insufficient attention if they are isolated, located outside recognized heritage areas, or simply overlooked, as is the case of the *troje* of San Nicolás Tolentino Buenavista. Since restoration projects are regulated by the INAH, which operates within this legal framework, interventions involving earthen construction systems tend to receive consistent oversight only when they are visible and formally recognized. In practice, this process often depends on the willingness of property owners or practitioners to request permits, as official supervision typically begins with this administrative step.

If a building is isolated and no permit is requested, INAH is often unaware of interventions until irreversible changes have already occurred. Furthermore, current legislation does not adequately address the specific complexities of earthen construction systems, and lacks clear technical guidelines tailored to their conservation. As a result, poorly conceived interventions, particularly those involving incompatible materials, can themselves become a source of deterioration. Such cases are common, as the introduction of rigid materials into systems such as adobe or rammed earth frequently leads to structural incompatibilities, especially in seismic regions. When materials with significantly different mechanical behavior are combined, the weaker system, typically the earthen structure, tends to fail, leading to progressive damage caused by the intervention itself.

In practice, few construction companies assume full responsibility for the design of restoration projects. Most interventions rely on contemporary materials that can negatively affect the original structure, and they are frequently carried out without adequate supervision, further aggravating the problem. While it is important to provide technical guidance to practitioners, it is equally necessary to raise awareness about the value of earthen heritage, which is often associated with perceptions of precariousness that hinder its conservation. Awareness efforts should extend beyond professionals to include workers and, most importantly, property owners, who ultimately make the key decisions regarding intervention and preservation.

5.3 Community participation and indigenous stakeholders in heritage management

The role of indigenous communities in heritage conservation processes remains a critical yet often overlooked dimension within heritage management frameworks. In the case of the *troje* of San Nicolás Tolentino Buenavista, its proximity to the *pueblo originario* of San Lorenzo Tezonco highlights the relevance of considering local stakeholders not only as passive observers, but as active participants in decision-making processes. This perspective is also supported by contemporary legal frameworks, such as the Cultural, Natural and Biocultural Heritage Law of Mexico City (GOCM, 2020), which establishes the obligation to consult indigenous communities (i.e., *pueblos originarios*) in decisions affecting their heritage and territory. However, the limited implementation of such frameworks in practice reveals a gap between regulatory intent and actual heritage management processes.

Consultation with indigenous communities in restoration projects should be understood as a fundamental principle, both from an ethical standpoint and within the broader framework of sustainable cultural management. Heritage sites are not merely architectural objects with historical or aesthetic value, they are

embedded within living social, symbolic, and territorial networks, where communities maintain ongoing relationships of memory, identity, and everyday use. In this sense, the exclusion of these communities from decision-making processes represents not only a technical omission, but also a form of cultural dispossession that reproduces historical patterns of marginalization. When restoration is approached solely as a material intervention, there is a risk of stripping heritage assets of their cultural meaning by neglecting their social and symbolic dimensions.

Incorporating community perspectives allows for the recognition of local knowledge, traditional practices, and culturally embedded meanings that cannot be fully understood through a purely technical lens. These forms of knowledge not only enrich the historical interpretation of heritage buildings, but can also contribute practical criteria for their conservation, use, and reinterpretation in the present. From this perspective, consultation is closely linked to the recognition of indigenous communities as rights-bearing subjects, in accordance with existing legal frameworks that establish their right to participate in decisions affecting their environment and cultural heritage. Moreover, community participation fosters processes of social appropriation, strengthening long-term conservation and reducing conflicts derived from interventions perceived as external or imposed.

6. Conclusions

This study demonstrates that the deterioration of the *troje* of San Nicolás Tolentino Buenavista cannot be understood solely as a consequence of material vulnerability, but rather as the result of long-term interactions between technical conditions and heritage management processes. By correlating archival documentation (1970–2009) with field observations, the research identifies a clear relationship between administrative decisions and progressive structural degradation.

Three key findings emerge from this analysis. First, delayed responses to documented structural risks allowed minor pathologies to evolve into critical failures, including partial collapses. Second, the introduction of incompatible materials, particularly rigid systems within earthen construction, generated mechanical imbalances that accelerated deterioration. Third, external interventions, such as the construction of nearby infrastructure, contributed not only to physical damage but also to the loss of spatial and cultural integrity. Together, these factors confirm that deterioration was cumulative and closely linked to management practices rather than to a single technical failure.

A central contribution of this study is the identification of heritage management itself as a potential risk factor. In contexts where coordination is lacking, protocols are unclear, or authorization processes are delayed, management may act as a threat rather than as a protective mechanism. This shifts the perspective from viewing conservation as a purely technical challenge to understanding it as a multidimensional process involving administrative efficiency, regulatory clarity, and technical knowledge. The case also highlights structural limitations within existing legal frameworks in Mexico, particularly the lack of specific guidelines for historic earthen constructions. This underscores the need for more integrated regulatory approaches that incorporate technical, administrative, and social dimensions of conservation. In parallel, the findings emphasize the importance of strengthening awareness among stakeholders, including local communities, practitioners and property owners, to ensure informed decision-making and appropriate interventions.

Finally, although no documents explicitly report seismic damage to the historic *troje*, the documented impact of the 1985 and 2017 earthquakes on earthen structures in Mexico suggests that such effects may have been underreported or overlooked. This points to gaps in documentation and damage assessment, reinforcing the need for more comprehensive evaluation methods that combine archival research with structural analysis. Overall, this study contributes to a broader understanding of how misaligned management systems can actively drive the deterioration of earthen heritage, highlighting the urgency of developing coordinated, technically informed, and context-sensitive conservation frameworks.

Proposed Adaptation of the GUT Criticality Matrix for the Maintenance Management of Concrete Pavements in Fuel Stations: A Comparative Approach between Mechanical Damage and Chemical Attack

Larissa GUIMARÃES[1], Marília ARAÚJO[2]

[1] Instituto Nova Engenharia, Brazil, englpcarneiro@gmail.com
[2] Instituto Nova Engenharia, Brazil, marilia@construpat.com.br

Abstract: The maintenance management of concrete pavements in fuel station networks requires rigorous prioritization of interventions within a context characterized by the simultaneous occurrence of pathological manifestations, operational risks, and budgetary constraints. The absence of hierarchical assessment tools specifically tailored to this type of infrastructure often results in delayed corrective actions, with significant technical, environmental, and economic impacts throughout the service life of the pavement system.

This study proposes the adaptation of the GUT Criticality Matrix (Gravity, Urgency, and Trend) for the maintenance management of pavements in fueling areas, integrating the assessment of mechanical damage and deterioration associated with chemical attack.

The methodology is based on a multi-case study conducted at 16 fuel stations, using a systematized visual inspection protocol that included the mapping of cracking, abrasion-induced wear, surface disintegration, and failures in joint sealing systems.

The research establishes differentiated weighting parameters capable of distinguishing operational safety risks from environmental risks and evaluates the effectiveness of the adapted matrix as a decision-support tool for defining preventive maintenance strategies.

The findings are applicable to concrete pavements in service subjected to highly aggressive environments, contributing to the improvement of maintenance management practices in infrastructures exposed to the combined action of cyclic loads and chemical agents.

Keywords: Maintenance Management; GUT Criticality Matrix; Concrete Pavements; Building Pathology; Fuel Stations.

1. Introduction

The deterioration of concrete pavements in operational areas represents a significant issue in infrastructure engineering, particularly when these systems are simultaneously subjected to intense mechanical loading and chemically aggressive environments (ACI 2013; FHWA 2015; Neville 2011). In fuel stations, this condition is especially critical, as fueling lanes are exposed to cyclic traffic from heavy vehicles and frequent contact with hydrocarbons and petroleum derivatives, creating a scenario conducive to the progressive degradation of concrete (Neville 2011; FHWA 2015).

The interaction between mechanical stresses and physicochemical processes promotes the development of pathological manifestations such as cracking, joint spalling, surface wear, and chemical contamination, compromising both the structural performance and durability of the pavement (Neville 2011; FHWA 2015, ASTM 2020). Furthermore, discontinuities such as joint sealing failures act as preferential pathways for the infiltration of aggressive fluids, intensifying deterioration mechanisms and potentially causing environmental impacts associated with subgrade contamination (FHWA 2015; DNIT 2004a).

In this context, the systematic identification and classification of pathological manifestations constitute fundamental steps for assessing pavement condition and planning effective maintenance strategies (ASTM 2020; DNIT 2004b). Methods based on standardized visual inspection, such as those established by ASTM

(ASTM D6433) and procedures from Departamento Nacional de Infraestrutura de Transportes (DNIT), enable the characterization of damage extent and severity, providing a consistent technical basis for decision-making (ASTM 2020; DNIT 2004b).

Concurrently, the maintenance management of infrastructure assets requires the incorporation of criticality and risk criteria in order to prioritize interventions under budgetary and operational constraints (ISO 2014). Decision-support tools such as the GUT matrix (Gravity, Urgency, and Trend) are widely used for problem prioritization, allowing not only the assessment of damage severity but also the urgency of intervention and the potential for deterioration over time (Kepner and Tregoe 1981; Seleme and Stadler 2010).

However, the traditional application of the GUT matrix in engineering systems presents limitations related to subjectivity in parameter assignment, especially when based solely on the evaluator's perception (Kepner and Tregoe 1981; Seleme and Stadler 2010). This limitation becomes even more critical in pavements exposed to combined deterioration mechanisms, in which the isolated assessment of physical severity may not adequately reflect the associated functional and environmental risks.

Given this context, this study proposes an adaptation of the GUT matrix for the maintenance management of concrete pavements in fuel stations, incorporating measurable physical parameters and objective technical criteria for criticality assessment. The developed methodology integrates the analysis of pathological manifestation severity with functional and risk aspects, aiming to reduce subjectivity in the decision-making process and to improve the prioritization of interventions in environments subjected to the combined action of mechanical loads and chemical agents.

2. Theoretical Framework

The deterioration of concrete pavements results from the interaction between physical, mechanical, and chemical mechanisms that progressively affect their structural and functional performance (ACI 2013; Neville 2011). Discontinuities such as cracks, joint failures, and surface degradation facilitate the infiltration of water and aggressive substances, contributing to the progression of deterioration and the reduction of pavement service life (ACI 2013; ABNT 2014). In operational areas subjected to cyclic traffic from heavy vehicles and exposure to hydrocarbons, such as fuel stations, damage associated with mechanical loading coexists with processes related to infiltration and chemical degradation of concrete (ACI 2013; Neville 2011). The simultaneous action of these mechanisms may intensify deterioration and compromise the structural integrity and durability of the pavement over time.

Repeated exposure to fuels and petroleum derivatives may promote chemical attack processes within the cementitious matrix. Although hardened concrete exhibits relative stability when exposed to pure mineral oils, commercial fuels often contain organic compounds capable of reacting with cement hydration products, particularly under oxidative conditions or in the presence of acidic fractions associated with biodiesel blends (Neville 2011). These reactions may lead to partial dissolution of the cement paste, increased capillary porosity, and reduced surface strength, thereby favoring progressive degradation of the concrete (ACI 2013).

In this context, a combined deterioration mechanism is established, in which physicochemical processes and mechanical loading act synergistically. Surfaces previously weakened by chemical attack become more susceptible to abrasion and spalling when subjected to stresses induced by heavy vehicle traffic (FHWA 2015). Additionally, structural discontinuities such as cracks or poorly sealed joints may act as preferential pathways for infiltration, facilitating the percolation of aggressive fluids and contributing to support loss phenomena, such as fines pumping (DNIT 2004a; Neville 2011).

The evaluation of rigid pavement condition is based on the systematic identification and classification of pathological manifestations, constituting a fundamental step in characterizing its structural and functional state. Technical standards such as ASTM D6433 and Departamento Nacional de Infraestrutura de Transportes (DNIT 061/2004) establish standardized criteria for visual inspection and defect classification

based on their extent and severity, recognizing these parameters as key indicators of pavement condition (ASTM 2020; DNIT 2004b). The application of these criteria enables an objective characterization of the physical state of the structure and provides a consistent technical basis for maintenance planning.

Beyond physical condition, infrastructure asset maintenance management requires consideration of functional criticality and the risk associated with deterioration progression. The guidelines of International Organization for Standardization (ISO 55000) establish that maintenance decisions should integrate asset condition assessment with operational impact and risk level, aiming to ensure performance and reliability (ISO 2014).

In this context, prioritization tools are frequently employed to support decision-making processes in maintenance management. Among these, the GUT matrix (Gravity, Urgency, and Trend) stands out, as its structure enables the ranking of problems based on damage severity, urgency of intervention, and the trend for deterioration over time, constituting a widely used tool in management and criticality analysis processes (Kepner and Tregoe 1981; Seleme and Stadler 2010).

3. Methodology

3.1 General Structure of the Proposed Method

The proposed method consists of adapting the GUT matrix (Gravity, Urgency, and Trend) for the classification of the criticality of pathological manifestations in concrete pavements, based on the integration of measurable physical deterioration parameters, operational criteria, and risk-related aspects. The structure of the method was developed with the objective of reducing the subjectivity associated with the traditional application of the GUT matrix, establishing objective and reproducible technical criteria for prioritizing maintenance interventions, in accordance with the asset management principles established by International Organization for Standardization (ISO 55000) (ISO 2014).

The proposed adaptation is based on the introduction of the Pathological Condition Index (ICP), defined as the product of three independent parameters that characterize the observed condition of the pathological manifestation: extent (E), intensity (I), and functional impact (F). The extent parameter represents the proportion of the affected area relative to the analyzed functional area, while intensity describes the level of observed physical degradation, and functional impact represents the influence of the pathological manifestation on pavement performance and functionality.

The Pathological Condition Index (ICP) is determined according to Equation (1):

$$ICP = E \times I \times F \tag{1}$$

The ICP does not replace the normative severity classification defined by ASTM D6433; rather, it constitutes a complementary index specifically developed to support prioritization processes in asset management by integrating physical and functional parameters into a single metric.

In the proposed method, Gravity (G) is not assigned directly through qualitative judgment, as in the traditional application of the GUT matrix. Instead, Gravity is derived from the Pathological Condition Index (ICP), establishing a correspondence between the measurable physical condition of the pathological manifestation and the severity level used in the matrix.

The relationship between the Pathological Condition Index and Gravity is defined through a discrete classification function, as represented in Equation (2), in which G corresponds to the assigned gravity level and ICP represents the index calculated based on measurable physical parameters.

$$G(ICP) = \begin{cases} 1, & \text{if } 1 \leq ICP \leq 5 \\ 2, & \text{if } 6 \leq ICP \leq 15 \\ 3, & \text{if } 16 \leq ICP \leq 30 \\ 4, & \text{if } 31 \leq ICP \leq 60 \\ 5, & \text{if } 61 \leq ICP \leq 125 \end{cases} \tag{2}$$

Based on the obtained values, gravity can be classified according to Table 1.

Table 1 – Gravity (G) Classification as a Function of the Pathological Condition Index (ICP)

Pathological Condition Index (ICP)	Gravity (G)	Classification
1 to 5	1	Very Low
6 to 15	2	Low
16 to 30	3	Moderate
31 to 60	4	High
61 to 125	5	Very High

The final criticality of the pathological manifestation is obtained as the product of the three parameters of the GUT matrix, as presented in Equation (3):

$$\text{Criticality} = G \times U \times T \tag{3}$$

where G represents the severity of the pathological manifestation, derived from the Pathological Condition Index; U represents the urgency of intervention; and T represents the trend of deterioration progression, considering the physical mechanisms and exposure conditions that influence its evolution.

The proposed structure has a heuristic nature and was developed based on risk engineering principles and the operational logic of the GUT matrix. The adoption of a multiplicative formulation for the Pathological Condition Index is grounded in the interdependent nature of the parameters extent, intensity, and functional impact, in which the combination of high values results in a non-linear increase in severity, reducing compensation effects between variables that are common in additive approaches. Similarly, the criticality defined as the product of Gravity, Urgency, and Trend maintains consistency with the classical structure of the GUT matrix, preserving the combined influence of the factors that govern the prioritization of interventions.

The adopted scales reflect the nature of the evaluated parameters: extent, intensity, and functional impact represent discrete states of observable physical condition and were defined in four levels, in order to balance discrimination capability and field reproducibility. In turn, the parameters Urgency and Trend, associated with decision-making and damage progression, were defined in five levels, allowing greater sensitivity in differentiating operational scenarios and deterioration regimes.

The conversion of the Pathological Condition Index into Gravity levels was established through increasing ranges that preserve the hierarchy of observed deterioration and allow its compatibility with the GUT matrix scale. The final classification of criticality was structured into four priority levels, aiming to simplify the application of the method in maintenance management while enabling clear definition of intervention strategies, without compromising the model's sensitivity, which is ensured by the preceding calculation stages.

3.2 Pathological Manifestations and Condition Assessment Parameters

The pathological manifestations considered in this study were selected based on systematized visual inspections carried out on concrete pavements in fuel stations, identifying the most relevant occurrences in terms of frequency and functional impact. The identification and classification of these manifestations were

based on the terminology and criteria established by Departamento Nacional de Infraestrutura de Transportes (DNIT 060/2004), which defines the main defects in rigid pavements and their associated mechanisms (DNIT 2004a).

Based on these criteria and on field-observed conditions, the following pathological manifestations were considered: joint sealant failure, joint spalling, cracking, corner break and localized failures, surface wear, and superficial chemical contamination.

The characterization of the physical condition of each pathological manifestation was performed through the classification of the parameters extent (E), intensity (I), and functional impact (F), as defined in Section 3.1.

The extent parameter (E) was defined as the relative proportion of the element affected by the pathological manifestation, in accordance with deterioration assessment criteria based on damage extent established by ASTM (ASTM D6433) (ASTM 2020). The adopted classification is presented in Table 2.

Table 2 – Classification of the Extent Parameter (E)

Classe	Relative extent of the affected element
1	Up to 10% of the affected element
2	Between 10% and 30%
3	Between 30% and 60%
4	Greater than 60%

The intensity parameter (I) represents the level of observed physical degradation and is defined based on measurable characteristics such as crack width, depth of material loss, and degree of surface deterioration, in accordance with the severity criteria established by ASTM (ASTM D6433) and concrete durability guidelines (ACI 2013; ASTM 2020). The adopted criteria are presented in Table 3.

Table 3 – Classification Criteria for the Intensity Parameter (I)

Pathological Manifestation	Low (1)	Moderate (2/3)	Critical (4)
PM 01 – Joint Sealant Deficiency	Sealant with superficial cracks, still adhered	Dried sealant or partial loss of adhesion / Sealant with continuous failures	Sealant absent
PM 02 – Joint Spalling	Depth less than 5 mm	Depth less than 5 mm / Between 5 mm and 20 mm	Depth greater than 20 mm
PM 03 – Cracking	Crack width < 0.3 mm	0.3–1.0 mm / 1.0–3.0 mm	> 3,0 mm
PM 04 – Corner Break and Localized Failure	Depth < 10 mm	Depth between 10 mm and 25 mm / Between 25 mm and 50 mm	Severe loss, depth > 50 mm or affecting a large portion of the slab thickness
PM 05 – Surface Wear	No significant aggregate exposure	Partial aggregate exposure / Generalized exposure	Significant loss of surface thickness

Pathological Manifestation	Low (1)	Moderate (2/3)	Critical (4)
PM 06 – Superficial Chemical Contamination	Staining without texture alteration	Visible with slight alteration / Impregnation with surface texture alteration	Severe impregnation with signs of concrete degradation

The functional impact parameter (F) represents the influence of the pathological manifestation on pavement performance, considering aspects such as infiltration, loss of support, and impairment of load transfer. This parameter allows the incorporation of functional effects associated with the observed damage into the physical assessment (ACI 2013; Neville 2011). The adopted criteria are presented in Table 4.

Table 4 – Classification Criteria for the Functional Impact Parameter (F)

Pathological Manifestation	Low (1)	Moderate (2/3)	Critical (4)
PM 01 – Joint Sealant Deficiency	No evidence of infiltration / Potential infiltration	Visible infiltration / Presence of fines or contamination within the joint	Evidence of loss of support, pumping, or associated structural degradation
PM 02 – Joint Spalling	No significant functional impact	Minor interference in load transfer / Significant interference	Evident functional loss or structural impairment of the joint
PM 03 – Cracking	Superficial crack without immediate functional impairment	Visible infiltration / Presence of associated degradation	Structural impairment or slab instability
MP 04 – Corner Break and Localized Failure	Potential impact without instability	Onset of local integrity loss / Compromise of slab corner stability	Significant structural impairment or risk of progressive failure
PM 05 – Surface Wear	Potential impact on durability	Increased surface permeability / Impairment of surface strength or texture	Significant functional impairment with associated structural risk
PM 06 – Superficial Chemical Contamination	Potential impact on surface durability	Localized functional alteration / Impairment of surface durability	Significant degradation with risk of progressive deterioration

The combined classification of the extent, intensity, and functional impact parameters enables an objective characterization of the physical condition of pathological manifestations, providing a consistent technical basis for the calculation of the Pathological Condition Index and the subsequent evaluation of criticality according to the proposed method.

3.3 Urgency and Trend Classification

In addition to the physical severity of the pathological manifestation, the prioritization of interventions must consider operational factors and the likelihood of deterioration progression. In this context, the Urgency (U)

and Trend (T) parameters were defined based on observable technical criteria, incorporating functional, regulatory, and environmental aspects into the criticality assessment, in accordance with the asset management principles established by International Organization for Standardization (ISO 55000) (ISO 2014).

In this adaptation, the Urgency parameter does not represent the relative importance of the assessed area, since fueling lanes present a homogeneous intrinsic operational criticality. Instead, it represents the available time window for intervention before the evolution of the pathological mechanism to functionally or environmentally critical degradation states, in line with condition-based maintenance and asset management principles established by ISO 55000.

The Trend parameter (T) represents the rate and likelihood of future deterioration progression and is defined based on the active pathological mechanisms and exposure conditions. This parameter is defined independently of the current severity level and reflects the intrinsic kinetic behavior of the degradation mechanism under prevailing environmental and operational conditions, in accordance with durability and deterioration principles established by the American Concrete Institute (ACI 201.2R-13) and the classical literature on construction pathology. The technical criteria adopted for assigning these parameters are presented in Table 5.

In the present model, aspects related to environmental risk are not treated as an independent variable but are incorporated into the Urgency (U) and Trend (T) parameters. Urgency reflects the need for intervention in view of the potential for short-term functional and environmental impairment, while trend incorporates the progression dynamics of deterioration associated with exposure to aggressive agents, such as hydrocarbons. Thus, manifestations with potential for infiltration or contamination tend to assume higher values in these parameters, reflecting their greater environmental impact. In this way, environmental risk is considered in an integrated manner within the criticality assessment process, in accordance with a risk-based management approach.

Table 5 – Measurable Criteria for the Urgency (U) and Trend (T) Parameters

Parameter	Low Range (Scores 1–2)	Moderate Range (Score 3)	Severe/Critical Range (Scores 4–5)
Urgency (U) *(Context, Timeframe, and Standards)*	Long term: Damage with slow progression, with no expectation of functional, structural, or environmental impairment in the short term	Medium term (serviceability limit state reached): Damage with potential to evolve into functional or environmental impairment in the medium term	Immediate action (zero timeframe): Damage with a high probability of rapidly evolving into functional, structural, or environmental impairment
Trend (T) *(Kinetics under Traffic)*	Stabilized / Slow: Inactive progression (e.g., old shrinkage cracks) or long-term natural wear.	Linear: Continuous mechanical degradation, progressing proportionally to traffic volume	Exponential: Accelerated dynamics (e.g., fines pumping, or continuous chemical dissolution)

The final criticality is determined as the product of Gravity, Urgency, and Trend, as defined in Equation (3). Based on the obtained values, criticality was classified into priority levels for intervention, as presented in Table 6, enabling the consistent application of the method in maintenance management.

Table 6 – Criticality Classification

Criticality Range	Classification
1 – 15	Low
16 – 40	Moderate
41 – 80	High
81 – 125	Critical

3.4 Field Application of the Method

The proposed method was applied to concrete pavements in sixteen operating fuel stations located in the state of Bahia (Feira de Santana, Candeias, Lauro de Freitas, Imbassaí, and Camaçari), a region with a tropical climate characterized by high temperatures and a seasonal rainfall regime. The stations were selected based on the operational representativeness of fueling areas subjected to mixed traffic and exposure to potentially aggressive agents.

The analyzed pavements consist of cast-in-place concrete slabs with distribution reinforcement (welded wire mesh) and a typical thickness of 20 cm. It was observed that four units are between 5 and 10 years old, while the remaining ones are over 10 years old. It is noteworthy that no structured record of recent maintenance was available for the analyzed pavements.

The inspections were conducted in February by more than one evaluator with a background in civil engineering, using a standardized inspection form in accordance with the procedures established by ASTM (ASTM D6433) (ASTM 2020).

For each occurrence, the parameters extent (E), intensity (I), and functional impact (F) were determined, enabling the calculation of the Pathological Condition Index and Gravity. Subsequently, the Urgency (U) and Trend (T) parameters were assigned, allowing the calculation of criticality. The data were organized into a structured database, enabling comparative analysis between manifestations and evaluated units.

4. Results and Discussion

4.1 Database Structuring

The application of the proposed method resulted in the structuring of a database containing records of the pathological manifestations identified during the inspections carried out on the evaluated pavements. For each occurrence, the parameters extent (E), intensity (I), and functional impact (F) were organized according to the criteria defined in Section 3, enabling an objective characterization of the physical condition and the calculation of severity and criticality indices.

Table 7 presents an example of the data structure used for the classification of pathological manifestations in one of the evaluated pavements.

Table 7 – Database structure for the classification of pathological manifestations

Station	Pathological Manifestation	Extent (E)	Intensity (I)	Functional Impact (F)
S011	Joint Sealant Deficiency	4	4	3
S011	Joint Spalling	1	1	2

4.2 Calculation of the Pathological Condition Index and Gravity

Based on the structured data, the Pathological Condition Index (ICP) was calculated for each identified pathological manifestation using the parameters extent (E), intensity (I), and functional impact (F). From the ICP value, Gravity (G) was assigned, followed by the determination of the Urgency (U) and Trend (T) parameters, enabling the calculation of criticality according to the proposed method.

The adoption of maximum criticality values as an analytical parameter is grounded in a conservative asset management approach. In infrastructures susceptible to environmental liabilities and structural failures, the prioritization of interventions must necessarily be guided by the highest operational risk scenario (worst case), ensuring that acute manifestations are not underestimated or diluted by global statistical averages of the pavement.

The parametric conversion of physical degradation into discrete numerical indices ensures that pathological manifestations of different natures are assessed under a unified risk metric, mitigating the subjective biases inherent to purely visual inspection. Table 8 presents the structure used for determining these parameters in one of the evaluated pavements.

Table 8 – Example of ICP and criticality calculation

Station	Pathological Manifestation	E	I	F	ICP	G	U	T	Criticality
S011	Joint Sealant Deficiency	4	4	3	48	4	3	3	36 (Moderate)
S011	Joint Spalling	1	1	2	2	1	1	3	3 (Low)
S011	Superficial Chemical Contamination	3	3	4	36	4	3	4	48 (High)

4.3 Criticality Classification of Pathological Manifestations

The application of the proposed method enabled the classification of the criticality of pathological manifestations identified in the evaluated pavements, allowing for comparative analysis among different types of deterioration. The results revealed variations in criticality as a function of the deterioration mechanism and the associated functional impact.

Preliminary analysis of the calculated criticality values indicates that manifestations associated with surface deterioration and chemical exposure tended to present higher criticality levels than those predominantly related to mechanical deterioration. This behavior suggests that the proposed method is capable of distinguishing different deterioration mechanisms according to their potential impact on pavement performance and durability.

Table 9 presents the consolidation of the obtained results, considering the maximum criticality values observed for each type of pathological manifestation.

Table 9 – Criticality classification by type of pathological manifestation

Pathological Manifestation	Maximum Observed Criticality	Classification
Joint Sealant Deficiency	36	Moderate
Joint Spalling	12	Low
Cracking	27	Moderate
Corner Break and Localized Failure	18	Moderate
Surface Wear	48	High
Superficial Chemical Contamination	60	High

The results reveal variations in criticality levels as a function of the nature of the manifestation and its associated functional impact, showing that certain manifestations reached high classifications, while others remained predominantly within low to moderate levels. The obtained classification demonstrates that the method enables the discrimination of different deterioration patterns based on objective criteria, establishing a consistent technical basis for the interpretative analysis presented in the subsequent section.

4.4 Comparative Analysis between Mechanical Damage and Chemical Attack–Related Deterioration

The consolidation of the results presented in Table 9 highlights distinct patterns of behavior between predominantly mechanical manifestations and those associated with loss of watertightness and exposure to aggressive chemical agents. Mechanical-type manifestations exhibited maximum criticalities classified between low and moderate. Although such pathologies may compromise local structural performance, their progression was shown to be primarily linked to mechanical loading imposed by cyclic traffic, with evolution conditioned by stress redistribution and the integrity of slab support, as described in the technical literature on rigid pavements.

In contrast, manifestations associated with joint sealant failure and superficial chemical contamination reached higher criticality levels, including high classifications. A greater influence of these mechanisms was observed on the Urgency (U) and Trend (T) parameters, particularly when associated with the risk of infiltration of aggressive fluids and the acceleration of concrete degradation processes. This behavior is consistent with durability principles established by the American Concrete Institute (ACI), according to which the ingress of aggressive agents is a determining factor in intensifying deterioration and reducing the service life of the material.

From a pathological perspective, the inherently aggressive environment of fuel stations amplifies the criticality of these surface anomalies. Chronic spillage of hydrocarbons, especially commercial mixtures containing biodiesel fractions, induces oxidation reactions that release organic acids onto the pavement surface. These compounds react directly with portlandite (calcium hydroxide) in the cementitious matrix, leading to dissolution and softening of the hardened paste. Consequently, the concrete exhibits reduced abrasion resistance and increased capillary porosity, becoming a highly permeable medium. This irreversible degradation cycle increases the Trend (T) parameter in the adapted matrix, highlighting the severity of chemical exposure.

The comparison between the groups indicates that, while mechanical damage is predominantly related to immediate structural performance, manifestations associated with chemical attack present a greater potential for progression and cumulative impact on system durability. This distinction reinforces the importance of considering the dominant deterioration mechanism when interpreting the obtained criticality levels, validating the adoption of management protocols that prioritize the restoration of system watertightness as a primary conservation premise.

4.5 Applicability of the Method for Intervention Prioritization

The application of the adapted method enabled the systematic classification of the criticality of the observed pathological manifestations, allowing the prioritization of interventions based on objective technical criteria.

The analysis of the set of evaluated manifestations across the 16 fuel stations indicates that, although most occurrences present criticality levels ranging from low to moderate, the highest values are concentrated in specific manifestations, particularly those associated with surface wear and superficial chemical contamination.

When analyzing the maximum criticality per pavement, as presented in Table 10, it is observed that all evaluated units fall within moderate to high priority levels, indicating that the presence of these higher-impact manifestations is a determining factor in defining overall criticality.

Table 10 – Criticality classification by pavement

Station	Maximum Criticality	Priority Classification	Station	Maximum Criticality	Priority Classification
S001	36	Moderate	S009	36	Moderate
S002	36	Moderate	S010	36	Moderate
S003	36	Moderate	S011	48	High
S004	18	Moderate	S012	36	Moderate
S005	60	High	S013	36	Moderate
S006	36	Moderate	S014	36	Moderate
S007	36	Moderate	S015	36	Moderate
S008	60	High	S016	36	Moderate

The consolidated results reinforce the distinction previously observed between assessments based solely on physical severity and those grounded in an integrated risk analysis. The practical relevance of the proposed methodological adaptation is evidenced by the reallocation of intervention priorities when considering combined environmental and mechanical risk. From the perspective of a traditional GUT matrix, manifestations with high visual impact, such as cracking, would tend to be prioritized. However, the obtained results indicate that manifestations associated with loss of watertightness and chemical contamination assume greater relevance in intervention prioritization, highlighting a divergence from conventional approaches predominantly based on visual severity.

This behavior is attributed to the direct influence of these manifestations on the Urgency (U) and Trend (T) parameters. The absence of adequate sealing not only constitutes the root cause for the onset of pumping phenomena and the consequent loss of slab support, but also acts as a direct pathway for subgrade contamination by hydrocarbons.

From a maintenance management perspective, the proposed method may also support the optimization of maintenance planning by directing available resources toward manifestations with greater deterioration potential and associated environmental risk. This approach enables more efficient allocation of maintenance budgets and may contribute to reducing the need for extensive corrective interventions through earlier and more targeted preventive actions.

The results are consistent with established technical practice in pavements subjected to aggressive operational environments, reinforcing the applicability of the method as a robust decision-support tool aligned with durability principles and risk-based management.

5. Conclusion

This study presented an adaptation of the GUT matrix for the maintenance management of concrete pavements in fuel stations, grounding the Gravity (G) parameter in a Pathological Condition Index based on measurable physical parameters. The proposed structure reduced the subjectivity inherent in the traditional application of the tool and improved the consistency and reproducibility of criticality classification.

The application of the method in sixteen operational units demonstrated its feasibility under real service conditions and enabled a comparative assessment of predominantly mechanical damage and manifestations associated with loss of watertightness and chemical attack. The results indicated that, while mechanical damage tends to produce localized structural effects governed by traffic loading, manifestations related to infiltration and chemical contamination exert a greater influence on urgency and deterioration trend, reflecting a higher potential for long-term degradation.

The findings demonstrate that integrating physical severity, operational context, and deterioration potential provides a more comprehensive assessment of pavement condition than approaches based solely on visible damage. The proposed model therefore constitutes a robust technical framework for intervention prioritization in environments exposed to the combined action of cyclic loads and chemical agents, consistent with asset management and concrete durability principles. Although the method demonstrated applicability under real operating conditions, the study was limited to sixteen fuel stations within a specific geographic context. Future studies involving larger datasets, different climatic conditions, and long-term monitoring may contribute to further validating and refining the proposed classification framework.

Abstract: This paper proposes a data structuring framework for as-built BIM models, focusing on asset management and risk mitigation in fire protection systems. The research advances the transition from geometry-centric to systems-centric models, enabling the visualization of functional interdependencies among components. The methodology utilizes the Navistools plugin to establish a link between Autodesk Navisworks and an external SQL-based database. This integration facilitates the management of extensive metadata, including asset hierarchies, unique identifiers (GUIDs), and dependency parameters. Validation was conducted at the José de Alencar Theater, a landmark public building in Brazil requiring precise Operation and Maintenance (O&M) strategies. Results demonstrate the effectiveness of visual management in simulating failure scenarios, highlighting cascade effects within detection and suppression loops. Through color-coded viewpoints and status tables, it becomes possible to instantaneously identify zones affected by the inoperability of specific elements, such as pumps or control valves. This data structuring approach enhances decision-making in both emergency and maintenance contexts, promoting operational efficiency and proactive risk mitigation.

1. Introduction

Construction asset information must be properly structured to support decision-making during the operation and management phase (Nicał and Wodyński, 2016). In this context, a common database is required to store the information needed throughout the various stages of Architecture, Engineering, and Construction (AEC) and Operation and Maintenance (O&M) (Spilling, 2016). Building Information Modeling (BIM) can enable this information to be stored within a single digital model (Love et al., 2015). However, several difficulties are observed, such as fragmented information, inadequacies in building management (Tsay, Staub-French, and Poirier, 2022), and the slow issuance of work orders (Gao and Pishdad-Bozorgi, 2019). Other challenges relate to the lack of clear roles within the organizational team and the exchange of information between the BIM model and the facility management system (Matarneh et al., 2019).

Nevertheless, BIM remains a transformative technology in the field of facility management (Salzano et al., 2023; Peng, Au-Yong, and Myeda, 2024). A BIM model works as a shared knowledge tool, forming a reliable basis for decision-making during the facility's life cycle (Farghaly et al., 2018). The information required for Asset Management (AM) can be extracted from the model and linked to a database that stores information related to the built asset to form the Asset Information Model (AIM) (Kivits and Furneaux, 2013). The AIM becomes a set of information containers related to the operational phase (ABNT NBR ISO 19650-1, 2022), providing a fundamental basis for improving its management.

Studies by Harode, Ensafi, and Thabet (2022) propose a framework for defining the documentation, requirements, and procedures necessary to establish a systems-centric as-built BIM model. A model with multi-level building system classification allows the maintenance team to visualize components and their

system information in emergency situations. To mitigate fire damage in buildings, proactive management, prevention, and response activities are essential. In the stages preceding incident response actions, the inspection and monitoring of installation elements—such as sprinkler and alarm systems—are fundamental to effective facility management (Bae, Cha, and Jiang, 2025). However, the integration between BIM models and asset management faces semantic and taxonomic barriers (Pärn, Edwards, and Sing, 2017).

To address this issue, this study proposes a four-level structuring utilizing a SQL environment to direct data flows for fire protection system management. The objective is to develop an Asset Information Model (AIM) for smoke detection and fire protection systems to support maintenance management. The model is prepared to deliver the necessary information for critical operations and to address operational challenges, aiming at both safety and efficiency.

2. Theoretical Background

2.1 Information management on buildings

Building information models has the potential to support quick access to relevant data during emergency situations (Schönfelder et al., 2024). The semantic richness of elements and the information flow among project stakeholders characterize the application maturity (Succar, 2009). These flows must be perceived and designed, as their properties will define the characteristics of the databases and the platforms for access, input, and exchange. Thus, the definition of containers and their semantic structures are crucial stages for information and project management. Some approaches include the Information Container for Linked Document Delivery (ICDD) (ABNT NBR ISO 19650-1, 2022; Hagedorn et al., 2022) and its integration into a Common Data Environment (CDE) (Karlapudi, Prathap, and Menzel, 2021), incorporating languages such as SPARQL or SQL into asset information management (Kim et al., 2024) and guiding the choice of compatible platforms.

Leveraging the potential of computerized models requires properly structured information to mitigate interpretation errors and reduce response times. At the core of this data structure is the ontological definition, which assigns meaning to the labels of each element. This grouping task is vital for simplification; establishing systems and subsystems defines meaning based on interrelationships, breaking down complexity into smaller, more comprehensible clusters (Succar, 2009). This process can be defined as taxonomy, which is the description of terms and their relationship within a specific knowledge domain. Developing an object taxonomy can provide a common terminology that facilitates knowledge sharing, helps identify knowledge gaps in the field, and supports decision-making (Usman et al., 2017).

Data structuring plays a fundamental role in ensuring that building information models remain accessible and comprehensible for asset management teams (Ensafi, Harode, and Thabet, 2022). Modern buildings frequently incorporate highly complex and interconnected systems, including mechanical, electrical, security, and automation systems. In such environments, specialized teams are typically responsible for the operation and maintenance of individual systems. Given this multidisciplinary nature, organizing information requires distinct semantic frameworks tailored to the specific needs of each technical specialty.

The implementation of unique identifiers underpins data consistency, interoperability, and traceability throughout the facility life cycle, facilitating the integration of dynamic information flows (Kim et al., 2024) across web-based platforms (Hagedorn et al., 2023) and relational databases (Bae, Cha, and Jiang, 2025). Such methods for information allocation and organization are well-established within the field of data science. Specifically, Structured Query Language (SQL) serves as the industry-standard tool for developing and managing relational databases, offering robust logical frameworks for storing complex, interrelated datasets (Silberschatz, Korth, and Sudarshan, 2020). Integrating relational databases with digital building has become increasingly feasible through advancements in BIM. Such integration allows for the management of complex metadata tied to assets, streamlining hierarchical organization, dependency mapping, and life cycle monitoring (Wong and Lee, 2022; Hagedorn et al., 2023). As a result, BIM models are

shifting from geometric representations toward comprehensive information repositories that empower decision-making throughout the facility's operational life.

2.2 Fire Safety System Management

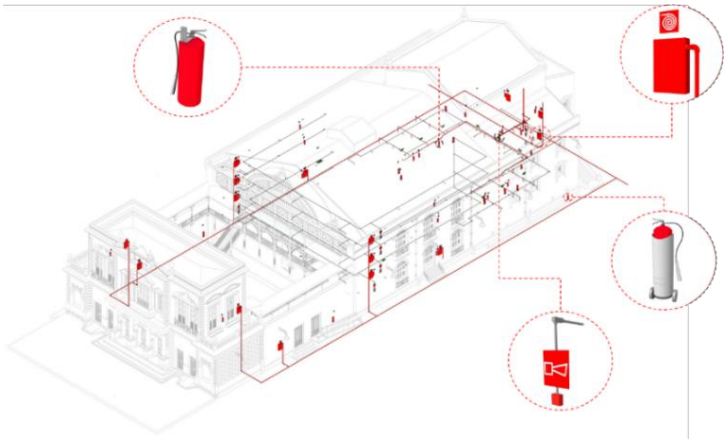
The incorporation of automated and intelligent approaches has expanded the role of BIM as a critical infrastructure for managing operational data, supporting essential maintenance activities (Wang et al., 2025) and improving process quality (Leygonie, Motamedi, and Iordanova, 2022). This is particularly relevant for Fire Safety Equipment (FSE), where long life cycles and high costs often lead to deficiencies in inspection and maintenance (Liu, Zhang, and Zhu, 2012). Since irregular inspections and outdated layouts can compromise protection and increase fire risks (Shafiq et al., 2022), the recurrence of discrepancies between management platforms and actual equipment status remains a significant challenge. Consequently, implementing automated structures for status verification within a BIM-based framework is essential to enhance the efficiency and reliability of fire safety systems (Lin et al., 2025; Pishdad-Bozorgi et al., 2018).

Maintenance management based on the individual identification and precise location of each equipment is essential in FSE. To this end, technologies such as GPS (Ergen, Akinci and Sacks, 2007), RFID (Elghamrawy and Boukamp, 2010), UWB (Teizer, Venugopal and Walia, 2008), and 3D LiDAR (Wang et al., 2022) are commonly used. However, these solutions may require additional devices, leading to increased costs (Brilakis, Park and Jog, 2011). In this context, BIM models derived from point clouds enable the representation of the built environment and the linkage of physical elements to their associated data, supporting both design and maintenance management.

Thus, BIM-FSE models contribute to improving the efficiency and effectiveness of inspections by providing structured equipment inventories, supporting navigation to the components, and enabling the systematic updating of information associated with fire system assets (Aziz et al., 2023). Complementarily, digital twins extend these capabilities by enabling the real-time representation of the conditions of physical systems, distinguishing themselves from traditional BIM models and supporting dynamic processes for decision-making and operational optimization (Opoku et al., 2021; Tuhaise, Tah and Abanda, 2023).

3. Methodology

Based on the As-Is model developed by Bessa, M. et al. (2025) (Figure 1), this methodology integrates document review, on-site technical diagnosis, and semantic enrichment to ensure a Level of Development (LOD) consistent with Operation and Maintenance (O&M) requirements. The study, conducted on the Fire Protection System of the José de Alencar Theater, focuses on a high-complexity section of the building. This approach facilitates the transition from a predominantly geometric representation to a systems-oriented Asset Information Model (AIM), specifically engineered for risk management and operational efficiency.



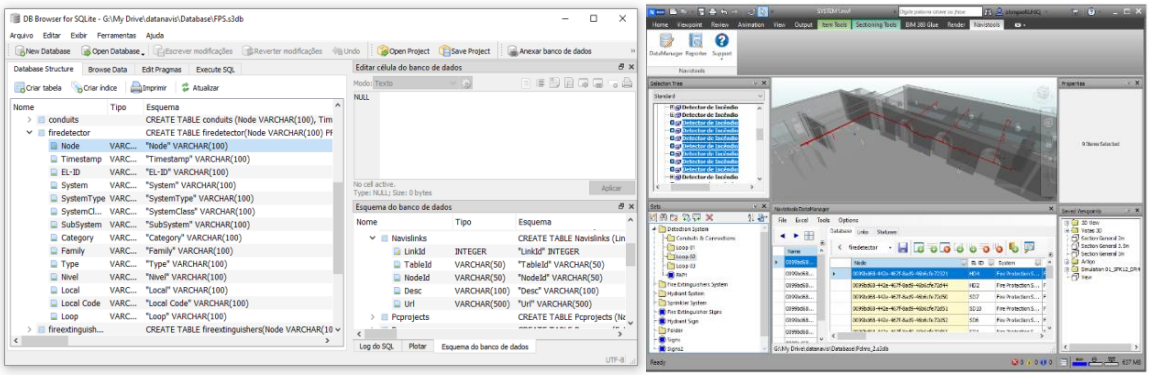


Figure 1 - BIM model of the fire protection system

The BIM model served as geometric and informational framework for the structuring and integration of data critical to O&M. This digital repository encompasses the primary fire protection subsystems: manual suppression (including portable and wheeled fire extinguishers); automatic water-based suppression (the sprinkler network); the Standpipe and Hose System (comprising hydrants and sectional control valves); and the detection and alarm systems.

3.1 Database Organization and Management

The implementation of a relational database linked to model elements enhances the flexibility and accessibility of system information, enabling the management of semantic richness and the selective sharing of data among stakeholders, with access control based on user profiles. This approach contributes to information security and improves communication throughout the building lifecycle. The adoption of SQL allows data and embedded intelligence to be structured and captured in an organized manner, facilitating queries, ensuring data integrity, and maintaining persistence beyond geometric files. The use of a unique primary key (GUID) mitigates errors and optimizes the processing and updating of records.

The database (Figure 2a) was developed in the .s3db format using DB Browser for SQLite (DB4S, 2024), adopting SQL version 3.0 due to constraints of the DataManager and Reporter plugin (Codemil, 2025), also known as NavisTools, which visually integrates data into Autodesk Navisworks. Figure 2b presents a section of the database (index “firedetector”) and the database schema, highlighting the linkage established by NavisTools through the “navislinks” table.

(a) (b)

Figure 2 - (a) Database structure interface in DB Browser for SQLite (b) Navisworks interface illustrating the NavisTools DataManager and Reporter visual platform.

3.2 Fire Protection System Taxonomy

The implementation of BIM for asset management necessitates a paradigm shift, transitioning from purely geometric requirements to the identification of data critical for operational success. Such information should be structured according to a pyramidal classification that spans from early project stages to the Operation and Maintenance (O&M) data gathered during the facility's lifecycle (Becerik-Gerber et al., 2012). To manage this complexity, taxonomies are employed to categorize system attributes and document portfolios, utilizing hierarchical classifications that prioritize spatial location, unique identifiers, and technical specifications (Farghaly et al., 2018). For critical systems like fire protection, a robust taxonomy is essential to ensure data management that supports rapid and accurate decision-making in high-occupancy venues, such as theaters and cinemas.

The taxonomic structure for the fire protection systems in this study follows the iterative ontology development process outlined by Noy and McGuinness (2001). After defining the domain and scope, the focus shifted from geometric data to critical non-geometric requirements. A four-level class hierarchy was then established, extending from the macro-system level (Fire Protection System) to element-specific

attributes (SubSystem Name). This structure ensures a distinct separation between broader domain knowledge and practical operational data.

3.3 Scenario Simulation

The creation of the loop property was intended to capture interdependencies within suppression and detection systems. By defining the LOOP parameter in SQL, the model facilitates the visualization of the "scale effect," allowing, for example, the identification of which sprinkler heads or detectors will be deactivated if a valve is isolated for maintenance (Figure 4). This approach is critical for risk mitigation, as it enables "what-if" analyses prior to any physical intervention. Mapping these loops ensures that the fire protection system is not indiscriminately deactivated, allowing preventive risk measures to be implemented in the affected zones during downtime while maintaining adequate protection in areas not impacted by maintenance activities.

3.4 Visual Management

The developed model provides an accurate graphical representation of the components and building systems. To achieve its informational role, the geometry, spatial orientation, and three-dimensional coordinates of the elements reflect as-is conditions, meeting appropriate Level of Development (LOD) and Level of Accuracy (LOA). The correct representation of in situ conditions enables O&M teams to locate, identify, and inventory assets across the entire building portfolio, reducing uncertainties and rework. In particular, for elements concealed behind walls, ceilings, or floors, reliable BIM models prevent unnecessary destructive interventions during corrective maintenance, renovations, or retrofits.

Within the Lean Construction framework, visual management—or Mieruka—is a fundamental principle for rendering complex information immediately accessible, thereby accelerating effective decision-making (Nguyen, 2009). By eliminating ambiguities and reducing the cognitive load required to interpret vast datasets, Mieruka transforms abstract information into intuitive, actionable visual cues. In this study, visual management serves as the interface that bridges the complexity of SQL-structured data with the Autodesk Navisworks coordination environment. This approach involves pre-configuring the model with specific viewpoints and operational scenarios designed to optimize Facility Management (FM) response. Consequently, highlighting a detection or suppression loop within the model, coupled with the identification of affected zones, allows for an instantaneous situational diagnosis.

4. Results

4.1 Database Management and Taxonomy

The database structuring ensured that the fire system's semantics were preserved independently of the original authoring platform. In this example application, 14 parameters were associated with the automatic sprinkler system (Table 1). Leveraging a database language contributes to both organization and customization, allowing each category—as defined by the management team—to receive a structure tailored to its intended use.

Among the associated parameters is the GUID (Globally Unique Identifier), which serves as the Primary Key for the SQL database. This ensures the semantic richness and information persistence advocated by Succar (2009). From an ontological perspective, the GUID functions as the defining attribute for the identity of the 'concept' (the fire asset), ensuring that the relationship between the geometric object in Navisworks and the non-geometric data in SQL remains unambiguous and imperishable.

Regarding structural adjustments for database management, the GUID is configured within the Navistools plugin as the 'Key Property.' This configuration enables a link (via DataManager) that automates data synchronization between the visual platform and the relational database. This eliminates information

redundancy and inconsistency—common challenges in delivering As-Built models for O&M—resulting in a model that supports updates without losing functional interdependencies."

Table 1 – Parameters, description and objectives in the cluster sprinkler (Level 4).

Parameter	Description	Objective
GUID	Permanent identifier that ensures the bidirectional link and integrity between the 3D geometry and the SQL database.	Data preserving
EL-ID	Secondary asset identifier based on the authoring software's native ID (e.g., Revit ID) for audit traceability.	Identification
SYSTEM	Level 1: Defines the building macro-system to which the asset belongs (e.g., Fire Protection).	System Property
SYSTEMTYPE	Level 2: Classifies the system by its primary function and functional grouping (e.g., Automatic Suppression)	System Property
CLASSIF	Level 3: Details the technology or operating method of the subsystem (e.g., Hydraulic Suppression).	System Property
SYSTEM NAME	Level 4: Identifies the specific technical name of the subsystem or network (e.g., Sprinkler System).	System Property
Category	Native object category in the BIM environment, used for standardizing filters and automatic groupings.	Class Property
Family	Identifies the technical template or design "family" that defines the object's graphical and functional properties.	Class Property
Type	Concise technical specification of the asset's model or variant within its family.	Class Property
Name	Human-readable description for rapid asset identification by field and management teams.	Communication
Local	Identification of the floor or physical location area of the asset within the building.	Rastreability
Local Code	Unique code of the environment (room/space) according to the project's official numbering plan.	Rastreability
***Loop* (Laço)**	Defines the operational "loop" or ring to which the asset is connected, allowing for the tracking of dependencies	Fail Analysis Impact
Installation Date	Historical record of the installation date for warranty control, service life, and technical depreciation..	Life Cycle
Days next task	Predictive parameter that calculates the remaining time until the next preventive maintenance, mitigating failure risks.	Risk Mitigation

The hierarchical structuring of the fire system serves as an ontological foundation that transitions the BIM model from a purely geometric representation to a systems-centric one. This hierarchy acts as a meaning-making mechanism, transforming isolated components into cohesive information clusters that make interdependencies explicit and reduce the cognitive load in asset management. In practice, this 'taxonomic understanding' allows facility managers at José de Alencar Theater to query the SQL database by functional classes rather than generic IDs—searching for 'Detection System - Loop 01' instead of an isolated element. This operational context facilitates rapid fault isolation and enables the automated creation of Selection Sets in Navisworks based on these defined levels (Figure 6a).

The 'Loop' parameter acts as a logical cluster that replicates the physical topology of the fire protection network. This allows the system to identify not only an equipment’s location but also its functional 'ring,' making explicit the interdependencies that cause cascade effects in maintenance or failure scenarios. The results demonstrate more agile and secure data handling, where access to technical information no longer requires physical manuals but occurs directly within the Navisworks.

Furthermore, a natural convergence exists between BIM and Data Science when efforts are directed toward creating a digital ecosystem with integrated data flows. Native parameters—such as category, family, and Element-ID—act as identity anchors, while SQL serves as an expansion medium, establishing a strategic decoupling between geometry and metadata. This architecture allows for the systemic enrichment of the asset without compromising the integrity of the original model, simplifying the complexity inherent in

overlapping maintenance data, standards, and performance metrics. Thus, database management acts as an algorithm for taxonomic organization, ensuring that information flows in a structured and persistent manner, transforming raw data into actionable intelligence for the building's life cycle.

4.2 Scenario Simulation

This section presents two scenarios demonstrating the practical application of a systems-centric BIM model in supporting emergency maintenance. To facilitate operational interpretation, the model employs a color-coded graphical representation (Figure 3), where each system and its respective operational loops are visually distinct. This configuration enables the immediate identification of systems and circuits involved in each simulated event, streamlining the analysis of the functional scope and impact of each occurrence.

Figure 3 - Integrated visualization of fire protection systems, with color coding to distinguish different systems and their respective operational loops

4.2.1 Emergency Simulation – SKP13 Activation (Room C DR4)

Using the viewpoints previously configured in the “Sprinkler System – Loop 02” folder, it was possible to automatically identify the components of the sprinkler system associated with Room C DR4, including pipes, fittings, sectional control valves, and terminal devices (Figure 4). To validate the system-oriented model, an emergency scenario was simulated involving the unintended activation of device SPK13, with the aim of evaluating the model’s capability to support the identification of the affected subsystem, the delimitation of the impact area, and the definition of hydraulic isolation actions.

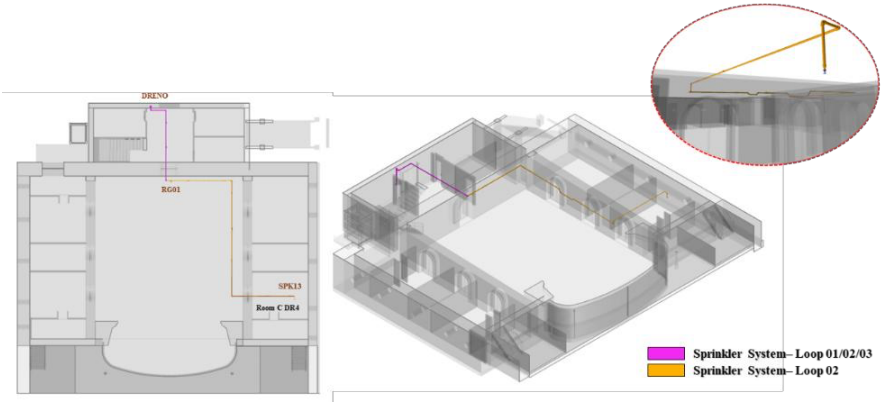

Figure 4 - Emergency simulation with activation of SPK13 and isolation of Loop 02 of the sprinkler system, including spatial tracking of the hydraulic network and identification of the sectional control valve.

In the analyzed scenario, SPK13 was identified as part of Loop 02, which serves devices SPK03 through SPK13. This loop-based organization allowed the automatic isolation—via the corresponding viewpoint—of all hydraulic circuit components, including branch lines, risers, fittings, and control valves, thereby clarifying the functional extent of the event. The analysis identified RG01 as the critical element for the complete

hydraulic isolation of Loop 02, where its closure isolates sprinklers SPK03 to SPK13. Post-isolation, the model facilitated spatial tracking of the piping route to SPK13, enabling the verification of critical network sections during leakages or localized failures (Figure 4). This functionality is vital for the targeted inspection of fittings, directional changes, vertical segments, and interfaces with other building systems.

4.2.2 Emergency Simulation – SD14 Activation (Room D DR1)

In this second emergency simulation, a fire event was triggered by detector SD14 within the building's detection and alarm system. During operation, the alarm control panel signaled an activation without immediate visual confirmation, necessitating the rapid identification of the triggered device, its associated room, the communication loop, and the specific addressing panel. Utilizing the pre-configured viewpoints for the detection system, the model automatically identified detector SD14, its precise spatial coordinates, and its corresponding location within Room D DR1.

Analysis indicated that SD14 belongs to Addressable Loop 03, enabling the operational response to be directed precisely to its corresponding control panel. This loop-based organization allowed for the automatic isolation of all devices within the circuit, facilitating the verification of potential communication failures or infrastructure degradation. Furthermore, the model enabled the tracking of Loop 03's conduit routing, from main segments to individual detector branches. This capability is essential for identifying critical points—such as directional changes, junctions, and shared segments—thereby supporting rapid on-site inspections during actual fire events (Figure 5).

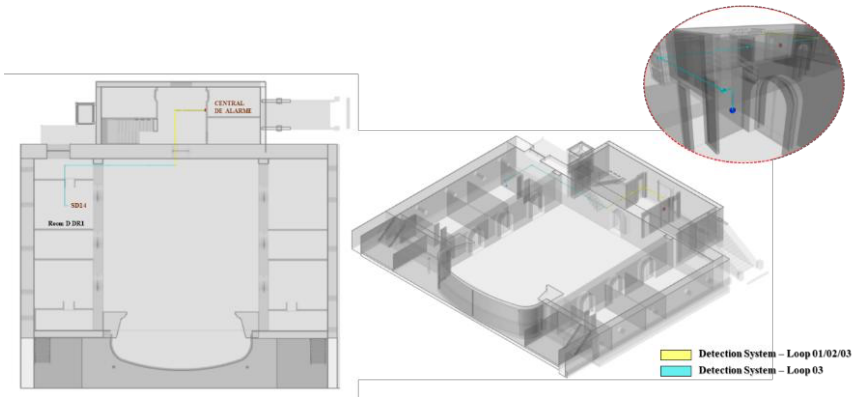

Figure 5 - Emergency simulation with activation of SD14 and isolation of Loop 03 of the detection system, including spatial tracking of the infrastructure.

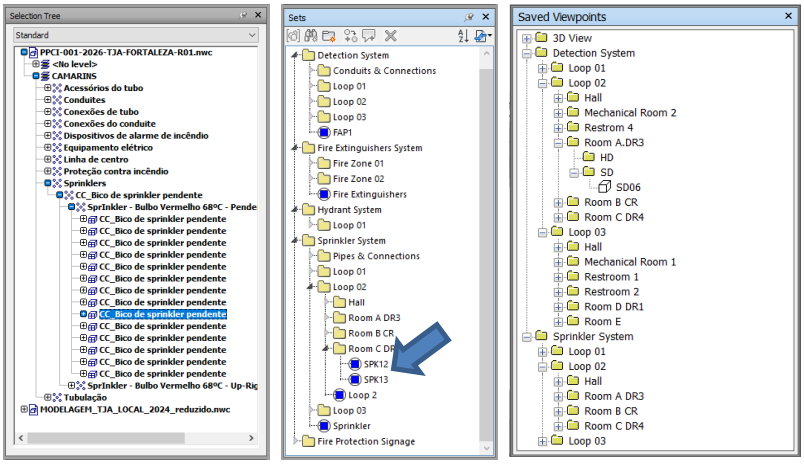

4.3 Visual Management

A systems-centric BIM model configured for O&M enables the application of rule-based filters to functional and relational attributes, allowing for the precise identification, isolation, and selective visualization of components during emergency events. By storing these dynamic visualizations as hierarchical viewpoints, *the model reorganizes navigation and supports rapid decision-making, aligning visual representations* directly with the building's operational logic (Figure 6b). This structure further highlights the interdependencies between multi-disciplinary components, facilitating cross-impact analysis and allowing facility management teams to instantaneously assess the relationships between technical systems, spatial configurations, and occupied areas during an incident.

The filters and search rules required to generate selection sets and viewpoints are defined during the model preparation phase for delivery to the owner, ensuring that, at the start of operation, the model is ready to support emergency response. In addition, new viewpoints can be incorporated throughout the building lifecycle to address operational demands or emerging risk scenarios. In this study, the viewpoints were hierarchically organized to support emergency maintenance, enabling navigation both by operational loop

and by the served space, facilitating the identification of circuits and the visualization of associated assets, such as smoke detectors (SD), heat detectors (HD), and infrastructure elements.

Each space is subdivided into asset-specific folders containing viewpoints that integrate the corresponding subsystem with the architectural model. In this way, viewpoints are simultaneously categorized by loop, space, and equipment type, providing multiple pathways to access operational information. It should be noted that, as this hierarchical structure is directly linked to the physical and functional configuration of the analyzed building, it is project-specific and must be adapted when applied to other facilities, as illustrated in Figure 6b.

Figure 6 – (a) Selection Tree window, representing the logical structure of the native source program; (b) Sets window for asset management; Viewpoints window for hierarchical organization by loops and spaces.

5. Conclusions

The study demonstrated that the integration between the BIM model and the SQL database, enabled by the NavisTools plugin, overcomes the Level 3 semantic interoperability challenges pointed out by Pärn et al. (2017). The use of GUID as a primary key ensured the persistence of the “semantic richness” encouraged by Succar (2009), allowing critical maintenance and lifecycle information to remain undamaged despite the volatility of geometric files. This decentralized data architecture proved to be an effective solution for managing complex assets, avoiding the overload of native models and facilitating the flow of information among stakeholders.

The application of a four-level functional taxonomy, combined with the methodology proposed by Noy and McGuinness (2001), enabled the transformation of the geometric model into a systems-centered AIM. The clustering of elements into operational loops simplified the inherent complexity of the fire protection system of the José de Alencar Theater. The results demonstrated that organizing data into clusters not only structures the asset inventory but also assigns functional meaning to assets, allowing the management team to instantly visualize interdependencies and impact zones in failure scenarios.

The structuring of viewpoints integrated with automated selection sets demonstrated the potential of Visual Management as a decision-support tool. The transition to an interface that associates non-geometric data (such as “Days to next task”) with 3D spatial representation optimizes response time in O&M activities. It is concluded that the proposed methodology transforms BIM from a static resource into a dynamic data ecosystem, essential for the proactive safeguarding of cultural assets of high social and artistic relevance, where technical accuracy is inseparable from heritage preservation.

Finally, this study contributes to the field of construction management by proposing a data science–driven approach that decouples geometry from information. This flexibility allows the database to be continuously expanded without interfering with the original BIM model, offering a viable and scalable pathway for managers to implement efficient digital asset management.

Abstract: This paper presents a data-driven methodological workflow for the analysis of visitor flows, applied to the architectural and landscape system of Pitti Palace and Boboli Gardens in Florence (Italy). This heritage site combines the periodic monitoring of stone façades – prone to deterioration and detachment – with high visitor pressure, as millions of people visit its five museums each year. The method relies exclusively on raw data already available to site managers, namely tabular records from the ticketing system, thereby ensuring transferability and privacy protection without visual user tracking. The analysis covers 18 months in 2024-2025 and begins with the selection and filtering of relevant variables, including entry times to the museums and ticket categories. The resulting dataset is processed through big data approaches combining unsupervised Machine Learning and statistical analysis, with a focus on identifying homogeneous clusters by overall attendance, seasonality, and user categories. For each cluster, temporal distribution analyses enable the identification of trends and outliers. The workflow can then be extended to infer visit sequences and dwell times by integrating on-site measurements of access durations and travel times among the site's museums, enabling the reconstruction of flow dynamics across the complex. The proposed workflow is intended to support site managers in decision-making processes to optimise visitor flows and address heritage conservation issues, while enhancing user safety and comfort.

Keywords: use of heritage; preventive conservation; people-centred approach; time-series analysis; crowding assessment

1. Introduction

The management of heritage site is increasingly recognised as a multidimensional challenge that extends well beyond the conservation of historical materials (UNESCO et al. 2013; UNESCO et al. 2026). People-centred and human-centred approaches to heritage conservation seek to balance the relationships between people, buildings, and landscapes, recognizing that the physical presence of users within heritage spaces constitutes a variable that shapes conservation outcomes (Wells 2020) and should be integrated into monitoring and preservation activities. The first core of these concepts relies on the Declaration of Amsterdam (ICOMOS 1975) and on the idea of integrated conservation, as an effort to adapt existing conservation approaches to the ever-changing challenges of the human environment (Houbart 2016). Within this framework, managing these dynamics becomes a structural component of preventive conservation and of strategies aimed at assessing risks, ensuring long-term preservation alongside safety and comfort (Vandesande and Balen 2018; Della Torre 2021; Moioli 2023).

This need is particularly urgent in high-attendance heritage sites such as large museum complexes, historic gardens, and architectural systems, where the requirements of physical conservation of both collections and buildings must be continuously reconciled with visitor experience, comfort and safety, managing

overcrowding conditions and heterogeneous visitor profiles. In such contexts, maintenance actions, monitoring campaigns and conservation works cannot be planned independently of visitor flows, since attendance regimes and circulation patterns directly influence operational feasibility of the work and the quality of the visitor experience. For instance, the impact of visitor density on material deterioration of collections and buildings represents a challenging area, with number of studies investigating the correlation between visitor presence and indoor microclimatic conditions (Camuffo 2019). More broadly, estimates of visitor intensity and visit duration provide practical exposure proxies for preventive planning, supporting the identification of critical time windows and sensitive areas where conservation measures and operational strategies should be prioritised. From this perspective, when visitor numbers reach the scale typical of major heritage sites, the relevant system extends beyond indoor museum rooms to include outdoor spaces, entrances, and connecting paths that structure flows across the site and its immediate surroundings. A systemic approach that looks beyond the museum threshold and encompass the urban public spaces is therefore not optional, but necessary.

The scale of this challenge is widely recognised, and major museums have begun to place visitor reception and spatial decongestion at the centre of their institutional strategies. A significant example is the Louvre Nouvelle Renaissance project, an ambitious redesign of one of the world's most visited museums, which focuses on improving the outdoor spaces, including the main square and the areas surrounding the complex (Louvre Museum 2026). Currently, research on visitor flow management in heritage sites has evolved along a distinct trajectory, drawing on technologies and methods primarily derived from urban mobility research and retail analytics within different scales. Bluetooth data (Versichele et al. 2014; Yoshimura, Krebs, and Ratti 2017), Wi-Fi sensors (Gao and Schmöcker 2021), GPS tracking, and video-based computer vision systems (Huang et al. 2020; Ding et al. 2023) have been used to reconstruct the spatial and temporal distribution of visitors across a range of heritage sites. At the urban scale, user-generated content and georeferenced reviews have supported the analysis of visitor behaviour in historic city centres (Girardin et al. 2008; Barrena-Herrán, Modrego-Monforte, and Grijalba 2025), while at a territorial scale, open-source data from platforms have been used to map tourism distribution and identify patterns of spatial concentration (Bishop et al. 2025; Paliska, Brezovec, and Sedmak 2026). More recent methodological frameworks have moved toward integrated, time-dependent assessments of user exposure and vulnerability in historic urban environments. These recognise that the comfort and risk profile of a heritage space changes continuously as a function of who is present, when, and in what numbers (Bernardini et al. 2024; Sparvoli et al. 2026; Quagliarini et al. 2026), offering insightful tools of assessing spatio-temporal variations of exposure and vulnerability of users. These approaches have generated valuable insights, but typically they require dedicated sensing infrastructure, reliance on third-party platforms, visual tracking systems that raise privacy concerns, and often involve qualitative assumptions that treat users as evenly distributed across outdoor spaces. In contrast, official museums' ticketing systems generate continuous, high-resolution records of admissions and represent a widely available source that can support visitor-flow analysis without additional tracking infrastructure, giving precise information on their spatio-temporal distribution.

In this perspective, the historic city centre of Florence, a UNESCO World Heritage site since 1982 (UNESCO 1982), provides a relevant context. The city is among the most affected by overtourism in Italy (ISTAT 2026), and the density of museums, together with documented co-visitation patterns within the local cultural network, significantly amplifies visitor flows throughout the city (Oliva et al. 2020). Within this framework, The Uffizi Galleries complex is one of the city's principal attractors (Giusti 2024), and has implemented measures to decongest the public circulation spaces connecting museums, particularly those surrounding the Uffizi Gallery museum. For this, ticketing data have been used for specific optimization tasks, such as the predictive modelling of queue formation at Uffizi Square (Attanasio et al. 2022). Within the Uffizi Galleries complex, the Pitti Palace and Boboli Gardens system represents a paradigmatic case, combining high and seasonally variable attendance with ongoing conservation and maintenance needs across both indoor museum and extensive outdoor areas. The system requires continuous maintenance and monitoring

activities, especially in areas near historical architectures constructed with Pietraforte sandstone, the typical Florentine historical construction material characterised by an intrinsic propensity to delaminate and detach (Salvatici et al. 2020; Mariotti et al. 2026), and the wide green heritage in the Boboli Gardens, as living heritage. This condition makes the reconciliation between material conservation and visitor-flow management not merely operational but safety-critical, and ticketing data can inform tailored campaigns that reduce the impacts on the visit.

2. Research Aim and Contribution

The research aims to improve the coexistence of conservation needs related to historical materials, the human efforts required to preserve them, and the variable pressure generated by visitors. This paper proposes a data-driven methodological workflow that transforms raw ticketing records into a structured representation of visitor flow within the Pitti-Boboli system in Florence, enabling heritage managers to integrate user-presence data into conservation planning, maintenance scheduling, and operational decision-making. The novelty lies in the use of museum ticketing data which, despite being routinely collected by institutions, have received limited attention in the visitor-flow management as a primary resource for reconstructing visitors' spatio-temporal distribution and visit sequences across a complex heritage site. The resulting outputs can enable professionals to plan actions that optimise accessibility and usage patterns, mitigate potential negative impacts from conservative activities, enhance the use of built heritage, and support the valorisation of cultural heritage places.

3. Materials and Methods

3.1 Study area: the Pitti Palace and the Boboli Gardens system within the Uffizi Galleries complex

Pitti Palace and the Boboli Gardens, which are part of the Uffizi Galleries museum system, have significantly impacted the number of visitors to Florence. The Uffizi Galleries complex – comprising three primary sites: the Uffizi Gallery, the Pitti Palace, and the Boboli Gardens – attracted more than 5.2 million visitors in 2024 (Italian Ministry of Culture 2025). This articulated museum complex extends across the city centre on both sides of the Arno River, with Pitti Palace and the Boboli Gardens situated in the Oltrarno district. The three sites are historically connected by the Vasarian Corridor, which was recently re-opened following a restoration programme.

From a cultural, functional and spatial perspective, the Pitti Palace and the Boboli Gardens are intrinsically connected (Figure 1). The palace's Renaissance core was constructed using Pietraforte, which exemplifies a fundamental technique of rusticated ashlar construction, thereby contributing to the consolidation of Florentine building traditions. For the original construction and subsequent expansions over the following centuries, Pietraforte was sourced from the Boboli hill, one of the main quarries that supplied building material to the city. From 1549, the Boboli Gardens were designed on the slope behind the palace, featuring a geometric and regular arrangement of trees and flowerbeds. It is therefore possible to interpret the transformations of the palace and the garden as the evolution of a single, integrated architectural–landscape system. In its current state, the Pitti-Boboli system functions as a unified visitor system, characterised by flexible access and non-linear visitation patterns. Visitors are able to access Pitti Palace from Piazza Pitti and select from a variety of curated itineraries within the building. Additionally, the Boboli Gardens are accessible from within the palace and via supplementary entrances located throughout the city. These characteristics contribute to the system's particular suitability for the investigation of visitor flow as a spatio-temporal phenomenon, which cannot be confined to a single indoor museum environment. For the purposes of the visitor-flow analyses presented in this paper, the system is operationally represented through five admission-controlled nodes: the Boboli Gardens and four museums within the Pitti Palace,

namely the Palatine Gallery, the Gallery of Modern Art, the Museum of Fashion and Costume, and the Treasury of the Grand Dukes.

From the perspectives of conservation and operations, the case study is also paradigmatic, as both the palace and the garden require continuous care. The garden's green heritage is inherently "living", while the indoor museum spaces demand ongoing attention to preserve historic collections. Furthermore, the external façades built in Pietraforte are exposed to pressures related to time, environment, climate change, and human-induced factors that affect conservation conditions. In this context, the coexistence of high visitor volumes and ongoing conservation needs represents a central management challenge. Since 2018, the Uffizi Galleries have conducted periodic monitoring campaigns of the Pietraforte sandstone façades (Landi et al. 2019) to respond to these challenges. The scheduling of maintenance actions and site operations is therefore contingent upon a clear understanding of the temporal and spatial distribution of visitor presence across the system, with the dual objectives of ensuring safety and comfort while maintaining compatibility with conservation requirements (Mariotti et al. 2023; Quagliarini et al. 2025; Mariotti et al. 2026).

Figure 1 – View of Pitti Palace (a), Boboli Gardens (b) and the representation of the system entrance and exits (c) over the study period (photos and graphics by Alessandro Ceppetelli, 2025)

3.2 Multi-source data

In accord with the research scope, the analysis is based on quantitative data in the form of raw tabular records, which are already available to site managers via the ticketing system. This choice facilitates the investigation of visitor flow without the deployment of additional tracking infrastructure and supports the transferability of the workflow to comparable sites. The observation period extends over an 18-month timeframe, from January 2024 to June 2025, and involved two datasets. The initial dataset is a daily record of the total number of visitors to both the Pitti Palace and the Boboli Gardens, with daily entries divided into primary ticket categories – regular, reduced, and free admission – in line with the Italian regulatory framework for admission fees to state-owned cultural sites. These categories are recognised as management-relevant descriptors. In the case of the Pitti-Boboli system, the ticketing offer encompasses regular, reduced, and free-admission single tickets, which are issued for either the Pitti Palace or the Boboli Gardens, as well as combined single tickets, which grant access to both sites. Moreover, a range of additional ticket categories are available, including those that grant access to the broader Uffizi Galleries system or other combinations associated with specific cards valid in the historic city centre.

The second is an entry-level dataset with hourly timestamps, organised on a per-entry basis. For each day, records are kept of individual entrances to the nodes under consideration in the study. The records encompass a unique ticket identifier, the timestamp of the entrance, the category of the ticket, and the accessed node. The employment of a numerical code as the identifier ensures that it cannot be associated with a specific individual, thereby ensuring the privacy of the subject.

3.3 Method and workflow

The research method follows a data-driven workflow, based on data presented in 3.2, to analyse visitor flow in the complex heritage site of Pitti-Boboli system. The procedure is applied over the entire observation window and is designed to be replicable across other sites and observation periods. The workflow combines statistical analysis (Attanasio et al. 2022) and unsupervised Machine Learning with the aim of producing management-oriented indicators and outputs suitable for the site-manager to integrate user-presence data into conservation planning. Workflow consisting of the following steps:

- **Cluster-based characterization of typical visiting days through daily raw data analysis**
  - *General characterization and descriptive statistics*: the analysis begins with the main daily dataset, as presented in 3.2. Daily entrance records are aggregated into time series. Descriptive statistics are computed to characterise the dataset and its variability over the selected period. Time series and frequency distributions of entrances are analysed to quantify the temporal concentration of visitors and to provide a first representation of attendance patterns.
  - *Seasonality characterization and selection of representative periods based on unsupervised clustering*: to identify homogeneous attendance regimes within the observation window, k-means clustering is applied to the processed dataset. Clusters are interpreted in relation to overall attendance levels, seasonal dynamics, and ticket categories, enabling the definition of comparable demand profiles. In parallel, seasonality is characterised through the analysis of temporal patterns in the daily entrance time series, framing clusters within broader seasonal phases. Based on these outputs, representative periods are selected for more detailed analysis at higher temporal resolution.
- **Typical visitors' flow characterization through hourly raw data analysis**
  - *Selection of the variables and of the period of study*: selection and filtering of the variables required to describe visitor flow and definition of the period of study.
  - *Visit sequences and mean time of visit:* the workflow can be extended to reconstruct visit sequences across the five admission-controlled nodes by linking successive admissions recorded for the same ticket. Time differences between consecutive admissions provide time-related indicators describing inter-node transitions. To support interpretation, inter-node travel times are measured on-site by timing representative pedestrian paths between nodes.

The workflow has been designed to be generalisable across multi-venue heritage sites because it requires only standard ticketing fields. In scenarios where entry-level timestamps are not available, the pipeline can still be applied at daily scale for seasonality identification, while higher-resolution analyses become possible whether per-entry records are provided.

4. Results

Results are organized according to the workflow phases as defined in Section 3.3.

4.1 Cluster-based characterization of typical visiting days

4.1.1 General characterization and descriptive statistics

Starting from the main daily dataset, all ticket categories included in the Uffizi Galleries daily report were considered, namely regular, reduced, and free-admission tickets. Descriptive statistics were computed to characterise the dataset and its variability over time. Daily entrance records were then aggregated into time series (Figure 2), and frequency distributions were computed to quantify the temporal concentration of visitors and provide a first representation of attendance patterns.

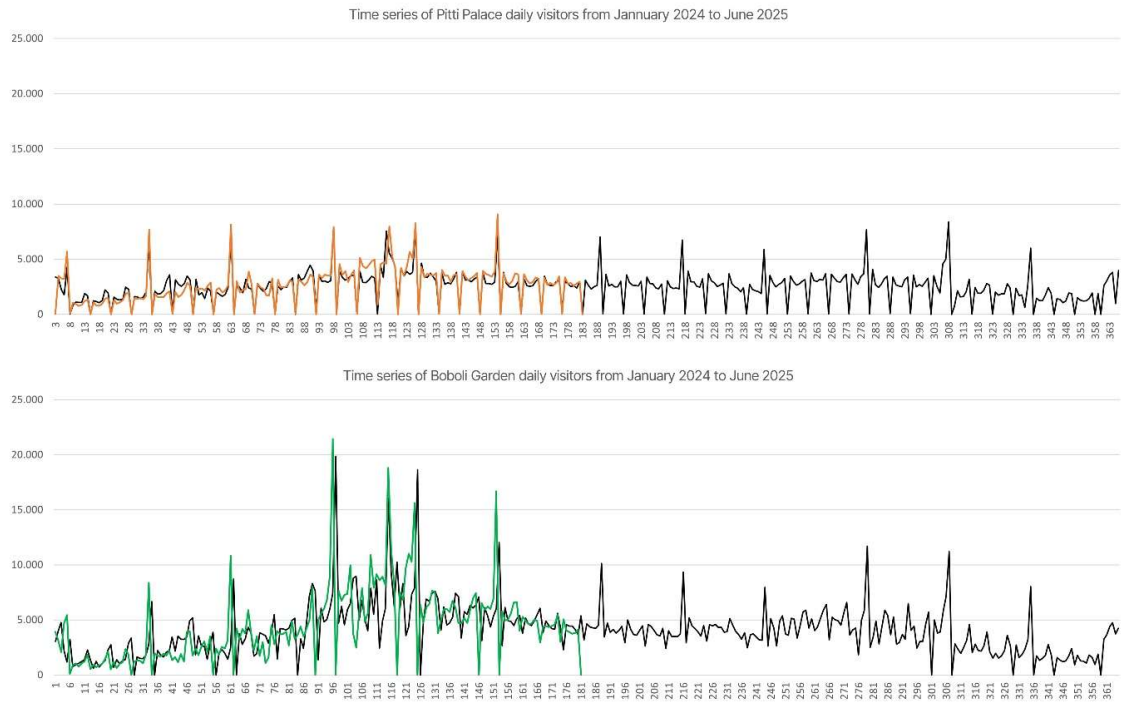

Figure 2 – Time series of entrances for both Pitti Palace and Boboli Gardens during the period from 1st of January 2024 to 30th of June 2025. The black lines refer to 2024, while the coloured lines refer to 2025

Overall, the two time series show both differences and similarities. The weekly pattern of the Pitti Palace is generally more stable over the year, with lower attendance in January–February and November–December. Peaks systematically occur on free-admission days. The weekly peak also varies across the year: during lower-attendance months, the highest values are typically observed on weekends, whereas during the rest of the year, the weekly peak is often observed on Tuesday. Moreover, all museums within the Pitti Palace are closed on Mondays in order to facilitate the regular maintenance of the exhibition spaces. The time series for the Boboli Gardens is more variable, suggesting a stronger sensitivity to external conditions. Compared with Pitti Palace, the overall pattern is wider and less predictable, whereas Pitti Palace visitors appear more

evenly distributed across the observation period. With respect to ticket categories, excluding free-admission days, free-admission tickets represent a significant percentage of daily entrances, equal to 19.32% for the Pitti Palace (540 mean visitors per day) and 17.10% for the Boboli Gardens (688 mean visitors per day). A general increase in total attendance is observed in the first semester of 2025 compared with the same period of 2024. The overall distribution remains similar, but peaks on weekends and free-admission days become more pronounced.

4.1.2 Seasonality characterization and selection of representative periods based on unsupervised clustering

In order to identify homogeneous attendance regimes within the observation window, the k-means clustering algorithm was applied to the dataset that had been processed. The results of this study are presented in Figure 3. The interpretation of clusters was undertaken in relation to overall attendance levels, seasonal dynamics, and ticket categories, thereby enabling the definition of comparable demand profiles. Concurrently, seasonality was characterised through the analysis of temporal patterns in the daily entrance time series, with the resultant clusters being framed within broader seasonal phases (Figures 4-5).

The clustering workflow was implemented in Python, utilising the pandas and numpy libraries for data management, the scikit-learn library for preprocessing and clustering, and the matplotlib library for visualisation. The K-means algorithm was applied to three daily admission features, namely total daily entrances to the Pitti Palace, total daily entrances to the Boboli Gardens, and the overall daily total for the system. The standardisation of inputs was achieved through the implementation of the StandardScaler method. Operationally, the clusters define four categories of daily visitors' affluence: low attendance-days (cluster 1), medium attendance-days (cluster 0), high to very high attendance-days (cluster 3), and exceptional attendance-days (cluster 2). The number of clusters was evaluated through the use of silhouette analysis, whereby the average silhouette score was computed from k=2 to k=10. In this assessment, the highest score was achieved by k=3 (0.531), while the second-best result was provided by k=4 (0.481). Despite the marginal reduction in the resultant score, the k=4 model was primarily selected because it allows the separation of medium attendance-days to high/very high attendance-days, that would otherwise have been grouped together. Moreover, the system-level behaviour demonstrates that Pitti manifests a more dispersed distribution in comparison to the more compact and linear pattern exhibited by Boboli, who functions as the primary driver of system attendance over the 18-month period (Figure 3).

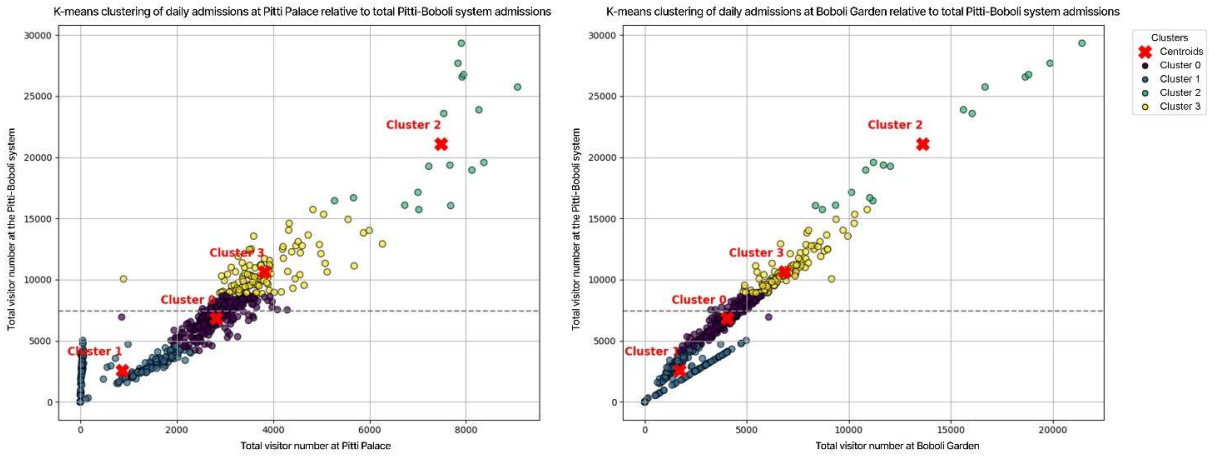

Figure 3 – Scatter plot of the k-means clustering of daily admissions. The left panel shows the results for Pitti Palace, and the right panel shows the results for Boboli Gardens

A monthly histogram representation (Figure 4) synthesises the distribution of days per month by cluster membership and supports the identification of distinct seasonal phases. For the Pitti–Boboli system, the results indicate three main periods: a low-to-medium attendance phase including January, February, November, and December; a medium-to-high attendance phase including March, June, July, August, and

October; and an exceptional-attendance phase including April, May, and September. Outliers are present and are largely associated with free-admission days, during which attendance increases sharply even during lower-attendance months (Figure 5).

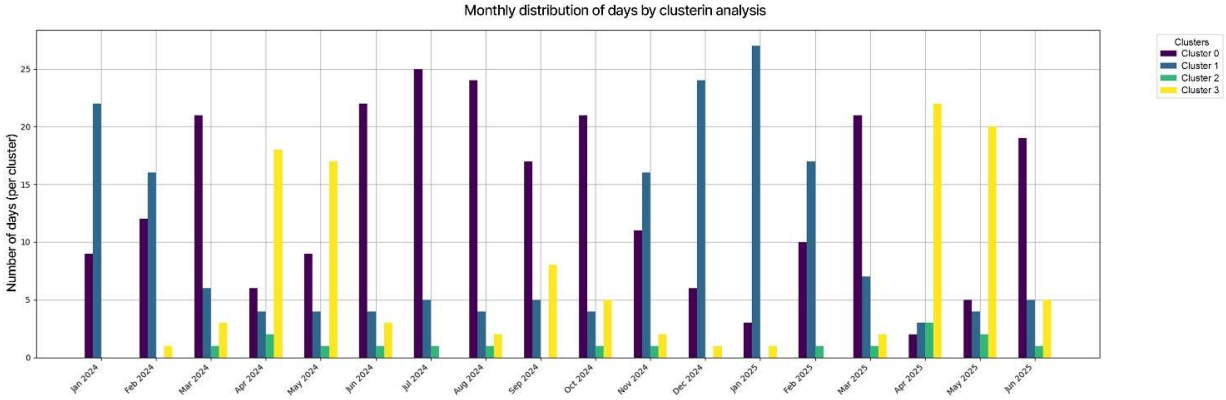

Figure 4 – Monthly distributions of days across attendance cluster for the identification of the seasonal phases

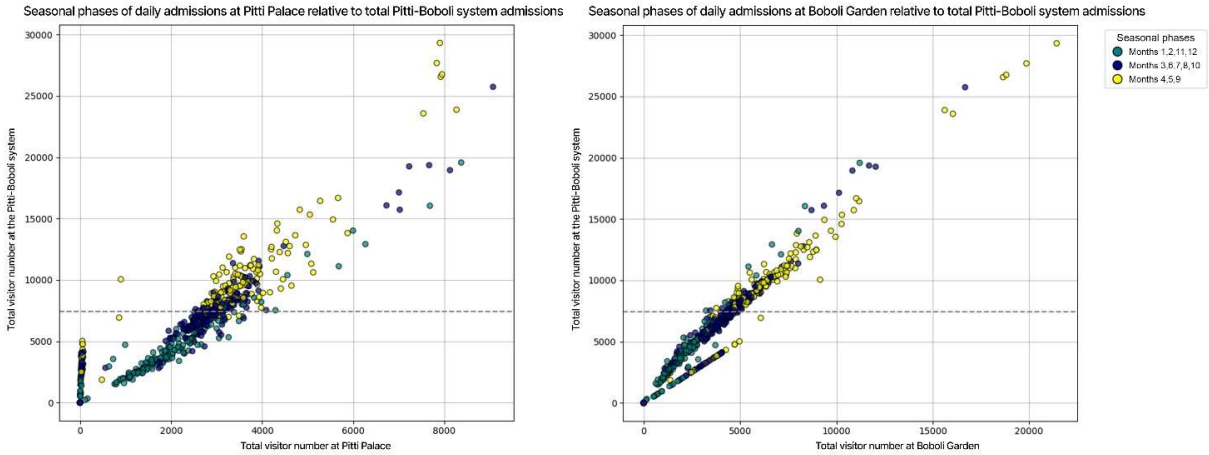

Figure 5 –Scatter plots showing the three main periods of visiting identified from the results of Figure 4: low-to-medium (petrol green), medium-to-high (violet) and exceptional (yellow) daily admissions. he left panel shows the results for Pitti Palace, and the right panel shows the results for Boboli Gardens

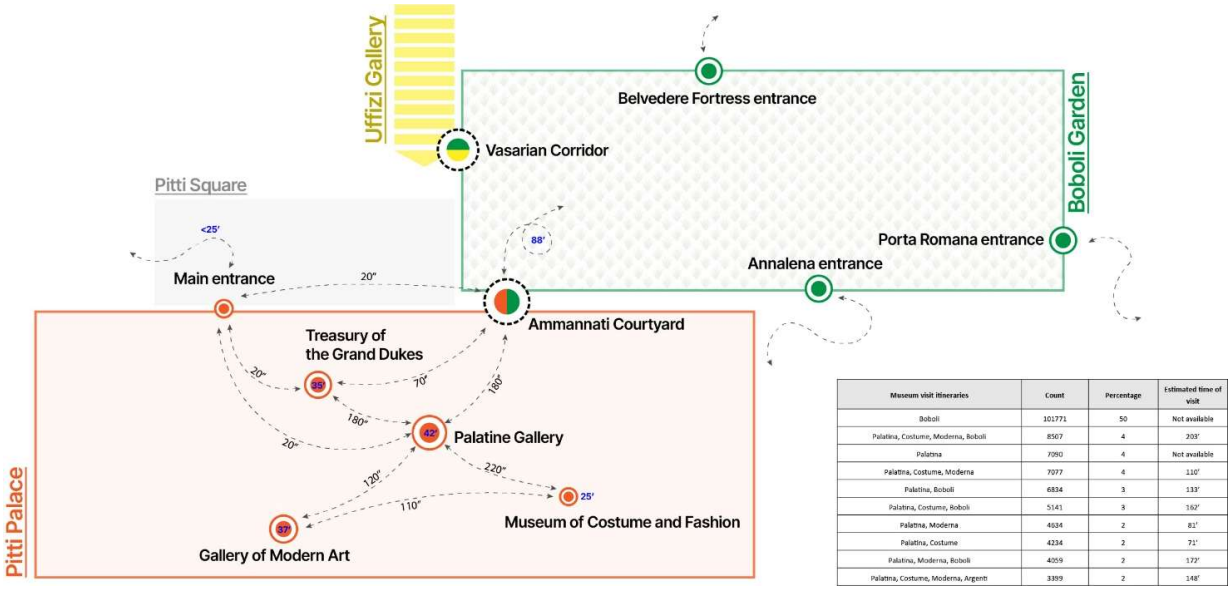
4.2 Typical visitors' flow characterization

4.2.1 Selection of the variables and the period of study

To study intra-day fluctuations in visitors' spatio-temporal distribution, entrance timestamps to each venue are required for a sample of visitors. The hourly dataset is composed of tables reporting the list of tickets used to enter each venue, including the entrance time. For the analyses presented here, a representative sample was selected within the medium-attendance regime previously identified. The sample includes six weeks: 16–23 June 2024, 12–18 August 2024, 02–08 September 2024, 23–29 September 2024, 07–13 October 2024, and 17–22 June 2025. These weeks were selected because their statistics are the closest to the representative values of the medium-attendance regime.



4.2.2 Sequence of visit and mean time of visit

The workflow can be extended to reconstruct visit sequences across venues and to estimate mean visit times, based on admission records and subsequent integration steps. By linking the entrance time and the visited venue for the same ticket, it is possible to describe transitions across the system and derive time-

related indicators. Figure 6 provides a schematic representation of the main venues within the Pitti–Boboli system and their main access points.

Within the selected sample period, the Boboli Gardens represent the main attractor, accounting for 50% of total entrances. The second venue by attendance is the Palatine Gallery, which is frequently the first museum visited within the system.

For each observed visit sequence, mean visit times were derived by computing the time difference between consecutive entrances. To support interpretation, inter-venue travel times were also measured on-site by timing the most direct pedestrian routes, excluding elevator use and assuming typical walking conditions. Based on these results, visit duration within the system ranges from approximately 70 minutes to over three hours, depending on individual preferences and visit composition. These results do not include combined itineraries involving the Uffizi Gallery and the Vasarian Corridor.

Museum visit itineraries	Count	Percentage	Estimated time of visit
Boboli	101771	50	Not available
Palatina, Costume, Moderna, Boboli	8567	4	203'
Palatina	7090	4	Not available
Palatina, Costume, Moderna	7077	4	110'
Palatina, Boboli	6834	3	133'
Palatina, Costume, Boboli	5141	3	162'
Palatina, Moderna	4634	2	81'
Palatina, Costume	4234	2	71'
Palatina, Moderna, Boboli	4059	2	172'
Palatina, Costume, Moderna, Argenti	3399	2	148'

Figure 6 – Schematic representation of the possible flows within the Pitti-Boboli system, showing mean venue visit times (blue) and mean inter-venue travel times (dashed arrows). The Ammannati Courtyard and the Vasarian Corridor act as the main hinges connecting Pitti Palace, Boboli Gardens and the Uffizi Gallery across the Arno River. The table summarises the main visit itineraries and provides an estimated total visit duration, excluding waiting time at the entrances

5. Conclusions and future works

The present paper proposes and tests a data-driven workflow that transforms raw ticketing records into management-oriented information on visitor flow in a complex indoor–outdoor heritage site. The workflow integrates daily time-series analysis and descriptive statistics with unsupervised clustering to identify homogeneous attendance regimes and seasonal phases. It then employs entry-level admissions to characterise flows' dynamics, reconstructing visit sequences across museums within the system.

Applied to the Pitti Palace–Boboli Gardens system, the analyses produced several useful results in line to the objectives of the research. Initially, the implementation of clustering facilitated the identification of varied attendance patterns, outliers, and a seasonality structure. Secondly, the distribution of visitors within the study period revealed stable profiles and recurrent weekly patterns. This finding supports the identification of predictable high-demand time slots and a data-drive preventive planning of interventions. Thirdly, sequence-based analysis indicated that the Boboli Gardens act as the primary attraction in the selected

sample and that the Palatine Gallery is the main museum visited in the Pitti Palace; the results provide empirical ranges for overall visit duration, from approximately 70 minutes to over three hours depending on visit composition.

These findings demonstrate that ticketing data can be structured into actionable indicators to support preventive planning and operational decisions. This includes the scheduling of maintenance and monitoring activities, as well as the mitigation of flow-related criticalities affecting visitor safety and comfort. For instance, maintenance actions could be deployed, in each building area, during those days and daytime with minimum visitors' attendance, focusing their priority also depending on space fruition levels. Visitors' flow monitoring could be recommended in critical attendance days and areas to prevent possible problems in their movement in the building, as well as to increase movement comfort levels or positively manage emergency and evacuation conditions. Visitors' flow can be optimized depending on their effective visiting plans, by creating alternative museum paths towards which visitors can be addressed (potentially reducing overcrowding). Safety and emergency planning can be managed by using dynamic conditions in building fruition, thus moving towards "dynamic" and scenario-based plans rather than static assumptions. In particular, these data can also inform evacuation assessment through simulation models, since this work provides basis for realistic distribution of users (by number and position) over space and time. This can also create benefits in the best, ideal localization of emergency staff members depending on crowding levels. Temporary solutions for outdoor comfort improvement (e.g. temporary sunsails and waiting areas) can be positioned in public open spaces depending on the use and crowding conditions. Finally, these analyses may prove crucial for designing monitoring strategies for the external façades of the complex, constructed from Pietraforte stone – particularly the Pitti Palace. Regular inspections conducted throughout the year can be coordinated with visitor flows, ensuring high safety standards without compromising the quality of the visitor experience.

The workflow proposed is transferable and scalable. The process is transferable due to the absence of a requirement for additional tracking infrastructure, and it can be applied in any context where admission systems provide comparable records. Furthermore, it is scalable due to the capacity for the extension of the same pipeline to longer time period and additional venues sites.

Future works will prioritise the integration of these findings with systematic qualitative evidence concerning visitor movement in outdoor spaces, the implementation of results in dynamic maps and three-dimensional models for immediate decision support, and the extension of the framework towards an integrated risk-oriented perspective. This will be achieved by coupling spatio-temporal exposure patterns with conservation information on material criticalities and monitoring outcomes. Such development will enable a more mutualistic, heritage- and people-centred planning of preventive interventions, thereby reducing disruption to the visit while supporting long-term conservation.

Abstract: In many cases, the most economically viable option for building rehabilitation consists of making minimal structural interventions and changing their use. When the buildings being worked on have a metal structure and belong to older periods, it is very common for the structure to have many exposed parts and for fire protection precautions not to have been taken when they were initially designed. In addition, these structures often have a high plastic potential, and both designers and property owners wish to leave elements visible, without fire protection. In the fire evaluation of structures, a decisive parameter is the time during which they must be able to withstand the action of the fire, which can be assessed in various ways. The mandatory regulations in Spain, the Technical Building Code, offer two procedures to evaluate the fire exposure time of a structure. These two procedures are also included in the Eurocodes. In this work, these two procedures are analysed and compared. The first is the most commonly used and is based on the direct application of a table. The second is rarely used and is somewhat more laborious; it is an analytical procedure that employs expressions taking into account various factors that influence the behaviour of the fire. The results show that the first of the procedures often provides structural fire resistance time values that are much higher than those obtained with the second. It is concluded that the use of the analytical procedure, present in both the Technical Building Code and the Eurocodes, constitutes a viable alternative in many cases.

Keywords: Fire; Steel; Equivalent fire for fire exposure; Fire curve.

1. Introduction

The effects of fires can significantly reduce the load-bearing capacity and stiffness of isolated elements and compromise the mechanical safety of the entire structure (Faghihi et al. - 2023; Randaxhe et al. - 2021). From a purely structural perspective, the statistics conducted by the European Convention for Constructional Steelwork (ECCS) for decades regarding collapses occurring in steel structures (ECCS - 1974), fire is one of the main agents of these collapses. The effects produced on recent collapses such as those that occurred in September 2001at the World Trade Centers (Usmani - 2005) or the Plasco building in Tehran in January 2017 (Behnam - 2019) only confirm what has been pointed out since the 1970s. Moreover, when the fire is caused by earthquakes, the consequences are greater (Chandra et al. - 2021) (Norouzi et al. - 2018). This highlights that the safety of the structure against collapse in the event of a fire must be properly studied.

The European codes of the 1970s (ECCS - 1978) establish the socially acceptable level of the probability of structural failure in a fully developed fire to be similar to that of seismic action. In both cases, not only are the actions not increased, but a certain reduction in their value is also allowed. This amounts to assuming a

higher probability of structural failure than that calculated under normal conditions, which is logical for accidental actions.

Since 1981, the basic Spanish fire protection standards NBI CPI 82 "Conditions for fire protection in buildings" have adopted the classic system of classifying structural elements based on their "Fire Resistance" measured in minutes to define the safety of a structure against fire.

Thus, "fire resistance time" is mentioned when one wants to express its behaviour in the event of a fire. This method has been used in Europe for many years since the 1980s and has its roots in the classical level of structural theory, purely experimental and empirical, of analysis through furnace tests of structural elements subjected to a conventional law of temperature variation over time defined by the ISO 834 standard (ISO - 834).

In this work, the results obtained through both procedures will be compared to assess the suitability of using each one. To do this, first, the fire action is presented; next, both procedures are outlined, and finally, a case will be resolved to analyse the results obtained.

2. Fire lesson

According to the recommendations of the European Convention for Constructional Steelwork (1978), a fire should be considered as an accidental situation during which it is necessary to ensure the load-bearing capacity and integrity of the structure for a sufficient period of time in order to:

- Allow the evacuation of the occupants of the building.
- Establish appropriate safety conditions for the provision of firefighting services.
- Limit the spread of the fire within the building itself and towards adjacent structures.
- To prevent, to some extent, the probable material damage resulting from the deterioration or collapse of the structure.

In general, it is considered that a structural element loses its load-bearing or functional capacity under the action of fire as a consequence of the loss of:

- Characteristics of load-bearing capacity.
- Thermal insulation capacity.
- Flame-tightness capacity.

In metal structures, only the load-bearing capacity is considered.

This limit state can be established with three conditions:

- Collapse criterion.
- Excessive strain rate criterion.
- Excessive deformation criterion.

Usually, only the collapse criterion is considered. According to this criterion, the limit state of exhaustion is considered to occur when the piece or structure subjected to temperature increases due to fire exposure and requested by the rest of the concomitant actions exhausts its load-bearing capacity as a result of any of the following phenomena:

- Transformation of the structure into a mechanism.
- Elastic or inelastic instability.

The critical temperature of a steel element is defined as the temperature of the steel at which the collapse criterion under fire action of the standards is reached, assuming the elastic limit of the material as a function of the temperature reached.

The validity of the design is based on verifying that the temperature reached by the element is below the critical temperature. The value of the temperature reached by the structural element largely depends on

the exposure time during the fire. In the regulations, there are two procedures to calculate this time. the use of them often leads to very different results.

3. Increase in temperature during a fire

One of the fundamental parameters for evaluating a structure against fire action is determining the evolution of the temperature in the fire compartment over time.

The first works carried out with the intention of standardising the value of the temperature rise that occurs during a fire bore fruit in 1975, with the publication of the ISO 834 standard, and in 1981, in Spain, with the UNE 23093, currently EN 1363 (EN 1363:2012). At the international level, the publication of the ISO 834 standard was fundamental in the regulation of fire safety in buildings, defining criteria such as mechanical stability, airtightness, and thermal insulation. The standard. The most well-known contribution of the standard is the definition of a logarithmic expression to determine the temperature reached in an enclosure where a fire has fully developed, based on the elapsed time. Figure 1 shows the curve of the ISO 834 standard.

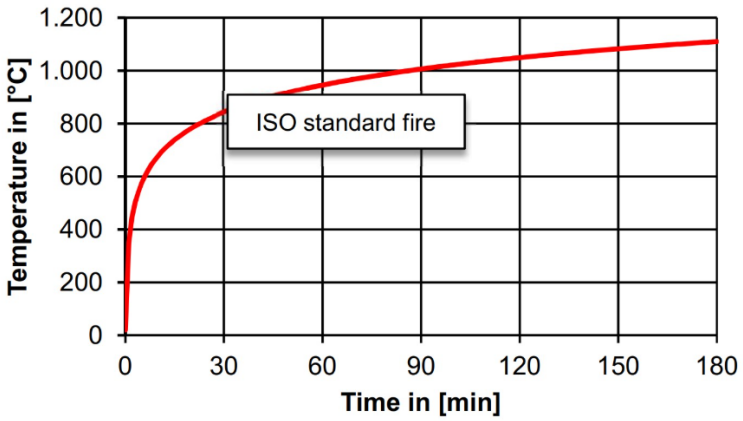

Figure 1 – Value of the temperature as a function of time. Image of the curve in the ISO 834

The image in Figure 1 is the graphical representation of the normalised time-temperature curve, a nominal curve currently defined in the UNE EN 1363-1:2015 standard to represent a fully developed fire model in a fire compartment (equation 1).

$$\theta_g = \theta_o + 345 \cdot \log_{10}(8t + 1)\ (^{\circ}C) \quad (1)$$

Being:

θ_g Gas temperature in the sector [°C]

θ_o Ambient temperature

t Time since the fire started [min]

In addition to using Equation 1 to obtain the temperature reached in a fire, other models can be employed, which have been developed since the 1970s and are more accurate. The results of the tests conducted by Arnault and published in 1974 (Arnault et al. - 1974) represented a significant advance in understanding the influence of various variables on the behaviour of a real fire. The test programs were based on the study of the influence on a real fire of the following three parameters:

- Fire load
- Open ventilation surface
- Nature of the walls that delimit the fire sector.

From these results, real fire curves were obtained that reflect the variation in ambient temperature over real time in the analysed fire compartment.

In the development of a real fire, the following factors influence it:

- Amount of heat energy potentially released during the combustion of the materials present in the enclosure.
  Porosity, shape, and distribution of the combustible materials.
- Ventilation conditions.
- Geometry and thermal characteristics of the enclosure walls.

Once the temperature in the enclosure has been obtained, either with the standardised ISO 834 curve or with more realistic models, the temperature that the structural elements will reach can be calculated. In the case of metal structures, the procedure for evaluating their response to fire action is based on obtaining the critical temperature that the structure can reach depending on the actions it must withstand and its geometric and mechanical characteristics.$(\theta_{s,cr})$ and compare it with the temperature it will reach as a consequence of the fire ($\theta_{s,max}$), which in turn is a function of the temperature reached in the chamber, which depends on the exposure time (equation 2).

$$\theta_{s,max} \leq \theta_{s,cr} \tag{2}$$

4. Time of fire exposure that a structure must withstand: Technical Building Code

According to the Technical Building Code, Basic Document SI on fire safety (Ministry of Housing and Urban Agenda – 2025), the fire resistance of a main structural element of a building (including floor slabs, beams and supports) is sufficient if either of the following two conditions is met: i) it achieves the class indicated in Table 1, which represents the time in minutes of resistance to the action represented by the standardised time-temperature curve, or ii) it withstands said action for the equivalent duration of exposure to fire obtained using an analytical procedure contained in Annex B of the document. Thus, CTE-DB-SI provides two distinct procedures for determining the necessary duration during which the structure must be capable of withstanding the fire action.

4.1 First procedure. Fire resistance table for structural elements

CTE-DB-SI provides a table setting out the minimum fire resistance requirements for structural elements, depending on the building's use and the evacuation height conditions

Table 1 – Sufficient fire resistance of structural elements

Use of the fire compartment in question	**Basement floors**	**Above-ground floors**		
		Building evacuation height		
		≤15m	**≤28m**	**>28m**
Detached house	R 30	R 30	-	-
Residential Housing, Public Housing, Teaching, Administrative	R 120	R 60	R 90	R 120
Commercial, Public sector, Healthcare	R 120	R 90	R 120	R 180
Car park (building used exclusively for this purpose or situated on land zoned for another use)	R 90			
Car park (located under a different use)	R 120			

4.2 Second procedure. Analytical procedure

This annex sets out the procedure for determining the equivalent fire exposure time which, as specified in CTE-DB-SI, may be used as an alternative to the fire duration to be withstood, for both structural and compartmentalisation purposes. The equivalent fire exposure time cannot be applied to timber or composite structures. The equivalent time is obtained by considering the geometric and thermal characteristics of the area, as well as the design fire load value.

This annex also sets out the expression of the standardised time-temperature curve defined in standard UNE EN 1363-1:2015, which is used as the fire curve in the methods for determining resistance described in this CTE-DB-SI. The Eurocode relating to fire action (CEN - 2002) specifies other nominal fire curves.

The expression provided by CTE-DB-SI is valid for structural elements made of reinforced concrete or steel. The design value of the equivalent time, $t_{e,d}$, in minutes is obtained based on the thermal properties of the building envelope, the ventilation of the space, the type of material constituting the structure, and the fire load present in the sector (expression 3).

$$t_{e,d} = k_b \cdot w_f \cdot k_c \cdot q_{f,d} \quad (3)$$

Being:

k_b, conversion factor based on the thermal properties of the building envelope; this may be taken as 0.07. Annex F of standard UNE EN 1991-1-2:2004 provides more precise values.

w_f, ventilation coefficient depending on the shape and size of the sector.

k_c, correction factor based on the structural material.

$q_{f,d}$, calculated value of the fire load density based on the use of the sector, in MJ/m^2.

The ventilation coefficient wf is calculated as follows (Equation 4):

$$w_f = (6/H)^{0.3}[0.62 + 90(0.4 - \alpha_v)^4/(1 + b_v \cdot \alpha_h)] \geq 0.5 \quad (4)$$

Being:

$\alpha_v = A_v/A_f$ the ratio of the area of the openings in the façade to the floor area of the sector, within the limits $0{,}025 < \alpha_v < 0{,}25$.

$\alpha_h = A_h/A_f$ the ratio of the area of the roof openings, A_h, to the floor area of the sector.

$b_v = 12{,}5\ (1 + 10\ \alpha_v - \alpha_v^2) \geq 10$

H height of the fire compartment (m)

Openings in facades or roofs include voids, skylights, windows (whether openable or not), glazed surfaces and, in general, any area likely to allow air to enter the area where the fire is taking place.

The correction coefficient K_c depending on the structural material, is obtained from Table 2 included in the CTE.

Table 2 – K_c correction factor values according to the structural material

Cross-sectional material	k_c
Reinforced concrete	1
Coated steel	1
Uncoated steel	13.7 · O

where O (Equation 5) is the aperture coefficient with the limits $0.02 \leq O \leq 0.2\ (m^{\frac{1}{2}})$

$$O = \frac{A_v\sqrt{h}}{A_t} \quad (5)$$

A_t is the total surface area of the building envelope (walls, floor and ceiling), including openings (m^2).

h is the average height of the vertical openings (m)

The design value of the fire load density, $q_{f,d}$, is determined on the basis of the characteristic fire load value for the sector, $q_{f,k}$, as well as the probability of ignition and the foreseeable consequences of the fire, as shown in (Equation 6):

$$q_{f,d} = q_{f,k} \cdot m \cdot \delta_{q,1} \cdot \delta_{q,2} \cdot \delta_n \cdot \delta_c \quad (6)$$

m is a combustion coefficient that takes into account the proportion of the fuel that burns in the fire. Where the burning material is of a cellulosic nature (wood, paper, textiles, etc.), m may be taken as 0.8. In the case of other types of material where the combustion coefficient is unknown, m may be taken as 1 to err on the side of caution.

δ_{q1} is a coefficient that takes into account the risk of initiation based on the size of the sector.

δ_{q2} a coefficient that takes into account the risk of ignition due to the type of use or activity.

δ_n a coefficient that takes into account existing voluntary active measures (Equation 7),

$$\delta_n = \delta_{n,1} \cdot \delta_{n,2} \cdot \delta_{n,3} \quad (7)$$

δ_c correction factor based on the consequences of the fire

The values of δ_{q1} are given in Table 3, contained in CTE DB SI; intermediate values can be obtained by linear interpolation.

Table 3 – Values of the coefficient δ_{q1} for the risk of initiation due to sector size

Area of sector A_t (m^2)	Risk of initiation δ_{q1}
< 20	1.00
25	1.10
250	1.50
2500	1.90
5000	2.00
<10000	2.13

The values of δ_{q2} are given in Table 4, which is contained in CTE DB SI.

Table 4 – Values of the δ_{q2} coefficient for the risk of onset due to use or activity

Activity	Risk of initiation δ_{q2}
Housing, Administrative, Residential, Educational	1.00
Commercial, Car parks, Healthcare, Public access	1.25
Premises with low special risk	1.25
Premises with medium special risk	1.40
Premises with high special risk	1.60

The values of the coefficient δ_n based on existing active measurements are given in Table 5, contained in CTE DB SI.

Table 5 – Values of the coefficient δ_n depending on the active measures in place

Automatic detection δ_{n1}	Automatic fire brigade alert δ_{n2}	Automatic expiry δ_{n3}
0.87	0.87	0.61

The values de δ_c for the potential consequences of a fire, depending on the building's evacuation height, are given in Table 6, contained in CTE DB SI.

Table 6 – Values of the coefficient δ_c due to the potential consequences of the fire

Discharge height	δ_c
Buildings with a downward evacuation height of more than 28 m or an upward evacuation height of more than one storey	2.0
Buildings with a downward evacuation height of between 15 and 28 m or an upward evacuation height of up to 2.8 m. Car parks beneath other uses	1.5
Buildings with a downward evacuation height of less than 15 m or used exclusively as a car park	1.0

In the case of buildings where it is unacceptable for them to be rendered out of service, or where there could be a high number of casualties in the event of a fire—such as hospitals—the values given must be multiplied by 1.5.

The characteristic value of the fire load density, $q_{f,k}$, is obtained by adding the characteristic value of the permanent fire load density, estimated by its average or expected value, and the characteristic value of the variable fire load density, estimated as the value that is exceeded in only 20% of cases.

The permanent fire load density corresponds to the cladding and other permanent combustible elements included in the design. It can be obtained from the specific values provided by the manufacturer of each product or, failing that, from tables of values for generic materials.

The variable fire load density can be assessed element by element, as indicated in standard UNE EN 1991-1-2: 2004, in which case protected loads may be taken into account, or it may be obtained from Table 7, for areas where fire load accumulations do not exceed those typical of the intended use, such as storage areas, intensive document archives, book depositories, etc. The fire load densities in Table 7 are on the safe side and are valid provided that the actual use of the building is as intended in the design. However, where the designer considers that, in a particular case, the fire loads will be significantly lower, they may avail themselves of the option provided for in the article and assess it themselves element by element, bearing in mind that, in such a case, the designer is responsible for that assessment and for reflecting in the final construction documentation the specific conditions of use that make it applicable, whilst the operator of the activity shall be responsible for compliance with those specific conditions of use.

Table 7 – Characteristic values for variable fire load density depending on the intended use

Intended use	Characteristic value of variable fire load density (MJ/m²)
Commercial	730
Residential	650
Hospital/Public Care Homes	280
Administrative	520
Educational	350
Public venues (theatres, cinemas)	365
Car parks	280
Premises classified as high-risk	160

5. Case study

In order to compare the differences in the assessment of a structure's fire resistance, a space used for teaching purposes will be studied. This is a classroom located on the first floor with an evacuation height of 4.00 m.

Determining the fire exposure time of the structure

In this case, the building is used for educational purposes, is situated on the first floor and has an evacuation height above ground level of 4 m (≤15 m).

Using the first procedure and these values, Table 1 indicates R 60; that is, the structure must withstand the effects of a fire for 60 minutes.

Using the second procedure, the equivalent fire exposure time is obtained from:

$$t_{e,d} = k_b \cdot w_f \cdot k_c \cdot q_{f,d}$$

Conversion factor depending on the thermal properties of the building envelope, k_b.

k_b = 0.07

Ventilation coefficient w_f:

$$w_f = (6/H)^{0.3}[0.62 + 90(0.4 - \alpha_v)^4/(1 + b_v \cdot \alpha_h)] \geq 0.5$$

H = 3.50 m

A_v = 48.00 m^2

α_v = 240 m^2

$\alpha_v = 0.2$

$\alpha_v = 0.0$

b_v = 37

Replacing:

$$w_f = (6/3.50)^{0.3}[0.62 + 90(0.4 - 0.2)^4/(1 + 37 \cdot 0)] = 0.9 \geq 0.5$$

Correction coefficient, Kc:

In this case, it is bare, unprotected steel:

$$K_c = 13.7 \cdot O$$

Being O = 0.088

$$K_c = 13.7 \cdot 0.088 = 1.12$$

Calculation value for fire load density, $q_{f,d}$.

$$q_{f,d} = q_{f,k} \cdot m \cdot \delta_{q,1} \cdot \delta_{q,2} \cdot \delta_n \cdot \delta_c$$

For educational purposes, the characteristic value of the fire load density, $q_{f,k}$. is taken directly from Table 7

$q_{f,k}$ = 350 MJ/m^2

m = 0.8 (all the materials present are of the cellulose type)

$\delta_{q,1} = 1.48$ (depending on the floor area of the section)

$\delta_{q,2} = 1.00$ (risk of ignition due to use)

A coefficient that takes into account existing voluntary active measures, δ_n

$\delta_n = \delta_{n,1} \cdot \delta_{n,2} \cdot \delta_{n,3}$ (existing voluntary measures)

$\delta_{n,1}$ = 0.87 (automatic detection)

$\delta_{n,2} = 0.87$ (automatic fire alarm)

$\delta_{n,3}$ = 0.61 (automatic shutdown)

$$\delta_n = \delta_{n,1} \cdot \delta_{n,2} \cdot \delta_{n,3} = 0.87 \cdot 0.87 \cdot 0.61 = 0.46$$

A factor that takes into account the potential consequences of the fire, δ_c

$\delta_c = 1.0$ (downpipe height of less than 15.0 m.)

Replacing:

$$q_{f,d} = q_{f,k} \cdot m \cdot \delta_{q,1} \cdot \delta_{q,2} \cdot \delta_n \cdot \delta_c = 350 \cdot 0.8 \cdot 1.48 \cdot 1.00 \cdot 0.46 = 190.6\, MJ/m^2$$

The equivalent fire exposure time is calculated as:

$$t_{e,d} = k_b \cdot w_f \cdot k_c \cdot q_{f,d} = 0.07 \cdot 0.9 \cdot 1.12 \cdot 190.6 = 13.45\, min$$

Thus, this second procedure results in a fire exposure time of 13.45 minutes, compared with 60 minutes using the first (standard) procedure in the table 1

The temperature reached by the gases in the enclosure after these times would be (Figure 1 and equation 1):

$$\theta_g = \theta_0 + 345 \cdot \log_{10}(8t + 1)$$

Substituting the times given above into this expression yields gas temperatures of 945 °C and 722.36 °C for 60 minutes and 13.45 minutes, respectively.

To verify the structural impact of the times obtained using both procedures, a 10.0 m span beam subjected to a uniformly distributed load corresponding to its permanent load and the teaching-use surcharge is examined; this consists of an HEB-240 section made of S 275 JR steel that is embedded in the floor slab to half its depth. Under these conditions, the shape factor is A_m/V=65 and the oversizing coefficient is μ_{fi}=2.58, assuming that the structure was initially designed under elastic and linear conditions and has been verified under plastic conditions. If the verification had also been carried out under elastic and linear conditions, μfi=1.76.

The temperatures reached by the steel, depending on its massiveness factor and the temperature reached by the gas in the enclosure, are 907 °C for a duration of 60 minutes and 349 °C for a duration of 13.45 minutes.

As a result of reaching these temperatures, the elastic limit of the steel drops to an extraordinarily low value of 16.5 MPa for a duration of 60 minutes. However, for an exposure time of 13.45 minutes, the elastic limit retains its initial value. It follows that, in the case of 60 minutes, it is necessary to provide protection for the structure; however, when the structure's exposure time to fire is 13.45 minutes, the structure does not need to be protected against the effects of fire. Table 8 summarises the above values.

Table 8 – Summary of the results obtained in the case study

Methods	Exposure time (minutos)	Gas temperature (ºC)	Steel temperature (ºC)	Yield Strenght (MPa)
Simplified method	60	945	907	16.5
Analytic method	13.45	722.36	349	275

6. Conclusions

This study has analysed two procedures included in the Eurocode and the CTE DB SI to determine the duration for which a structure must be capable of withstanding the effects of a fire. The analysis of the two methodologies and the resolution of a case study have led to the following conclusions.

- The mandatory regulations in Spain for calculating the time a structure must withstand the effects of a fire provide for two very different analysis procedures: one based on the application of a table and another analytical procedure.

- These two procedures are also covered by the Eurocode, which is not a mandatory regulation in Spain but is a reference standard.
- When these two procedures are applied, the times obtained yield very different values.
- Applied to a real-world case, the use of the table-based procedure results in a temperature in the structural steel that necessitates its protection, whereas with the analytical procedure the temperature reached is low enough that the elastic limit is not altered, making protection unnecessary.
- The above cannot be generalised to all situations. The values obtained for equivalent fire exposure time depend on multiple factors, and the value of the steel's elastic limit depends on the temperature reached within the enclosure and the massiveness factor of the cross-section.

Abstract: The deterioration of prestressed bridges is often caused by corrosion of reinforcement and prestressing tendons. This study evaluates the effects of different corrosion morphologies – uniform and pitting – on prestressing steel strands with diameters of 12.5 and 15.7 mm exposed to a salt-spray humid chamber for up to five weeks. Visual inspections revealed predominantly uniform corrosion in the smaller-diameter strands and non-uniform pitting corrosion in the larger-diameter strands. Tensile testing quantified reductions in ductility as functions of strand diameter and exposure duration. Although the 12.5 mm strands exhibited greater mass loss, the 15.7 mm strands experienced a more rapid reduction in ductility under identical exposure conditions, attributed to the presence of corrosion pits. To interpret these experimental observations, a finite-element model was developed in COMSOL Multiphysics® using specimen geometries obtained from the tests. Parametric simulations investigated the influence of friction coefficients and pit locations on stress distribution, deformation, and contact pressure. Results demonstrate that, beyond cross-sectional loss, pit location – particularly on inner wires or on the inner side of outer wires – induces significant local von Mises stress concentrations and increased deformation. These findings provide new insights into corrosion-induced mechanical degradation mechanisms in prestressing steel strands.

Keywords: corrosion; prestressed strands; pit corrosion; ductility; stress distribution

1. Introduction

Over the past decades, the European highway network has expanded significantly, leading to a substantial increase in bridge infrastructure (Wilkening et al. 2024). In Germany alone, statistics from the Federal Highway Research Institute (2023) indicate that nearly 69% of the more than 40,000 highway bridges are constructed using prestressed concrete. The structural performance of these bridges relies primarily on prestressing tendons composed of multiple high-strength steel strands. As the main load-carrying component, deterioration of prestressing steel can critically affect the structural behaviour and safety. Among deterioration mechanisms, corrosion is considered the most prevalent cause of damage in prestressed concrete structures (Nguyen et al. 2011). In particular, chloride-induced corrosion – caused by the ingress of contaminated water or de-icing brine, insufficient grout filling, or inadequate protection of anchorage zones – poses a major threat. Prestressing steel is especially sensitive to localized damage due to its high strength. Even moderate cross-sectional loss can result in disproportionate reductions in structural capacity; for example, Poston et al. (2003) reported that a strength reduction of approximately 25% in strands may lead to live-load capacity losses exceeding 50%. A further concern is that corrosion in prestressing tendons often develops without visible external signs, increasing the risk of sudden brittle failure. However, early detection and reliable quantification of corrosion remain challenging because the internal

arrangement of twisted wires prevents direct inspection and complicates the evaluation of corrosion severity and spatial distribution.

Research on the mechanical behaviour of corroded prestressing strands remains relatively limited, and experimental procedures are not yet fully standardized. Accelerated corrosion is commonly induced using electrochemical techniques; however, the resulting damage morphology may differ from natural corrosion processes (Darmawan and Stewart 2007; Enright and Frangopol 1999; Tu, Dong, and Fang 2019). Alternative methods, such as salt spray or climate chamber exposure, have been proposed to better simulate progressive chloride attack and wet–dry cycles, producing corrosion patterns closer to those observed in practice (Wang et al. 2020). Nevertheless, most experimental programs focus primarily on overall mass loss rather than on detailed characterization of uniform and localized pitting corrosion and its mechanical consequences. Several approaches have been used to quantify corrosion-induced cross-sectional loss. Mass loss can be estimated using Faraday's law based on electrochemical principles, as prescribed in ASTM standards, whereas localized pitting corrosion can be evaluated through pit-depth measurements using instruments such as pit-depth gauges. In the latter case, an idealization of the damaged cross section is required to estimate the effective loss of area, and the adopted methodology may influence the interpretation of corrosion damage and its mechanical implications.

The influence of corrosion on the mechanical properties of prestressing wires is also not yet fully understood. Li et al. (2022) reported negligible effects on elastic modulus and yield strength but significant reductions in ultimate strain, while Vu et al. (2009) observed degradation in on the same factors. For multi-wire strands, the mechanical response becomes even more complex due to stress redistribution, inter-wire contact, and friction effects. Consequently, numerical modelling is often required to complement experimental observations and to investigate internal stress mechanisms that cannot be directly measured. Several studies have combined experimental investigations with numerical modelling. Lu et al. (2016) conducted tests on corroded seven-wire strands and proposed a micromechanical damage model to explain failure mechanisms in prestressed concrete structures. Jeon et al. (2019) developed an equivalent material model based on a spring analogy to represent different corrosion geometries derived from experimentally measured pit depths. Giriraju et al. (2022) proposed analytical models for predicting the mechanical behaviour of corroded strands using tensile test results and a pitting factor to represent corrosion severity. Although these approaches provide valuable insights, further investigation is required to better understand the influence of corrosion location and inter-wire interaction on strand behaviour.

To address these limitations, the present study proposes an integrated experimental and numerical investigation of chloride-induced corrosion in prestressing steel strands. Corrosion was induced using controlled salt spray exposure for periods of two, three, four, and five weeks. Mass loss measurements, corrosion rate calculations, and photographic documentation of corroded cross sections were combined with tensile testing to evaluate the degradation of strength and ductility. Based on the experimental observations, a numerical model was developed to simulate stress distribution within corroded strands, incorporating both cross-sectional loss due to pitting corrosion and inter-wire friction with varying coefficients and spatial corrosion configurations. The main objective of this study is therefore to establish a relationship between corrosion-induced section loss, contact stress redistribution, and the resulting degradation of mechanical performance in prestressing steel strands. By linking experimental observations with physically based numerical modelling, this work aims to contribute to a more reliable assessment of corrosion damage in prestressed concrete structures.

2. Materials and Methods

2.1 Exposure Conditions

A prestressing steel strand is made from a number of wires twisted together in the same direction and with nearly the same lay length. The strand is then subjected to a finishing thermo-mechanical treatment. BEKAERT high strength, low relaxation, seven-wire strands (ST 1670/1860) with nominal diameters of 12.5 and 15.7 mm and length of 950 mm were used for this study. These strands are commonly used in the construction of prestressed concrete bridges and were therefore selected for testing. Technical specifications from the strands were measured in 12 specimens and are given in Table 1.

First, the geometry and initial mass of all prestressing strands were measured. For the corrosion investigation, three specimens of the same diameter were prepared for each exposure duration, while three uncorroded specimens of identical diameter served as reference samples. Corrosion was accelerated using a salt spray chamber, in which the temperature was maintained between 39 and 42 °C and the relative humidity was 100 %. A 3 % sodium chloride (NaCl) solution was continuously sprayed onto the specimens in the form of a fine mist. These aggressive environmental conditions enabled significant corrosion levels to develop within a relatively short period. The strands were exposed in the chamber for 2, 3, 4, and 5 weeks. Naming of the samples is as follows: non corroded (NC), 2 weeks (2W), 3 weeks (3W), 4 weeks (4W) and 5 weeks (5W). The tests were conducted in accordance with DIN EN ISO 9227:2022-02 (2022). After removal from the chamber, the specimens were covered with corrosion products (rust). Prior to further examination, photographic documentation and mass measurements were carried out. Since the corrosion products hindered the evaluation of the actual corrosion damage, the strands were untwisted and cleaned by sandblasting. After cleaning, the wires were reassembled into strands, and their mass was measured again, followed by photographic documentation and visual inspection.

Table 1 – Material properties of the strand

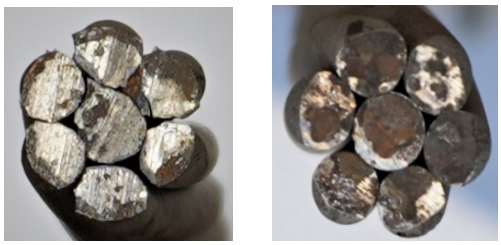
Nominal Diameter (mm)	Average Cross Section Area (mm^2)	Average Maximum Tensile Force (kN)	Average Yield Strength (MPa)	Average Elastic Modulus (GPa)	Weight per meter (g/m)
12.5	94.1	177	1708	190	726.3
15.7	152.2	280	1733	188.8	1172

2.2 Tensile Tests

Tensile tests were conducted on both uncorroded and corroded prestressing steel strands to assess the degradation of their mechanical properties. The tests were performed in accordance with DIN EN ISO 15630-1:2019-05 (2019). To prevent premature failure of the strands at the clamping points during testing due to the applied gripping force, the strand ends were first sheathed with aluminium tubes and secured with adhesive. The total specimen length was 950 mm. The strands were marked at 100 mm intervals, and a gauge length of 100 mm was defined for strain measurement. Strain was determined from the crosshead displacement of the testing machine, which was continuously recorded during the test and normalized by the defined gauge length. The prepared specimens were subsequently mounted in the tensile testing machine and loaded at a displacement rate of 5 mm/min until failure occurred. After testing, the specimens were removed from the testing apparatus, visually inspected and photographed for documentation..

2.3 Corrosion Assessment

To assess corrosion, the chosen method was the calculation of corrosion rates through the obtained values of mass loss. The specimens were weighed before and after exposure in the salt spray chamber and, after cleaning. Then, through simple subtraction of the values the mass loss can be obtained. The calculated mass loss represents the total loss over the entire length and cross section of the test specimen. In order to obtain more information corrosion rates (CR) were also calculated using the chemical characteristics of the steel and the mass loss, by Equation 1, which follows the principles of the Faraday Laws and is fully detailed on the



standard ASTM G102-89 (2015), where W is the weight loss (mg), D is the steel density (g/cm³), A is the cross-sectional area (cm²) and T is the time (hours).

$$CR = (87.6 \times W)/(D \times A \times T) \quad (1)$$

3. Experimental Results

3.1 Visual Inspection

Visual inspection of the specimens revealed that the corrosion morphology varied with both exposure duration and strand diameter. Figure 1 presents specimens of 12.5 mm and 15.7 mm strands after rust removal following 5 weeks of exposure. For the 12.5 mm strands, corrosion pits were observed to be relatively uniformly distributed along the outer wire surfaces. In addition, corrosion was present on the contact interfaces between individual wires, indicating that the aggressive environment was able to penetrate between the wires of the strand. For 15.7 mm strands, they exhibited significantly deeper pits at the same exposure duration. Notably, corrosion was also detected on the inner wire, suggesting that the corrosive environment can reach internal components of the strand even under the tested conditions. These observations challenge simplifications adopted in previous studies. For example, Jeon et al. (2019) assumed in their numerical analysis that corrosion of the inner wire could be neglected, arguing that such damage occurs rarely and is difficult to examine experimentally. However, the results obtained in the present study indicate that both inner and outer wires are susceptible to corrosion, even for similar exposure durations. Consequently, neglecting inner-wire corrosion may lead to an underestimation of the overall deterioration of prestressing strands, and its potential influence should therefore be considered in analytical and numerical investigations.

a) b)

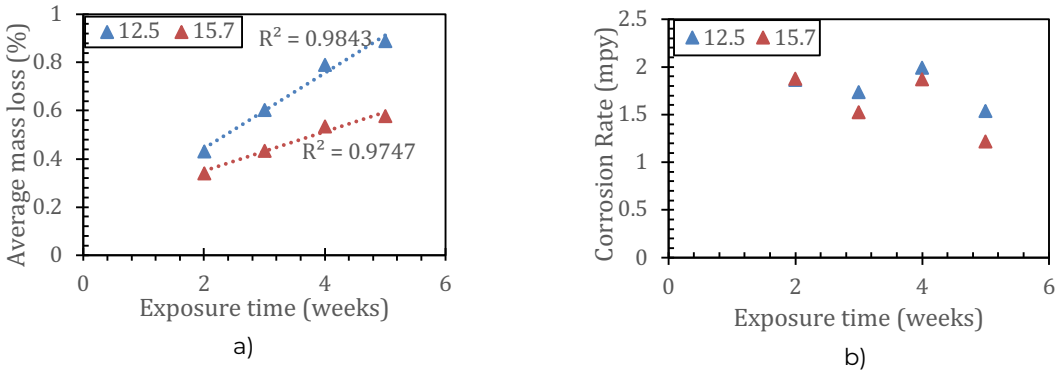
Figure 1 – Photos of strands after 5 weeks of exposure to the salt chamber for a) 12.5mm and b) 15.7mm strands

3.2. Mass Loss and Corrosion Rate

Figure 2 a) illustrates the relationship between average mass loss and exposure time for the 12.5 mm and 15.7 mm strands. The average value calculated among the three samples was chosen for better visualization of results. As expected, the mass loss increases with increasing exposure duration for both strand diameters, indicating a progressive development of corrosion under the accelerated salt spray conditions. At early exposure stages (2 weeks), the difference in mass loss between the two strand diameters is relatively small. However, as the exposure time increases, the divergence between the two trends becomes more pronounced. The 12.5 mm strands consistently exhibit higher mass loss values than the 15.7 mm strands for comparable exposure durations. Furthermore, the results show an approximately linear increase in mass loss with exposure time, as indicated by the high coefficients of determination (R^2 = 0.9843 for 12.5 mm strands and R^2 = 0.9747 for 15.7 mm strands). This suggests that, within the investigated exposure period,

the corrosion process progresses at a nearly constant rate. The greater mass loss observed in the smaller-diameter strands may be attributed to their higher surface area to volume ratio.

Concerning corrosion rates, Figure 2 b) shows the corrosion rate for the 12.5 mm and 15.7 mm strands over the exposure period. The corrosion rates fluctuate slightly but generally remain between approximately 1.2 and 2.0 mpy (mils per year) for both diameters. Notably, the corrosion rates for the 12.5 mm strands are consistently marginally higher than those of the 15.7 mm strands, which aligns with the observed mass loss trends. The relatively stable corrosion rates over time correspond with the approximately linear increase in mass loss for both strand sizes, indicating a near-constant corrosion progression under the accelerated salt spray conditions. This consistency reinforces the interpretation that corrosion advances at a steady rate during the investigated exposure period.



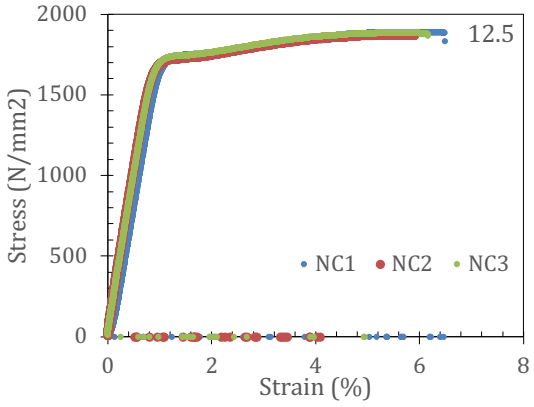


Figure 2 – Corrosion progression according to the exposure time in terms of a) mass loss and b) corrosion rate

3.3. Tensile Tests

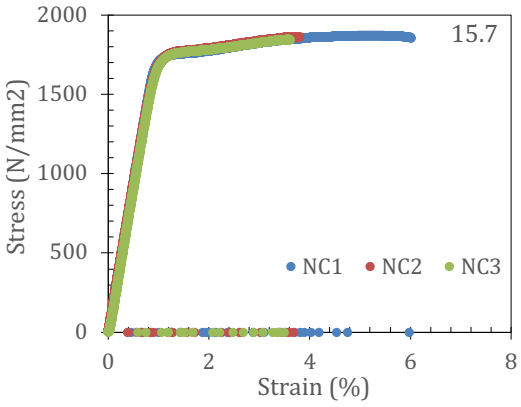

Figure 3 presents the tensile test results for the two strand diameters over different exposure periods. The data indicate that ductility decreases with longer exposure times and increasing mass loss. For the smaller 12.5 mm strands, significant plastic deformation is still observed after 2–4 weeks of exposure, whereas the larger 15.7 mm strands exhibit only a limited plastic region, suggesting brittle failure shortly after yielding, particularly noticeable after 5 weeks of exposure. Figure 4 a) quantifies ductility loss by showing the average maximum deformation for each sample set. The analysis and error bars show that the 12.5-mm strands exhibit virtually no variation, while the 15.7 mm strands exhibit considerable variability, even within the same set.

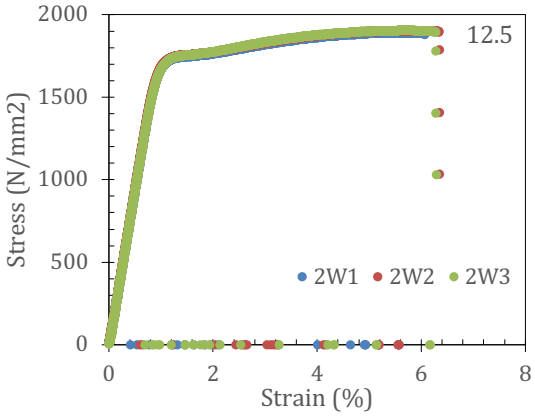
Interestingly, although 12.5 mm strands experience greater overall mass loss (see Section 3.2), the larger 15.7 mm strands lose ductility more rapidly under equivalent exposure conditions. This difference arises from corrosion morphology. Small-diameter strands corrode more uniformly, causing gradual thinning and a proportional reduction in ultimate elongation. In contrast, larger strands often develop deep, localized pits, which act as stress concentrators and crack initiation sites. This behaviour is likely linked to the strand geometry: 15.7 mm strands have larger interstices and occluded cells, where chloride-laden moisture can accumulate, promoting deep pitting. Smaller strands shed corrosion products more easily, favouring uniform, shallower attack. Post-test visual inspections confirmed these observations. All wires failed in the smaller strands, whereas in the larger strands, the most corroded wires failed first after exposure periods longer than 2 weeks. This supports the hypothesis that the failure of individual wires governs the behaviour of larger strands. This also explains the bigger variation within the same dataset for bigger bars, since then the individual characteristics play a bigger role, while for smaller, the “bulk” properties tend to be more prominent.



Despite the pronounced changes in ductility, elastic properties such as yield strength show only slight reductions with corrosion (Figure 4 b). Surface micro-cracks propagate slowly under small strains, minimally affecting bulk stiffness. After yielding, deformation accelerates crack propagation, reducing overall ductility. It is worth noting that field conditions, such as stress-corrosion cracking or hydrogen embrittlement, could produce more severe micro-cracks and may degrade elastic properties more than observed in these controlled tests.

4. Numerical Analysis

Because experimental results can be strongly influenced by testing conditions, a numerical model was developed to better understand the stress distribution within corroded prestressing strands. The model accounts for cross-sectional loss due to pitting corrosion – identified as a major influencing factor – as well as inter-wire friction by considering different friction coefficients and spatial corrosion configurations within the strand cross-section. Unlike previous approaches, the proposed framework explicitly investigates the effect of corrosion-induced reductions in contact stresses on the global mechanical behaviour of the strand and evaluates how the location of corrosion damage influences stress distribution among the wires.

The numerical model was implemented in COMSOL Multiphysics® (version 5.6) and developed following the modelling approaches presented by Utting and Jones (1987), Huang (1978), and Kumar et al. (1997). Wire friction was represented using the Coulomb friction coefficient μ. The material properties were taken from the software structural steel database and adjusted according to manufacturer data: density 7810 kg/m^3, Young's modulus 195.9 GPa and Poisson's ratio of 0.30. A linear elastoplastic material model was assumed. The strand geometry consists of seven wires: one straight inner wire surrounded by six outer helical wires. The model dimensions were defined using the mean values obtained from the measured geometry of the 12.5 mm diameter strands, assuming identical diameters for all wires. The outer wires are symmetrically arranged around the inner wire with a 60° angular spacing, and the total modelled strand length was set to 100 mm. The geometric parameters used in the model are summarized in Table 2. Figure 5 a) illustrates the geometry.

To define the corrosion configurations used in the simulations, the failure classification proposed by Remitz and Empelmann (2020) was adopted. Cross-sectional loss due to corrosion was calculated using the hemispherical pit model proposed by Val and Melchers (1997). For simplicity, only strands with a nominal diameter of 12.5 mm were considered here. Pit geometry was idealized as a circular cross-sectional loss; therefore, corrosion in the inner wire was represented as a cylindrical pit. To ensure comparable cross-sectional loss among the outer wires, corrosion was also applied along the helical geometry of the wires. Using the difference function in COMSOL, the damaged volume was subtracted from the original wire geometry to obtain the residual cross section. Figure 5 b) shows how the damaged area was subtracted from the strand and modelled.

For simplification, the pit height was assumed to be 5 mm in all cases. Pit depths of 1.00 mm, 2.00 mm, and 3.00 mm were considered for some configurations, while depths of 0.486 mm, 0.935 mm, and 1.300 mm were used for others. These values were selected so that the resulting reductions in cross-sectional area were comparable across different corrosion configurations. Regarding friction parameters, previous studies such as Erdönmez (2020) suggest that a Coulomb friction coefficient of 0.115 very well represents inter-wire friction. To evaluate the influence of friction on stress distribution, two additional values close to this reference value (μ=0.10 and μ=0.14) were also considered for both non-corroded and corroded strands. In total, 21 numerical cases were analysed (Figure 6). Cases 1–3 represent non-corroded strands analysed with different friction coefficients, while cases 4–6 correspond to corroded strands subjected to the same friction parameters. The reference value 0.115 was subsequently used for cases 7–21. Cases 7–18 investigate four different corrosion configurations with increasing pit depth. Finally, cases 19–21 consider identical total cross-sectional loss as in the previous cases but distributed among multiple wires, representing combinations of the four failure types. This approach allows the evaluation of how identical overall strand section loss may lead to different stress distributions depending on how corrosion damage is distributed among the wires.

Table 2 - Geometric parameters of the strands used in the model

Inner wire	Outer wires

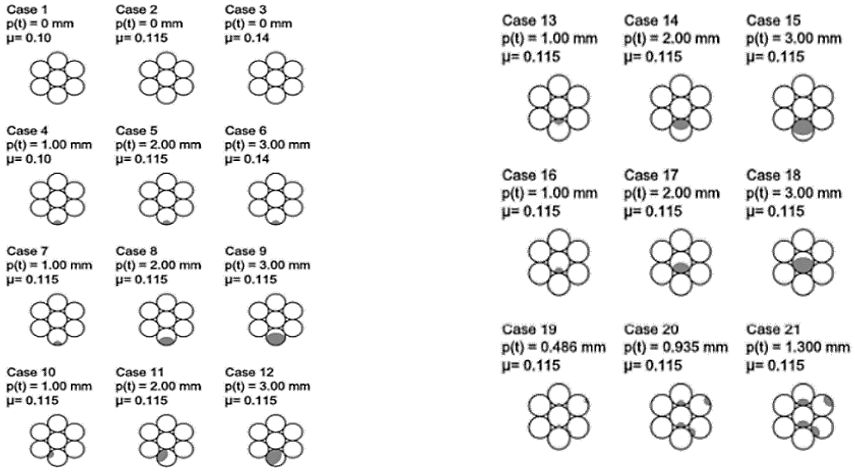

Figure 6 – Overview of studied cases

4.1 Results

The following section presents and discusses the results of the simulations for a tensile test with a force of 100 kN. It compares the maximum deformation, the maximum von Mises stress, and the contact pressure related to non-corroded and corroded strands with different friction coefficients and different distributions of the pits.

4.1.2 Influence of friction coefficients

Simulations indicated that strand deformation decreases with increasing frictional force as expected irrespective of corrosion. Regarding contact pressure, the highest values occur at the wire contact points, particularly near the strand ends where wire displacement intensifies due to elongation during testing, as illustrated in Figure 7 a). Stress distributions show little variation when comparing similar friction conditions within the non-corroded and corroded groups. However, under the same load, corroded strands exhibit generally higher stress levels than non-corroded ones. For uncorroded strands (cases 1 to 3), the maximum

von Mises stress increases with higher friction coefficients, whereas for corroded strands, it decreases as friction increases. These trends are summarized in Figure 7 b).

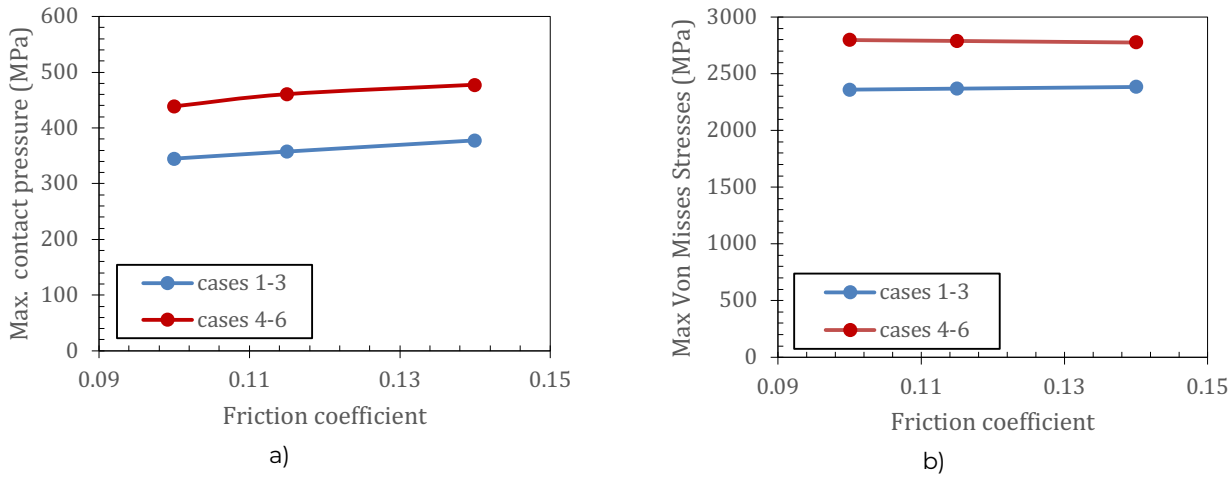

Figure 7 -Influence of the friction coefficient on a) the contact pressure and b) the stress distribution

4.1.2 Variation of section loss versus deformation, contact pressure and stress distribution

Figure 8 a) shows the relationship between deformation and cross-sectional loss for a constant friction coefficient of μ=0.115. As expected, deformation increases with increasing section loss. For mild corrosion (1.33% section loss), deformation remains relatively consistent across all cases. However, for severe corrosion (9.66% section loss), the deformation varies significantly depending on the corrosion location. When corrosion occurs on the external surface of the outer wires (cases 7–9), deformation changes only slightly, a trend also observed when corrosion is distributed among several wires (cases 19–21). In contrast, corrosion located on the inner surfaces of the outer wires (cases 10–15) produces a noticeable increase in deformation, particularly when the pits are in contact with the inner wire (cases 13–15). The largest increase occurs when corrosion affects the inner wire (cases 16–18), highlighting the critical influence of internal damage. Compared with the non-corroded strand (case 2), the severe corrosion case of the inner wire (case 18) results in an increase in deformation of approximately 0.8 mm.

Regarding the stress distribution, in all cases, higher stresses occur within the inner wires and along the inner surfaces of the outer strands. Local stress concentrations develop at the corrosion pits due to the reduction in cross-sectional area, except when corrosion occurs on the outer surface of the strand (cases 7–9), where stress peaks are minimal. When corrosion affects the inner surfaces of the outer wires or the inner wire, the maximum stresses occur near the damaged region. The relationship between section loss and maximum Von Mises stress is shown on Figure 8 b) and indicates good agreement with experimental observations, as failure tends to initiate at stress concentrations located at the corroded areas. For mild corrosion, pit location has a limited effect on stress levels. However, for severe corrosion, pits located on the inner surfaces of the outer wires (cases 12 and 15) or on the inner wire (case 18) produce significantly higher stresses compared with distributed corrosion, with case 18 exhibiting the highest stress concentration.

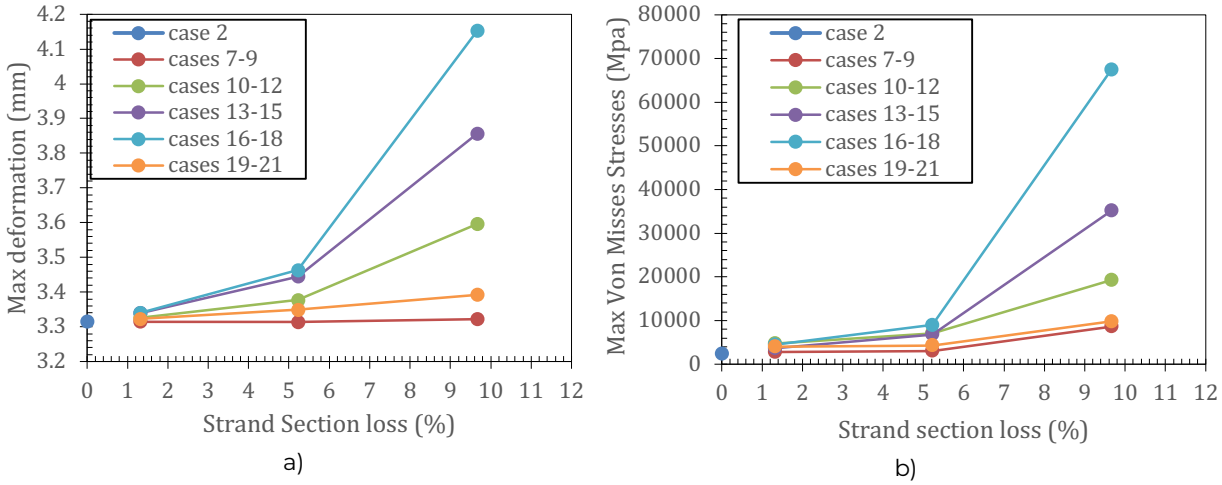

Figure 8 – Influence of varying section loss for studied cases on a) Maximum deformation and b) Stress distribution

5. Conclusions

This paper evaluates and discusses the influences of corrosion on the mechanical behaviour of steel strands used for prestressed concrete. Seven-wire prestressed steel strands with nominal diameters of 12.5 mm and 15.7 mm were subjected to aggressive conditions in a salt spray chamber for periods of 2, 3, 4 and 5 weeks. Tensile tests were conducted to assess the impact of corrosion on the mechanical properties and with the help of numerical simulations the following conclusions were obtained:

- Exposure in salt spray caused clear diameter-dependent corrosion morphology: 12.5 mm strands tended to corrode more uniformly (including at wire interfaces), while 15.7 mm strands developed deeper localized pits, and corrosion was observed on the inner wire – showing that internal corrosion can occur and should not be neglected in modelling.
- Mass loss increased linearly with exposure time for both diameters, with 12.5 mm strands showing higher mass loss overall and slightly higher corrosion rates, consistent with a higher surface area to volume ratio.
- Corrosion mainly reduced ductility rather than elastic properties: yield strength changed only slightly, but maximum deformation dropped markedly with exposure. Despite lower mass loss, 15.7 mm strands lost ductility faster because deep localized pits acted as stress concentrators, leading to earlier, more brittle failure; in these strands, failure was often governed by the most corroded individual wires.
- Simulations confirmed that corrosion location strongly controls mechanical response for severe damage: outer-surface corrosion had limited effect while inner-surface and especially inner wire corrosion produced the largest deformation increases and the highest stress concentrations, matching observed failure initiation at corroded regions.

Optimising resource value extraction in demolition and rehabilitation: A digital twin-transition approach - EU Horizon DISCOVER project

Jorge de Brito [1], José Dinis Silvestre [1], João Gomes Ferreira [1], João Pacheco [1], Rui Silva [1], Miguel Bravo [1], Renato Neves [1], **Isobel Andrews [1]**

[1] CERIS, Departamento de Engenharia Civil, Arquitectura e Ambiente, Instituto Superior Técnico (IST), Universidade de Lisboa, Lisboa Portugal.

Abstract: The construction and demolition sector generates approximately 38% of all waste annually in the EU. The resulting impact of around 820 million tonnes of waste from demolition and rehabilitation projects requires careful management. While it is recognised that there is value in construction materials extracted from demolition and rehabilitation sites via selective deconstruction strategies, recovery and reuse of such materials remains limited due to organisational and logistical challenges which currently render full selectivity infeasible during the end-of-life phase of buildings.

The DISCOVER consortium brings together 14 project partners from research and industry institutions across the EU, combining expertise on robotics and artificial intelligence with deconstruction techniques, waste management, and lifecycle assessment. The project partners are working together to address the challenge of increasing sustainable deconstruction strategies for optimised material recovery, with the goal of preserving the value contained in construction materials for secondary uses. The project integrates the findings and developed models into an automated robotic inspection system, feeding into digital twin BIM tools to build interactive pathways to the decision-makers in industry. Engagement with stakeholders in the industry and interaction with live demolition projects are continuously being utilised to build life cycle assessment models for demolition processes and outcomes for recovered materials and to train robotic inspection prototypes throughout the four-year project. Doing so is expected to lead to a reduction of construction and demolition waste by 55% and greenhouse gas emissions in the sector by 20%, improving overall circular practices in the construction life cycle.

This paper presents the DISCOVER proposals and methodologies for improving the sustainable management of building deconstruction, material extraction and circular treatment of construction and demolition waste (CDW) in the EU.

Keywords: Deconstruction, sustainability, digitalisation, inspection, materials

1. Introduction

Annually, the construction and demolition sector accounts for about 38% of the total amount of waste generated in Europe (Eurostat 2023). and about 24% of global extractions of raw materials (Bribián et al., 2011), making this sector the largest resource consuming and waste producing one in the EU (Luciano et al. 2022). Rehabilitation, including renovation, retrofitting and maintenance projects are estimated to be the second largest contributor to the total quantity CDW generated in the EU after demolition (Zhang et al. 2021). Rehabilitation is a necessary tool for conserving buildings and structures key cultural importance and is logically recognised as being more sustainable than new construction in infrastructure management generally, due to lower resource requirements (Popescu et al., 2024). However, with the ageing building stock in the majority of European cities, renovation works, including rehabilitation and maintenance, are estimated to be responsible for around 30% of the associated CDW generated by a building during its life (Sáez et al. 2018). While it is good news that efforts in the EU are resulting in an increase in rehabilitation of existing infrastructure, it is also necessary to consider the question of waste management from these projects, as removal of existing materials sometimes generates more waste in the short term than new construction projects.

The European Green Deal aims for a carbon neutral economy by 2050 (European Commission 2019). The construction and demolition (including rehabilitation and maintenance) sector also currently accounts for almost 40% of carbon emissions in society, with 11% related to material production, transportation and implementation

(United Nations and International Energy Agency 2019). Since construction materials also account for 24% of global extractions of raw materials (Bribián et al., 2011), it is reasonable to continue to pursue progress on the management of CDW.

The EU Horizons DISCOVER project was launched with the aim of reducing CDW in the EU by 55%, thereby reducing construction related emissions by 15%. This project is currently being undertaken, employing a combination of methods. The first stage involves the automation of pre-demolition or rehabilitation inspections processes using robotic innovations. Two prototypes, known within the project as Oliwall and Pokeye, are currently undergoing testing for this purpose. This involves laser scanning of the site to provide spatial information and automatic identification of the materials encountered on the site. This information is then linked to building information modelling (BIM) tools to allow industry professionals to have easy access to the information gathered. The model will be programmed to provide deconstruction methodology recommendations and end of life options for extracted materials to enable material recovery for circular reuse, with associated environmental and cost impacts.

The project also encompasses life cycle assessment (LCA) and life cycle costing (LCC) to consider and compare deconstruction and extraction strategies for the most valuable materials. The end result is an identification of the optimal deconstruction and recovery options for identified materials. Of key importance is that the outputs of the project will be made accessible to industry professionals via BIM plugin tools, which will assist with decision-making in the industry. This is an essential step in building effective change as approximately 70% of industry professionals currently use BIM tools to execute their professional activities (Hasek, 2021).

2. Objectives

The DISCOVER project addresses shortcomings in deconstruction processes by integrating robotics and digital technology to assist in sustainable assessments. This is structured into 6 key objectives, which combine to contribute to advancements in the field of sustainable deconstruction, firstly by developing intelligent learning models for material and component identification, integrating this into an autonomous inspection system and combining with environmental and cost analyses as follows:

Objective 1: To create a set of autonomous and synchronous robotics systems for the precise, fast and less labour-intensive analysis, identification and digitisation of materials and construction components from existing built works, based on mobile manipulators and new data fusion approaches.

Objective 2: To achieve fully automatic understanding of data coming from cameras, ground-penetrating radar (GPR), laser-induced breakdown spectroscopy (LIBS), etc., using sensor fusion techniques and machine learning algorithms, rapidly analysing the properties and characteristics of elements and materials (e.g. composition, dimensions, mass, technical properties, identification of asbestos, fixing and repair needs, etc.).

Objective 3: To create an integrated digital framework to synchronously process and visualise the data brought by the system, leveraging on the wealth of information on the Building Information Modelling (BIM) digital twin.

Objective 4: To enhance the circularity of construction and building elements and materials by an improved identification and management of deconstruction methods.

Objective 5: Development of a sustainability assessment framework to guide demolition methods, considering reuse and recycling of demolition assets and improvement of the sustainability of demolition activities.

Objective 6: To foster the adoption of robotic systems and collaborative BIM tools within the work processes of stakeholders in the construction industry, in special for the deconstruction process, to increase safety and productivity.

Together the objectives embody a system of progressive autonomy in building inspections and integrate digitisation of sustainable assessments in the planning and execution of deconstruction works.

3. State of the art

Robotics and AI are emerging technologies that have been identified as having a significant role to play in building deconstruction and promoting circularity of materials. The potential of robotics in enabling component reuse in the deconstruction sector has been found to be significant in its ability to assist in the transition to circular deconstruction via pre-works inspections in disassembly projects (Thakuri et al., 2024). This is supported by the opinion of industry professionals including engineers, architects, managers, manufacturers, suppliers, contractors, facility managers and circular economy experts worldwide, who, when asked about the challenges of implementing circular practices, indicate that they expect that AI, vision-based robotics and digital twin technologies will play a crucial role in scaling up the adoption of CE practices in the future. In addition, "Complexity in handling and managing CDW materials" was identified as one of the top three barriers to successful implementation of CE practices in the management of CDW (Swarnakar et al., 2025). This indicates strong industry support for innovative developments in this field, such as those the DISCOVER project is intending to achieve.

In the project works phase, whereby the demolition or rehabilitation works are taking place, material separation in combination with waste reuse and recycling has been found to reduce the environmental impact of CDW when compared with disposal of landfill, with around 77% reduction in climate impact (Coelho and de Brito, 2012). These findings are supported by case studies in both Spain and Italy, where selectivity of demolition processes was identified as being a key step in the reduction of carbon associated with the deconstruction stage (Mercante et al., 2011), (Vitale et al., 2017). **Examination of the environmental impacts of demolition processes and waste reuse often involves life cycle assessment.** LCA studies have observed a significant reduction of the environmental impacts associated with diverting CDW from landfill and treating it in a circular manner. One study quantifies this as a reduction of 36% in environmental impacts in person equivalent (PE) when waste is downcycled or recycled rather than landfilled, a figure which rises to 59% in environmental impact savings when recycling after selective demolition is employed, DISCOVER intends to increase this practice. Landfilling was also found by LCC analysis to be the most expensive end-of-life solution (Di Maria et al., 2018).

Meanwhile, the end-of-life phase and deconstruction processes is noted as being a phase that tends to be overlooked or given insufficient consideration in most LCA studies on building life cycle and that this stage should be further investigated to achieve the EU circular economy goals (Ivanica et al., 2022). Additionally, further study is needed on analysing the differences in the impacts of recycling and downcycling of recovered waste streams from deconstructed elements in LCA studies (Bayram and Greiff 2023), which is also something that DISCOVER intends to address.

When considering the digital integration of processes and analyses in the context of circular management of deconstructed infrastructure, BIM has been identified as being a critical industry tool and that the successful implementation of digital technologies in the management of end-of-life processes facilitate reuse of materials within a circular economy model (Thakuri et al., 2023). The authors indicate that the hypothesis could be usefully supported by the implementation of further research involving case studies to test the premise. This is further highlighted by an increasing number of construction professionals, who use BIM or other digital tools in their activities, currently estimated to be around 70% of construction professionals in the EU (Hasek, 2021), indicating that this is a reliable platform on which to convey knowledge and decision support tools.

4. Methodology

The DISCOVER project involves a multidisciplinary expert team from 14 research and industry institutions, across 7 EU countries working together to address the issues of material identification, spatial assessment and management of deconstruction scenarios and recovered materials with the goal of reducing

environmental impact of demolition activities and improving human safety for those involved. The methodology involves careful collaboration between partners.

4.1. Automated pre-demolition inspection

The first stage of the project, both for DISCOVER and in terms of any demolition or rehabilitation project is the pre-works inspection. The DISCOVER project aims to automate this phase of the project via robotic inspection. The robotic system will act as a substitute for human labour in the high-risk situations of pre-demolition or renovation sites, which often comprise potentially unstable situations or exposure to hazardous substances. It will have the capacity to scan buildings and infrastructure to gather data on geospatial elements, materials and building components, both visible as well as complex and concealed components. Two robotic prototypes are developed to perform these tasks - Oliwall and Pokeye. The goal of the robots is to act autonomously within deconstruction sites, performing spatial mapping of the works area and subsequent element and material identification via AI recognition, based on the geometric information supplied by Oliwall, and the subsequent testing of materials where necessary, via samples gathered by Pokeye.

An analysis of expected components and materials, based on the typical characteristics of the building stock in the EU, contributes to the robotic identification system. This key information is used to train the algorithm to identify these elements via the robotic scanning and minimally invasive testing. The integration of artificial intelligence algorithms will contribute to the rapid analysis of spaces set for demolition or renovation works as well as strong supporting indications of the building elements and characteristics of the materials, both visible and concealed. The robots are equipped with laser scanning, ground penetration radar (GPR) for identifying hidden elements in walls and floors and in the case of Pokeye, drilling and sampling apparatus.

4.2. Building Information Modelling (BIM) - the digital twin

The digitalisation phase of the project intends to integrate the geospatial and material information identified in the automated pre-works inspection phase of the project into a BIM Model. Additionally at this stage, optimal strategies and recommendations for deconstruction techniques are integrated, with varying degrees of selectivity and waste management, taking into account the environmental impacts and potential material value and costs.

This phase involves three key tasks:

1. Definition and implementation of a methodology for the conversion of the data collected by the robotic analysis of the works area into semantic BIM objects, including the definition of data formats and pipeline workflow as well as a python script for processing information and converting it into semantic BIM objects;
2. Development of a database containing building information, including the standard material list and the live data collected by the robotic inspections. This is programmed to facilitate subsequent data exploitation and interoperability in such a way that the information can be accessed by external industry operators and entities to inform decision-making in real life projects. This is an advanced stage that incorporates the information contributed by the robotic inspections and AI models with detailed analysis of deconstruction options and techniques, material extraction potential, associated costs and life cycle impact assessment for material recovery paths as well as material traceability throughout their multiple secondary use lives;
3. Construction of a user-friendly digital interface to facilitate use for industry professionals. This includes the development of a visually interactive model characterised by the creation of an open dataset of construction material textures for the machine learning which enables a user-friendly visual interface to facilitate access to the information supplied by the development of step 2 above.

The digitally integrated decision-making support tool will be continually optimised throughout the project by input from existing stakeholders in the industry and via the validation and testing of assumptions from the pilot case studies for different building types and policy contexts.

4.3. Recovery pathway modelling

A key phase of the project methodology involves reducing the environmental impact of deconstruction and disassembly projects by analysing different selectivity scenarios for deconstruction whereby buildings or components are taken apart piece by piece with the key aim being extraction of materials for recovery and reuse, with consideration of the cost of doing so and the resale value of materials. This involves detailed analysis of deconstruction scenarios and methods in terms of techniques, equipment, cost, time and labour with the goal of understanding the optimal strategies for extracting the maximum amount of recovered material, while retaining a feasible deconstruction timeline and budget.

The relevant techniques are studied, considering equipment energy use and emissions, water use, labour and time associated with each option. This information contributes to a detailed life cycle assessment of different deconstruction scenarios that assists in comparing available options for disassembly of buildings or building elements. Following from this, multi-life-cycle assessment and cost life cycles are considered for the materials recovered based on the selected deconstruction scenarios. The reuse and recycling options for each material studied will be considered and the environmental impacts and costs associated with different waste management strategies for each material stream will be compared for the optimal outcome. With input from the on-site robotic inspection system, a secondary material database will be maintained for the recovered materials as a key solution at this stage, with emphasis on material traceability to keep track of the multiple life cycle uses of extracted materials and the associated environmental and cost savings associated with each service life.

This data collected from the LCA of different demolition scenarios and material recovery paths and market value will be included as part of the digital plugin tool to allow this information to be accessible to decision-makers and project managers in the industry.

4.4. Data acquisition from live case studies

The robotic system, AI model and digital integration will be tested on live case studies from four sites across the EU, each representing different infrastructure types and policy backgrounds. The robotic prototypes will be employed to test the geospatial and laser scanning system, material identification, material sampling and integration into BIM to create a visual model. The case studies will also be used to test assumptions made about the feasibility of selective deconstruction recommendations as well as the LCA and LCC models and to assess the conditions created by different policy contexts.

The four pilot studies comprise one historic masonry-based structure in Lisbon, one mixed material, concrete framed structure in Brussels, a reinforced concrete infrastructure project in Warsaw and a mixed materials industrial structure in Barcelona. Each selected project is already marked for demolition. The same methodology can be also applied to renovation works or rehabilitation projects, considering materials to be removed. The robotic scanning aids in building BIM tools, assessment of materials to be removed and cost and environmental analysis of the extracted materials, helping to improve the current shortcoming and main area of criticism associated with renovation and rehabilitation projects - the management of extracted waste - and the case study pilot sites will help to support the project implementation.

5. Project progress

5.1. Robotic prototypes

The robot prototypes, Oliwall and Pokeye are the first of their kind to perform the task of pre-works inspection in existing buildings. Oliwall is operational and ready to be tested on site at the first case study site. Currently testing of Oliwall's capabilities within the laboratory is ongoing. Oliwall can gather geometric

data and correctly identify building elements and objects. It travels autonomously with the successful functioning of the safety feature which enables it to stop when encountering humans in its path for added safety. The prototype of Oliwall undergoing training can be seen in Figure 1 and testing of the mobile abilities in Figure 2.

Figure 1 - Oliwall in training (Universitat Politècnica de Catalunya, 2026)

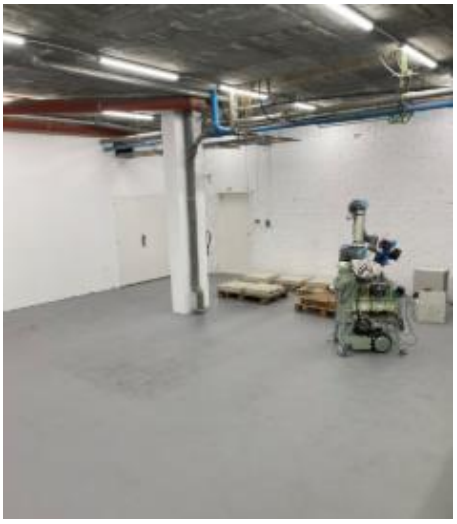

Figure 2 - Oliwall in motion testing (Universitat Politècnica de Catalunya, 2026)

Pokeye is also ready to be tested on a case study site. Currently, the definition of specifications for the autonomous invasive identification system, the development of portable analyser system for material inspection and robotic drilling for material extraction for further analysis are complete and the prototype of Pokeye is being finalised with the coordination tool and user interface almost complete.

5.2. Material list development

Expert analysis of materials commonly identified in older buildings and infrastructure has been carried out to contribute information to the training of Oliwall in the identification of the materials and elements. The material list has been divided into categories and indicators of the ease of extraction. These materials are methodically laid out and categorised by identification difficulty, reuse potential and commercial value as well as the likely risk of hazardous substances contained within them, as seen in Table 1.

5.3. AI algorithms in progress

Currently the AI algorithms are undergoing development and have contributed to the learning of the robot to correctly identify elements and objects. So far, the algorithm has been trained to visually identify objects and elements with 88784 images used in training.

5.4. Industry survey results regarding current best practices in demolition and motivations

Detailed surveys regarding current practices by active stakeholders in the demolition industry have been shared with companies and professionals in the industry across the EU and UK. The survey covers questions on the principal strategies currently employed in the industry considering different building types, current pre-demolition practices, general deconstruction techniques applied, the uptake of selectivity in deconstruction projects and incentives for increasing this practice as well as waste management strategies. The results of the survey have been analysed to determine the general status quo of the approach of different companies across Europe in regard to demolition activities. General insights include 31 survey results so far:

- The most identified pre-works inspection was visual expert inspection with identification of hazardous materials being the highest priority.

- Companies were asked to identify which incentives would encourage them to increase their selective practices in demolition projects. Figure 4 indicates that the most identified incentive was financial or fiscal benefits or penalties and policy requirements.

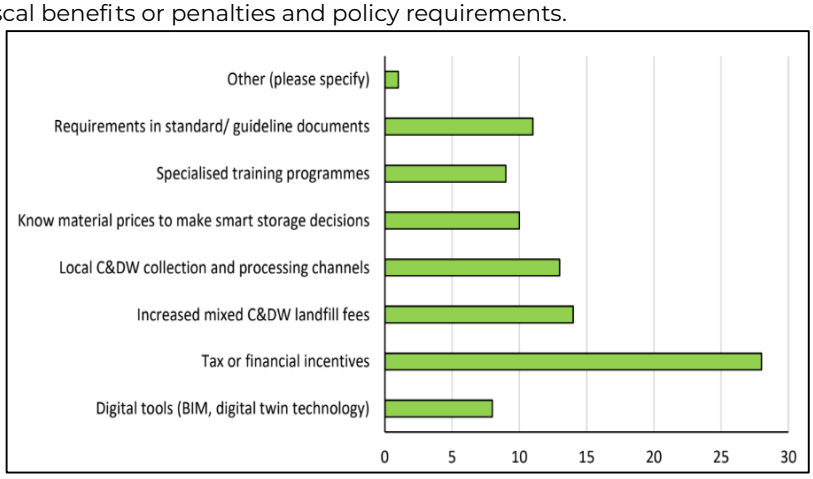

Figure 3 - Encouragement to apply selective demolition in the EU, as reported by demolition companies (Instituto Superior Técnico 2026)

- Generally, the findings showed that demolition companies most frequently use mechanical demolition with specialist equipment as a primary technique across a variety of building types. This indicates an associated promising versatility with this technique. Secondary techniques employed vary significantly across different building types. In many building types, manual demolition was identified as being the second-most employed option, which does indicate feasibility of increased selectivity processes;
- Insights on waste management from demolition projects indicated that currently in the EU 70% of CDW was reused onsite or sold to recycling facilities. Meanwhile nearly 30% of waste emitted from demolition sites is still being sent to landfill. If this is fully representative, this comprises about 238 million tonnes of CDW still ending up in landfill across the EU each year. This is evidenced in Figure 5 showing the survey results on outcomes of demolition waste.

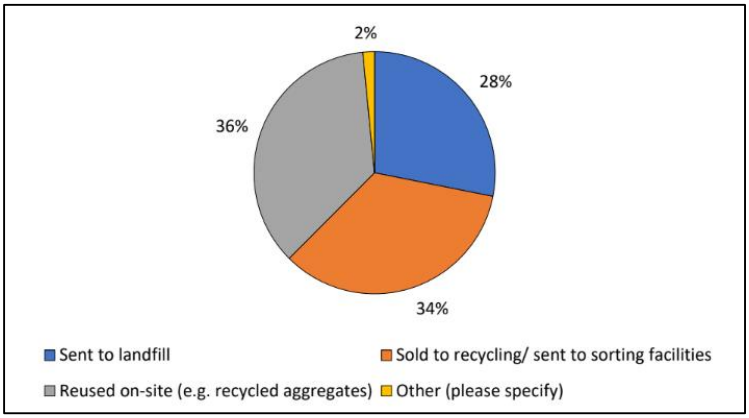

Figure 4 - Survey results showing current outcomes of demolition waste (Instituto Superior Técnico 2026)

5.5. LCI progress

Input from sister projects and project industry partners, as well as survey data, are being used for the development of a life cycle inventory to inform the LCA and LCC phase of the project. Detailed data collected will contribute inputs on energy and water use associated with most commonly used equipment for

deconstruction as well as labour hours, cost and risk exposure. This information will be used to analyse and compare different techniques for their relative environmental and cost impacts including the energy and water use as well as the output of recovered materials and their environmental savings and financial value.

Table 1 - Material list for the consideration of the AI algorithm training and scanning tools and consideration in the LCA and LCC analyses and material database (Universitat Politècnica de Catalunya, 2026)

Group	Material	Identification difficulty	Separation difficulty#	Reuse/recycling potential	Commercial value*	Possibility of hazardous substances	Remarks
Hazardous waste	Asbestos-containing materials	Hard	Normal/Hard	-	None	Asbestos	Highly varied applications ; visual recognition or (mostly) lab.
	Tar asphalt	Hard	Normal	-	None	Tar	Can be tested with PAK spray or lab analysis.
	Tar roofing	Hard	Hard	-	None	Tar	Can be tested with PAK spray or lab analysis.
	WEEE containing CFCs/HCFCs/HFCs	Normal	Normal	-	None	CFCs/HCFCs/HFCs	e.g. refrigeration, freezing and air-conditioning installations
	WEEE: fluorescent lamps	Easy	Easy	-	None	Mercury	Easy to identify, manual measurement is time-consuming.
	WEEE: ionising smoke detector	Easy	Easy	-	None	Radioactive	Easy to identify, manual measurement is time-consuming.
	WEEE / other materials containing PCBs	Normal	Normal	-	None	PCBs	e.g. transformers and capacitors.
	Gases in pressure containers	Easy	Easy	-	None	Dangerous substances	e.g. fire extinguisher, manual measurement is time-consuming
	oil tanks	Normal	Normal	-	None	Mineral oil	In plastic or metal; sometimes underground.
	Materials contaminated by fire	Easy	Normal	-	None	Soot	-
	Contaminated treated wood	Normal	Normal	-	None	Toxic chemicals	e.g. train sleepers, garden wood.
Others	Textile	Easy	Normal	Reuse + Recycling	Normal	-	e.g. carpet flooring.
	Light bulbs	Easy	Easy	-	Low	Small doses of mercury	Easy to identify, manual measurement is time-consuming.
	Gypsum and lime plaster	Normal	Hard	-	Low	Gypsum: sulphate + can contain asbestos	Interfering substances in stony material but selective removal is time-intensive - Future: possible sulphate norm for recycled aggregates (gypsum vs lime plaster).
	Porcelain	Easy	Normal	Reuse	Normal	-	Currently, no separate recycling pathway.
	Fibre cement board	Normal	Normal	Recycling	Normal	-	Similar looking to asbestos-containing fibre cement (high risk for contamination).
	Types of floor-insulation	Normal	Hard	-	Low	-	e.g. (1) concrete with expanded clay aggregates; (2) insulating screed/mortar (EPS beads) - (1) disposed of with debris, aggregates can be interfering substances (2) mixed waste.
	Composite and/or non-separable materials	Normal	Normal/Hard	Sometimes	Normal	-	e.g. sandwich panels, sectional doors, concrete slab with epoxy floor.

Note: WEEE = Waste Electrical and Electronic Equipment; *Commercial Value should not be the main criterion, given the variability. If an extended producer responsibility (EPR) is/will be implemented for a material, it has a significant impact on the price. #Indication of the easiness for a material to be dismantled (including the required equipment and taking into account the fixing method).

6. Expected outcomes

Results of the DISCOVER project are pending its conclusion. Expected outcomes and impacts of the project include technical innovations in robotics and artificial intelligence-based inspection, digital integration for management of secondary recovered assets for increased circularity, site safety and reduction of environmental impact. Figure 6 highlights the expected impact pathways for the output of the project based on the DISCOVER objectives.

Figure 6 - Expected Impact pathways of the output of the DISCOVER project

6.1. Technical expectations and industry level impact

The robotic system represents an innovation in the industry that fills a gap in the current approach to deconstruction in terms risk to human life and end of life management for buildings and materials. The robotic inspections will interact with artificial intelligence models developed in the project to allow for fast paced analysis of the components and material characteristics identified on site, which effectively replace expert individual inspection systems in high-risk situations. The data gathered from the AI integrated robotic inspections will feed into a BIM plugin tool. The BIM model provides an interactive tool for decision makers with a visual interface and information on materials and components present. It offers additional input regarding selective deconstruction recommendations based on a multi-criteria analysis including the material characteristics, cost, time and environmental impact comparison. This digital twin will work effectively for demolition and/or rehabilitation sites in different building types with varying material composition, historical and policy context across the EU. The BIM model, with input from the robotic model and AI inspection tools, will provide the user with:

- Visual interface of the works area;
- Building elements and material composition and quantities, both visible and concealed;
- Best practices and recommendations for selective deconstruction based on inputs of time, labour, cost and outputs of extracted materials;
- LCA and LCC analyses associated with different deconstruction scenarios and with material recovery scenarios to provide insights into environmental impacts and potential savings and material value within a circular management strategy.

The obtained materials extracted from the works projects will be traceable to facilitate the maximisation of circularity for materials extracted from project areas.

6.2. Environmental expectations

The goals of the DISCOVER project relate to the reduction of environmental impact of demolition of buildings and building elements as well as the associated human cost. Overall, the expectations following from the successful implementation of the methodologies described to develop the innovative approach to circularity in deconstruction include the following:

- Lower construction sector emissions by 15%;
- Increase reused components by up to 20% and reduce construction and demolition waste in the EU by 55%. (m.kat 2025).

7. Conclusions

DISCOVER is an EU initiative involving research and industry partners working on an innovative solution to reduce the impact of and realise the potential of the currently under-exploited resource of waste materials generated annually in the EU, originating from the deconstruction of infrastructure. DISCOVER intends to transform attitudes to waste in the deconstruction sector via innovative solutions in the field of robotics and artificial intelligence to accelerate automation of pre-works inspections, reducing the need for human involvement in high-risk environments and increasing the availability of spatial and material mapping of works areas via integration to a digital twin. The digital twin will provide a user interface for industry professionals whereby support tools are offered to aid in circular decision-making regarding techniques and methods for deconstruction and extraction of valuable materials for re-circulation and repeated use. The DISCOVER project is currently underway, having achieved several milestones and with expected outcomes at the end of 2028 to include advancements in the field of robotics and AI in deconstruction for improved circularity and sustainability in the management of CDW.

Resumo: A utilização de instrumentos portáteis de fluorescência de raios X foi essencial para investigações de análises multielementares no campo da arqueometalurgia. O objetivo desta pesquisa foi investigar a aplicação da fluorescência de raios X em um artefato metálico do sítio histórico Baluarte Porta da Terra. O arcabouço metodológico foi desenvolvido em seis etapas: atividade preliminar, análise de fluorescência de raios X, procedimentos de limpeza, análise de fluorescência de raios X, preparação metalográfica e análise de fluorescência de raios X. Foram identificados 14, 16, 14 e 13 elementos químicos, com percentual de Fe de 50,87%, 70,15%, 96,08% e 96,00% para as quatro condições: artefato bruto, limpo, amostra longitudinal e amostra transversal, respectivamente. Os metais do passado em grau de deterioração carecem de metodologias específicas para a obtenção de informações assertivas e bem-sucedidas no contexto da arqueometalurgia. Difundir teorias e práticas da fluorescência de raios X portátil pode criar, ampliar, acelerar e aprofundar informações necessárias para gerar análises conjuntas direcionadas à elucidação das informações dos materiais de construção dos patrimônios históricos.

Palavras chaves: Fluorescência de Raios X Portátil; Análises Composicionais; Procedimentos; Metal histórico.

Abstract: The use of portable X-ray fluorescence instruments was essential for multielement analyses in the field of archaeometallurgy. The objective of this study was to investigate the application of X-ray fluorescence to a metallic artifact from the Baluarte Porta da Terra historical site. The methodological framework was developed in six stages: preliminary activity, X-ray fluorescence analysis, cleaning procedures, X-ray fluorescence analysis, metallographic preparation, and X-ray fluorescence analysis. A total of 14, 16, 14, and 13 chemical elements were identified, with Fe percentages of 50.87%, 70.15%, 96.08%, and 96.00% for the four conditions: raw artifact, cleaned artifact, longitudinal sample, and transverse sample, respectively. Ancient metals in advanced stages of deterioration require specific methodologies to obtain accurate and successful information within the context of archaeometallurgy. The dissemination of theories and practices related to portable X-ray fluorescence may create, expand, accelerate, and deepen the information necessary to generate integrated analyses aimed at elucidating the construction materials of historical heritage sites.

Keywords: Portable X-Ray Fluorescence; Compositional Analyses; Procedures; Historical Metal.

1. Introdução

As investigações sobre os materiais metálicos representaram informações que ampliaram a compreensão da evolução da metalurgia (Hernandez-Escampa et al. 2010). O registro material do passado teve um papel importante no mundo (Wayman 2000), pois permitiu a datação e o controle do contexto espacial dos dados (Levy et al. 2008), reconstituindo aspectos pouco conhecidos da história, em razão da escassez de relatos escritos, da falta de fontes primárias arquivísticas e das lacunas da historiografia disponível (Campos and Granato, 2015). Logo, uma melhor compreensão do passado tornou-se cada vez mais importante, à medida que nossas vidas e nosso futuro se tornaram mais complexos (Wayman, 2000). Os registros arqueológicos dos materiais metálicos foram de grande importância para a compreensão das redes sócio-políticas existentes (Hsu et al. 2020), e a determinação da composição química de objetos individuais ajudou a localizar a origem do metal e, potencialmente, a data de produção (Alipour et al. 2021).

Os instrumentos de campo portáteis, baseados na tecnologia de energia dispersiva por fluorescência de raios X, reportaram as concentrações elementares dos materiais analisados (Bruker, 2025). As análises da composição de elementos metálicos por espectrometria de fluorescência de raios X por dispersão de energia (FRX-ED) requereram uma discussão prévia mais extensa (Llorens and Ruiz, 2018). Os instrumentos portáteis de fluorescência de raios X e suas aplicações ganharam considerável atenção na comunidade arqueológica nos últimos anos (Frahm and Doonan, 2013), mas a aplicação das técnicas nas amostras arqueológicas foi frequentemente limitada pela dificuldade na preparação das amostras (Hiller and Wess, 2006). Os arqueólogos históricos recorreram cada vez mais à química arqueológica para construir narrativas sobre colonialismo, escravidão, economias políticas, inovações tecnológicas e uma série de outros tópicos (Greer *et al.*, 2025), e a análise composicional global multielementar, realizada pela fluorescência de raios X, ajudou a aprofundar os conhecimentos químicos do passado.

O Laboratório de Perfil Técnico (Lapet), no Núcleo de Metrologia Arqueológica da Universidade Federal de Pernambuco, possui uma numerosa coleção de vestígios de materiais metálicos advindos de escavações arqueológicas, extraídos/coletados na região metropolitana de Recife-PE. Foram resgatados inúmeros artefatos metalúrgicos de escavações arqueológicas nos sítios históricos da cidade do Recife e depositados no Laboratório de Perfil Técnico, sofrendo um processo contínuo e avançado de corrosão (Souto Maior and Souza, 2019). Alguns artefatos metálicos não resistiram ao tempo, pois os estados mínimos de conservação para estudos arqueometalúrgicos não foram atendidos. Os pesquisadores ressaltaram que a deterioração de artefatos antigos dependeu de vários fatores, tais como composição dos materiais, processos de fabricação e ambientes aos quais foram expostos (Dwivedi and Mata, 2019). Portanto, a preservação do patrimônio cultural foi de importância fundamental para o desenvolvimento e o enriquecimento cultural de um povo, bem como guardou informações e registros da história humana, das crenças, dos costumes, do conhecimento tecnológico e das condições sociais, econômicas e políticas de um grupo em determinada época (Asfora, 2010). Urge incentivar, desenvolver e executar pesquisas científicas de ordem experimental para a obtenção de respostas analíticas sobre o passado desses artefatos metálicos.

2. Metodologia

O planejamento experimental da pesquisa foi dividido em seis etapas. A primeira etapa, denominada atividade preliminar, consistiu no resgate dos artefatos metálicos e na caracterização macroscópica. A segunda etapa foi a análise de fluorescência de raios X (FRX) do artefato nas condições iniciais (antes de qualquer manipulação ou tratamento). A terceira etapa foi destinada aos procedimentos de limpeza (manuais, mecânicos e químicos). Em seguida, foram realizadas as análises de fluorescência de raios X (FRX) dos artefatos nas condições limpas (menor incidência de contaminações e/ou impurezas). A quinta etapa foi a preparação da lâmina (amostra), composta pelo corte metalográfico e embutimento. Finalmente, a sexta etapa foi destinada à análise de fluorescência de raios X (FRX) do núcleo metálico (seções longitudinal e transversal). A Figura 1 apresenta o fluxograma do planejamento experimental.

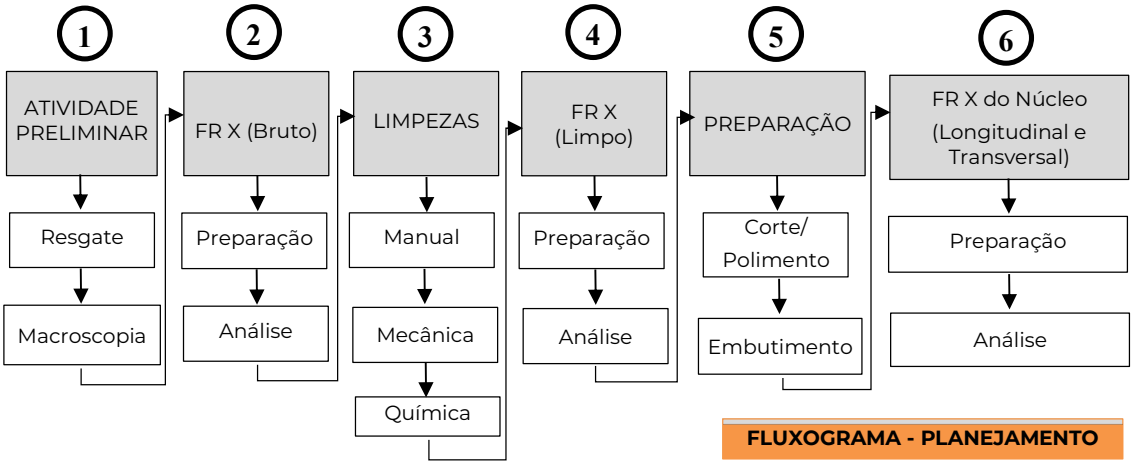

Figura 1 – Planejamento Experimental

2.1 Atividade preliminar

O artefato metálico foi resgatado das ruínas das construções do sítio histórico Baluarte Porta da Terra e etiquetado com a numeração nº 2553, contendo as seguintes informações: nível: DEC.06; município: Recife; UF: PE; quadrícula: A3; setor: A. O artefato foi resgatado em 18 de agosto de 2004 e identificado visualmente como matéria-prima metálica. As características macroscópicas realizadas no laboratório indicaram dimensão longitudinal de 10,99 cm e peso de 0,058 kg.

O sítio histórico Baluarte Porta da Terra fica localizado na área central, denominada Ilha do Recife no período colonial, e foi um dos primeiros lugares em Pernambuco onde foi registrada a ocupação de colonos europeus (Souto Maior and Souza, 2019). Os trabalhos arqueológicos tiveram início no canteiro do baluarte com um levantamento fotográfico, a locação da estação topográfica, a divisão interna em setores (A, B, C e D) e, finalmente, o procedimento de escavações e resgates dos artefatos (Medeiros, 2005). A Figura 2 apresenta uma planta de localização dos setores de escavações do sítio histórico Baluarte Porta da Terra.

Figura 2 – Setor de escavação do Baluarte Porta da Terra

Fonte: (Medeiros, 2005).

2.2 Fluorescência de raios X do artefato bruto

O equipamento portátil de fluorescência de raios X foi utilizado no artefato bruto, com tempo de aplicação de 60 segundos, realizando três leituras no mesmo ponto. O equipamento identificou os elementos químicos e estabeleceu a média das três leituras das concentrações em partes por milhão (ppm), posteriormente transformadas em porcentagens. O procedimento de análise consistiu na aplicação direta do instrumento de fluorescência de raios X no artefato bruto (Figura 3).

Figura 3 – Artefato metálico bruto nº 2553

2.3 Limpezas

O primeiro desafio para o estudo do artefato metálico foi o procedimento de limpeza, pois as concreções e as oxidações dificultaram o reconhecimento do tipo de fragmento metálico. Logo, foram realizadas limpezas em etapas sequenciadas para obter um resultado significativo. Nesta pesquisa, foi utilizada uma sequência dividida em três fases: limpeza manual, limpeza mecânica e limpeza química (**Erro! Fonte de referência não encontrada.**).

Tabela 1 – Tipos de limpezas realizadas no artefato metálico

Limpeza manual	Limpeza mecânica	Limpeza química
Utilizaram-se escovas de aço com água destilada para a remoção das partículas de concreções e oxidações encontradas na superfície da peça metálica.	Utilizou-se uma micro-retífica multiuso com brocas de cerâmica para a remoção profunda das partículas mais duras de concreções e oxidações agregadas à superfície da peça metálica.	Por meio de um processo eletrolítico com uma bateria de automóvel, cabos de 6 mm, água destilada, sal marinho e uma peça metálica sacrificada, foi realizada a limpeza química final.

2.4 Fluorescência de raios X do artefato limpo

O procedimento de análise de fluorescência de raios X portátil na amostra limpa foi similar ao procedimento realizado na amostra bruta, no qual houve aplicação direta do instrumento de fluorescência de raios X no artefato, no tempo de 60 segundos, realizando três leituras no mesmo ponto. A Figura 4 apresenta o artefato metálico após os procedimentos de limpeza.

Figura 4 – Artefato metálico limpo nº 2553

2.5 Preparação metalográfica

A preparação das lâminas requereu cuidados especiais. O tamanho da amostra foi fundamental para a análise de fluorescência de raios X, bem como a qualidade do corte, a regularização, a planicidade e o polimento superficial. Com a utilização de uma serra diamantada portátil, com um líquido refrigerante especial para cortes metalográficos, foram realizados cortes, fatias, secções e pedaços das partes longitudinal e transversal do artefato metálico (Figura 5).

Figura 5 – Serra de corte diamantada portátil para corte metalográfico

Após as extrações dos pedaços das amostras, as lâminas receberam lixamento na superfície da camada superficial com a utilização das lixas n° 500, 1500 e 3000. O procedimento de lixamento utilizou uma sequência de lixas com movimentos repetidos de ida e volta, na direção de cima para baixo da face da amostra, por 1 minuto. Em seguida, o procedimento consistiu em girar em 90° o sentido da face e realizar o lixamento por mais 1 minuto. Esse procedimento foi repetido 4 vezes e, finalmente, foi realizado o polimento com feltro verde e pasta diamantada de 1 e 1,4 µm na politriz (Figura 6).

Figura 6 – Regularização, polimento e acabamento da lâmina metálica

A última etapa de preparação das lâminas consistiu na impregnação com resina e no acabamento da superfície. Nesta fase, foi selecionado um molde padrão circular de policloreto de vinila (PVC), com altura de um centímetro. Em seguida, a resina foi preparada e lançada no molde para a criação da primeira camada de impregnação. Na sequência, a amostra foi depositada no molde e coberta com resina epóxi (Figura 7).

Figura 7 – Embutimento da lâmina metálica na resina Epoxi

2.6 Fluorescência de raios X do núcleo

A fluorescência de raios X foi aplicada no núcleo metálico da amostra (seções longitudinal e transversal) para identificar e quantificar os elementos químicos da matriz metálica, isenta de contaminações e pátinas agregadas à superfície durante as análises anteriores. O tempo de leitura foi de 60 segundos, com calibração para metais, utilizando instrumento de fluorescência de raios X modelo S1 TITAN, tensão de 15 kV e corrente de 13,9 µA. Os procedimentos de utilização do instrumento de fluorescência de raios X foram idênticos aos procedimentos utilizados nas duas oportunidades anteriores (Figura 8).

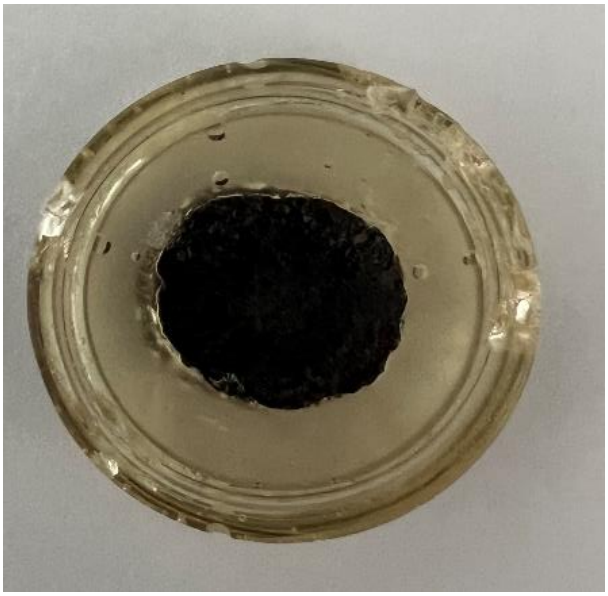

Figura 8 – Núcleo metálico embutimento na resina Epoxi

3. Resultados e discussão

Os resultados foram divididos em três subitens: 3.1 Artefato metálico bruto e limpo; 3.2 Amostras metálicas (seções longitudinal e transversal); e 3.3 Análise conjunta.

3.1 Artefato metálico bruto e limpo

As análises de fluorescência de raios X no artefato foram obtidas tanto na situação do artefato bruto quanto na do artefato limpo, apresentando análises multielementares de 14 e 16 elementos químicos, respectivamente (Tabela 2). Segundo Rogan *et al.* (2019), a fluorescência de raios X portátil foi baseada no princípio de que os elementos detêm uma energia de ligação única dos elétrons, associada ao elemento correspondente, capaz de detectar vários elementos químicos.

Tabela 2 – Resultados da fluorescência de raios X nos artefatos bruto e limpo

EQ	Fe	Ca	Co	Si	Cu	Al	Ti	Mn	Cr	Rb	Sn	Ba	Sd	Pd	Sr	Zr	Cd

CV (%)	22,53	117,76	141,42	4,46	141,42	118,31	77,14	38,57	141,42	0,00	15,71	20,20	47,14	20,20	111,65	141,42	0,00

Nota: EQ: Elementos químico; AB: Artefato bruto; AL: Artefato limpo; DP: Desvio padrão; CV: Coeficiente de variação; *n.i.:* não identificado.

A análise do artefato bruto foi comprometida pela pátina, concreção e oxidação. Conforme Llorens and Ruiz (2018), a corrosão do metal criou, na maioria dos casos, uma camada superficial de compostos (pátina), na qual encontraram-se todos os elementos químicos do metal saudável, mas com proporções de peso e/ou percentual muito diferentes das do próprio metal. Os resultados apresentaram informações imprecisas sobre a matriz metálica, observadas mediante a comparação dos resultados da fluorescência de raios X no artefato bruto versus o artefato limpo, como, por exemplo: quantidade significativa de Ca e Al no artefato bruto e quantidade desprezível desses mesmos elementos químicos na análise do artefato limpo; ausência de Co, Cu e Cr no artefato bruto, em contraponto com a presença desses elementos químicos no artefato limpo. De acordo com Handheld XRF (2024), dependendo da distância de aplicação e do tipo da dose (profunda ou rasa), o feixe pode atingir diferentes profundidades.

O problema observado durante a execução do programa experimental foi a investigação do artefato metálico bruto, pois a quantidade de contaminações, pátinas e concreções dificultou a manipulação e a obtenção de resultados sobre a composição global e multielementar do metal. Para Carl and Young (2016), a fluorescência de raios X na peça bruta permitiu estudos de superfície do artefato metálico, fornecendo benefícios para futuros estudos. O estado de conservação do artefato bruto foi crítico, estando totalmente coberto de pátinas e restos de construção, dificultando a identificação, manipulação e investigação. Segundo Aranda-Contamina *et al.* (2021), o estado de conservação dos objetos metálicos foi um ponto importante, e, como boa prática, a escolha de artefatos menos comprometidos permitiu melhor manipulação para eliminar a pátina superficial durante a limpeza.

3.2 Amostras metálicas (seções longitudinal e transversal)

As análises de fluorescência de raios X nas amostras foram obtidas para as seções longitudinal e transversal, resultando em análises multielementares de 14 e 13 elementos químicos, respectivamente (Tabela 3). Conforme Llorens and Ruiz (2018), os ensaios de fluorescência de raios X foram desenvolvidos para analisar a superfície do objeto, extraindo informações até uma profundidade de algumas dezenas de micrômetros.

Tabela 3 – Resultados da fluorescência de raios X das amostras seção longitudinal e seção transversal

Não foram observadas grandes alterações dos elementos químicos e de suas quantidades nas análises da amostra da seção longitudinal, quando comparadas às análises da amostra transversal. Os principais elementos químicos identificados foram Fe, Co e Ta, perfazendo 99,53% na amostra longitudinal e 99,48% na amostra transversal. Conforme Llorens and Ruiz (2018), os ensaios de fluorescência de raios X foram desenvolvidos para analisar a superfície do objeto, extraindo informações até uma profundidade de algumas dezenas de micrômetros. Este resultado reforçou a precisão da análise de fluorescência de raios X, quando realizadas nas regiões profundas e protegidas das amostras.

3.3 Análise conjunta

Foi realizada a aplicação da fluorescência de raios X no metal em quatro condições distintas, a saber: a primeira, no artefato metálico bruto (condições originais do artefato resgatado); a segunda, no artefato metálico limpo, após os procedimentos de limpeza manual, mecânica e química (eletrólise); e, finalmente, no núcleo metálico (seções longitudinal e transversal), produzido após os cortes metalográficos, nos quais foram identificados 14, 16, 14 e 13 elementos químicos, respectivamente. De acordo com Kaufman *et al.* (2016), a espectroscopia portátil de fluorescência de raios X permitiu análises rápidas, não destrutivas e minimamente invasivas, que serviram simultaneamente para caracterizar o metal.

O metal foi resgatado das ruínas do sítio histórico Baluarte Porta da Terra, coberto de terra e restos de construções. Durante as análises de FRX, foi identificado e quantificado o elemento Ca, sendo observado um grande percentual na amostra bruta e um pequeno percentual na amostra limpa. Em contraponto, quando analisado o núcleo metálico, esse elemento químico (Ca) não foi identificado. Possivelmente, o Ca foi resultado da contaminação por quartzo contido nos materiais de construção, tais como reboco e cimento, aderidos à superfície do artefato metálico. De acordo com María Gómez De Salazar and Soria (2000), materiais metálicos enterrados apresentaram elementos contaminantes, como o quartzo, agregados à superfície deles. Segundo Rogan *et al.* (2019), a otimização das configurações do FRX portátil para um elemento impediu a análise quantitativa de vários outros elementos de interesse. Por exemplo, para elementos como Ca e Fe, quando a quantificação pareceu aceitável, diferentes tipos de solo e faixas elementares alteraram significativamente a precisão da abordagem.

Aconteceram tentativas frustradas durante a fase de preparação da amostra para investigação do núcleo, como, por exemplo, a dificuldade do corte metalográfico para extrair uma amostra com área mínima capaz de receber o diâmetro total do feixe de raios X do instrumento. Conforme Kaufman *et al.* (2016), o ponto de detecção da FRX na amostra foi um quesito importante, pois, em algumas regiões pequenas, quando o diâmetro do feixe de FRX foi maior, a fluorescência produzida foi absorvida pelo material e, posteriormente, pelo ar, resultando na quantificação total menor que 100% dos elementos químicos. De acordo com Colpaert (2008), os elementos químicos intervieram diretamente na composição dos metais, como nos aços comuns definidos pelas percentagens de carbono, silício, manganês, fósforo e enxofre. O metal estudado apresentou o ferro como elemento majoritário presente nas quatro situações e outros elementos secundários (Tabela 4).

Nota: *n.i.*: não identificado; EQ: Elemento químico; AB: Artefato bruto; AL: Artefato limpo; ASL: Amostra seção longitudinal; AST: Amostra seção transversal; DP: Desvio padrão; CV: Coeficiente de variação; *AST de dimensões pequenas não obtendo 100% da identificação e quantificação multielementar.

As quantificações totais das análises de fluorescência de raios X do artefato bruto, do artefato limpo, da amostra longitudinal e da amostra transversal representaram o percentual total de 100%, com exceção da amostra transversal, que totalizou 99,98%. De acordo com Handheld XRF (2024), o diâmetro mínimo do feixe dos instrumentos de fluorescência de raios X portáteis, na distância mínima de 1,50 cm, correspondeu a 1,20 cm. Por isso, a amostra transversal, com diâmetro menor que 1,20 cm, apresentou resultado incompleto da quantificação total dos elementos químicos. Alguns elementos identificados e quantificados com pequenas porcentagens nas quatro análises ocorreram devido à contaminação ou às limitações na configuração do instrumento. Rogan *et al.* (2019) identificaram que mudanças simples nas configurações, como alterar a tensão emitida pelo FRX portátil, ampliaram a sensibilidade do instrumento para análises de elementos como, por exemplo, Cu.

A pesquisa confirmou que o artefato metálico foi uma liga ferrosa e teve como elemento principal o ferro, perfazendo um quantitativo de 50,87% no estado bruto, 70,15% no estado limpo, 96,08% no núcleo (ASL) e 96,00% no núcleo (AST). Corroborado por Jr. Callister and Rethwisch (1940), que afirmou que as ligas ferrosas foram aquelas em que o ferro foi o componente principal, mas o carbono e os outros elementos de ligas metálicas, provocaram mudanças bastante drásticas no diagrama de fases binário ferro-carbono. Conforme Llorens and Ruiz (2018), os instrumentos de fluorescência de raios X não identificaram elementos químicos

com número atômico pequeno, como, por exemplo, o carbono, com número atômico 6. Tal limitação reduz a possibilidade de identificação de algumas ligas, como, por exemplo, aquelas compostas pelo elemento químico carbono.

O cobalto não foi identificado na amostra bruta, possivelmente porque a quantidade de pátinas, concreções e oxidações limitou a sua identificação pelos raios X emitidos na superfície. No entanto, o cobalto foi identificado e quantificado nas duas outras análises (limpa e núcleo), e as evidências apontaram que provavelmente foi inserido intencionalmente para produzir uma liga ferrosa com características específicas. Dehaine *et al.* (2021) afirmaram que o cobalto forneceu propriedades físicas únicas, incluindo resistência ao calor, força e propriedades magnéticas, e teve uma ampla variedade de aplicações nas ligas metálicas.

A Tabela 5 apresentou a matriz de identificação dos elementos químicos com diferentes resultados nas análises de FRX aplicadas ao mesmo material em quatro condições distintas, a saber: artefato bruto, artefato limpo, amostra da seção longitudinal e amostra da seção transversal, tanto nos aspectos qualitativos (tipo de elemento químico identificado) quanto no aspecto quantitativo (quantidade em percentual). A análise conjunta sugeriu as seguintes observações: o único elemento químico identificado nas quatro condições foi o Fe, definido como elemento químico majoritário; Ca, Si, Al, Ti e Sr foram identificados no artefato bruto e limpo, mas ficaram ausentes nas análises das amostras longitudinal e transversal, podendo corresponder a contaminações aderidas ou tratamentos na superfície do artefato; Co, Ta e Sn foram identificados nas amostras longitudinal e transversal, fazendo parte do núcleo metálico, e podem ter sido inseridos para fornecer características específicas da liga; os demais elementos (Cu, Mn, Cr, Rb, Ba, Sd, Pd, Zr, Cd, Bi, Pb, W, Rh, V e Se) não foram identificados e/ou obtiveram quantidades irrelevantes/desprezíveis. De acordo com Llorens and Ruiz (2018), os problemas de análises de superfície por fluorescência de raios X foram inerentes às transformações que ocorreram entre o material original e o material analisado, como, por exemplo, o efeito da corrosão nos metais.

4. Conclusão

O instrumento portátil de fluorescência de raios X possibilitou, de forma prática, simples e precisa, a determinação qualitativa e quantitativa multielementar dos artefatos metálicos. A técnica foi baseada na excitação dos elétrons do átomo de um material por uma fonte de radiação (raios X primários), na qual foi liberada uma radiação secundária (fluorescência), com uma energia característica de cada elemento químico. Os raios X fluorescentes, ao atingirem o detector (placa de silício), identificaram e quantificaram os elementos químicos presentes nas amostras, pois cada elemento químico emitiu uma energia única. Os instrumentos mais modernos evoluíram e tiveram sua fonte de excitação composta por um tubo de raios X com ânodo de ródio, ideal para elementos químicos com número atômico entre 12 e 92. Por isso, alguns elementos, como carbono, oxigênio e sódio, entre outros com número atômico fora desse intervalo, não foram identificados.

A utilização da fluorescência de raios X permitiu confirmar os elementos químicos presentes na superfície do metal (contaminações), verificar a composição elementar em pontos estratégicos do artefato metálico e determinar, qualitativa e quantitativamente, a composição elementar do metal. Ficou comprovado que o artefato metálico foi constituído majoritariamente de ferro, apresentando uma pequena quantidade de cobalto no núcleo. As evidências iniciais foram claras quanto ao nível de tecnologia na produção de ligas metálicas utilizadas na construção do sítio histórico Baluarte Porta da Terra, desenvolvido pelos europeus.

Os resultados revelaram o potencial do FRX portátil no suporte a pesquisas na área de arqueologia, bem como a simplicidade da utilização e da realização do programa experimental, incentivando pesquisadores de áreas distintas das ciências exatas e da natureza. Ficou evidente que as análises por instrumentos portáteis de fluorescência de raios X serviram para encurtar as investigações sobre determinados materiais, agregando ou descartando a continuidade do programa experimental, economizando tempo, recursos financeiros e esforço humano nas pesquisas na área da arqueometalurgia.

Abstract: The Interlocking Concrete Block Pavement (ICBP) has been used in many countries as a sustainable paving alternative due to its durability, ease of maintenance, and improved drainage. However, the combined effects of traffic and climate lead to pavement deterioration over its service life. Maintenance and rehabilitation (M&R) interventions help delay this degradation process when properly applied, although they require financial resources and time. This study aims to evaluate whether it is possible to establish the optimal timing for M&R activities based on performance assessment and associated costs. The study was conducted on an 1,880 m road section, divided into ten homogeneous segments. Based on deflection data obtained from the Benkelman Beam Test, a back-analysis of the ICBP was performed to determine the stiffness of the block layer. Subsequently, a mechanistic-empirical elastic analysis was carried out using the AEMC software. From this, the service life, expressed as the number of Equivalent Single Axle Loads that the structure can still withstand, and the Residual Requests (RR) of the ICBP were determined. Four different scenarios for M&R activities were analyzed, and the costs of each scenario were estimated over the projected service life. It was observed that sections with lower stress absorption capacity in the block layer presented higher M&R costs. Furthermore, prioritizing preventive maintenance (RR = 60%), even at earlier stages and with higher frequency, results in lower costs over the service life. This methodology serves as a useful decision-making tool for establishing M&R strategies aimed at extending the service life of ICBP.

Keywords: Deflection, Performance assessment, Costs, Back-analysis, Elastic analysis.

1. Introduction

Compared to other types of pavements, the Interlocking Concrete Block Pavement (ICBP) presents several advantages, such as lower maintenance costs, greater ease in performing repairs, and improved stormwater drainage (Jamshidi et al. 2019; Mora et al. 2025; Sain et al. 2025). Additionally, this type of pavement shows better performance and cost-effectiveness compared to asphalt pavements for low- and medium-traffic roads (Gogoi 2019). Although the use of ICBP has been expanding worldwide, there are still gaps related to its management (Gogoi and Dutta 2019). This highlights the need for rational strategies to ensure safety, comfort, and performance throughout its service life.

Environmental factors and traffic contribute to the degradation of the ICBP structure, reducing its service life (Bezerra and Oliveira 2022). To mitigate this process, maintenance and rehabilitation (M&R) activities are required, usually planned through Pavement Management Systems (PMS). These systems are decision-support tools aimed at defining more efficient strategies to preserve adequate pavement conditions (Xiao et al. 2026). For this purpose, it is necessary to characterize structural conditions, which reflect the remaining load-bearing capacity (Jeon et al. 2025). In the case of ICBP, this characterization is performed using non-destructive methods such as the Benkelman Beam Test (BBT) and the Falling Weight Deflectometer (FWD) (Rathan and Sunitha 2021).

The typical ICBP structure consists of a surface layer made of concrete blocks supported by a bedding layer, as well as base, sub-base, and subgrade layers. Although the surface layer is composed of rigid elements, the structural behavior of ICBP is similar to that of flexible pavements (Rathan et al. 2021). Applied loads are

distributed among the layers, reducing stresses transmitted to the subgrade (Bezerra 2023). As a result, the layers respond elastically, generating recoverable deflections on the pavement surface. These deflections are used as indicators of the structural performance of ICBP (García and Corte 2021), as they express system deformability and support the design of reinforcements, as well as the definition of M&R strategies.

Laboratory determination of the elastic modulus (EM) for the block layer is complex and not yet standardized. An alternative approach is to perform a back-analysis (Rathan and Sunitha 2022). This process uses pavement deflections to estimate layer stiffness. With this, it is possible to conduct elastic analyses of ICBP and define management parameters. The structural condition of the pavement is related to its ability to withstand traffic loads, reflecting the current state of the structure compared to its initial condition. In this context, this condition can be quantified using RR, understood as a fraction of the design service life (Mikolaj et al. 2025). For ICBP, RR is directly related to vertical strain at the top of the subgrade. Therefore, its estimation is based on structural results obtained from mechanistic-empirical analysis (Rahman et al. 2018).

The management of ICBP based on structural parameters that indicate the remaining performance of the structure is characterized as a Condition-Based Maintenance approach. This approach is recognized as one of the main strategies for efficient transport infrastructure management (Gou and Liang 2026). Defining the optimal timing for M&R activities is essential to reduce costs and maximize pavement performance. Recent studies have sought to support this decision-making process: Gogoi et al. (2023) developed a multicriteria decision tool to establish a hierarchical maintenance plan for ICBP roads. Anitha et al. (2021) developed the concept of critical time to assess environmental performance and assist in scheduling interventions. These studies demonstrated effectiveness in improving the selection of M&R strategies.

Therefore, this study aims to analyze whether there is an impact on determining the optimal timing for M&R activities in ICBP, based on structural performance and intervention costs. The results are expected to contribute to the development of a decision-support tool, promoting more efficient use of resources and ensuring proper M&R of pavement structural conditions over time.

2. Methodology

Initially, the study area was defined, and structural data of the ICBP were collected (material characterization and deflection measurements). Subsequently, a back-analysis process was performed to determine the stiffness of the surface layer (block layer + bedding layer). Using these data, an elastic analysis of the structure was conducted, and RR was determined. After that, scenarios for M&R activities were proposed, and the costs of each scenario were established over the projected service life of the ICBP. Finally, the most technically and economically efficient strategy was defined. The Figure 1 summarizes the methodological structure of this study.

The study was carried out on a dual carriageway with a length of 1,880 m and a width of 7.2 m. The analysis was conducted in the 4th year of ICBP operation, with an estimated Equivalent Single Axle Load (ESAL) of 9.52×10^6. A service life horizon of 20 years was considered. The section is located in a port region, which justifies the robustness of the structure (Figure 2), designed to support heavy traffic with granular material in the lower layers over a sandy subgrade. The concrete blocks used were Unistein-shaped and laid in a herringbone pattern.

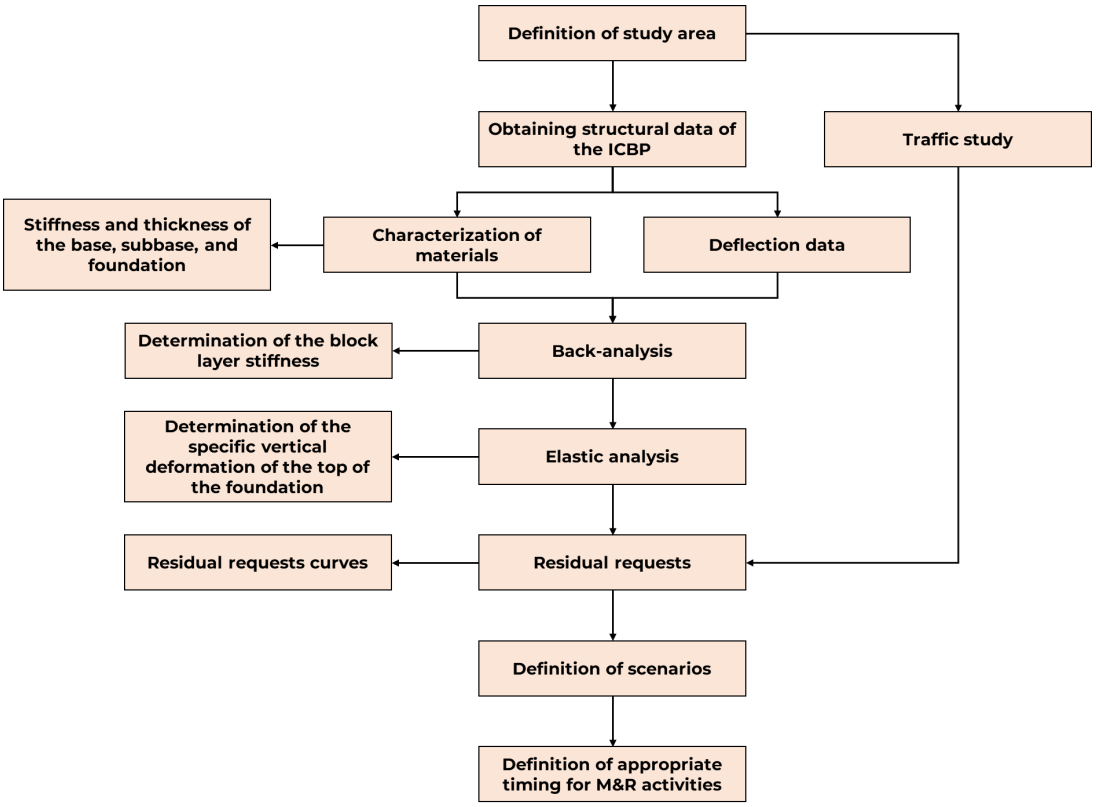

Figure 1 – Study structure (Authors 2026)

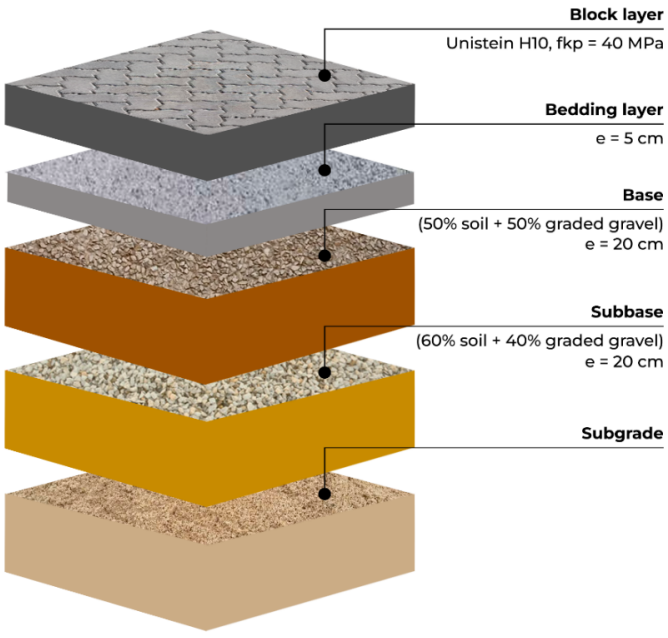

Figure 2 – ICBP structure (Authors 2026)

The section was divided into 10 homogeneous segments (ASTM 2019), with one section every 6 stations. The materials of the structure, except the bedding layer, were tested in the laboratory to obtain the stiffness of each layer. For this study, Shackel (1990) parameters were adopted for the bedding layer due to the difficulty of sampling and testing. Table 1 presents the geotechnical data for the materials used in the structure.

Table 1 – Geotechnical data of the materials

Layer	RM (MPa)	Poisson's ratio	Density (g/cm³)	Optimal humidity (%)	Composite RM model			
					K1	K2	K3	R^2
Bedding layer	15	0.30	1.65	-	-	-	-	-
Base	515	0.35	2.14	9.20	1124.65	0.46	- 0.22	0.82
Subbase	276	0.35	1.89	12.20	1281.95	0.56	0.01	0.92
Subgrade	235	0.40	1.79	11.00	696.05	0.44	-0.13	0.80

2.1 Traffic study

Based on vehicle counts at the study site, ESAL was calculated. The section presented an Average Daily Traffic (ADT) of 800 vehicles. Based on the American Association of State Highway and Transportation Officials method (AASHTO 1993), ESAL was projected over the 20-year service life of the ICBP (Table 2). These data were used to define RR for each section.

Table 2 – Traffic study

Year	ESAL	ADT	Year	ESAL	ADT
0	1.72×10^6	800	**11**	2.74×10^7	1369
1	3.53×10^6	840	**12**	3.05×10^7	1437
2	5.43×10^6	882	**13**	3.38×10^7	1509

2.2 Back-analysis

For this study, deflections were obtained using the BBT. However, it is important to note that this method was developed and calibrated for continuous surface pavements. Therefore, joints between the blocks may introduce variability in the measured results, and the deflection response may not accurately reflect the behavior of the flexible structure.

To address this, a statistical treatment based on the student's t-distribution was applied, considering a 95% confidence level (one-tailed), in order to determine the characteristic deflections of each section. The back-analysis was conducted using the BackCAP software (version 1.6.0), developed by Barroso et al. (2022). This software allows the definition of variation ranges for the resilient modulus (RM) of the materials, providing more representative results.

The equipment used in the measurements recorded deflections only at the center of the applied load (D0) and at a distance of 25 cm (D25), which made it impossible to determine the deflection basin of the ICBP. The material characterization data — RM, Poisson's ratio, and layer stiffness — together with the deflection values, were used as input data in the back-analysis software. The deflection results are presented in Table 3. Section 8 was excluded from the analysis due to inconsistencies in the deflection data collection.

Table 3 – Traffic study

Section	Station		Do (0,01mm)			D25 (0,01mm)		
	Start	End	Average	Standard deviation	Characteristic deflection	Average	Standard deviation	Characteristic deflection
1	0	6	43.00	3.83	**47.51**	8.50	1.91	10.75
2	8	14	37.50	3.42	**41.52**	7.50	3.42	11.52
3	16	22	39.00	5.03	**44.92**	5.50	1.91	7.75
4	24	30	41.00	3.46	**45.08**	7.50	3.00	11.03
5	32	38	41.00	2.00	**43.35**	7.00	8.27	16.74
6	40	46	47.50	17.84	**68.49**	10.50	6.81	18.51
7	48	54	42.00	12.65	**56.88**	10.00	4.32	15.08
9	64	70	91.33	9.87	**10.97**	16.67	5.77	26.40
10	72	78	92.00	2.83	**95.33**	9.50	2.52	12.46

For the back-analysis, the RM values obtained from laboratory tests were adopted. However, for the subgrade, free variation of RM was allowed, acknowledging that several factors may influence its mechanical behavior. For the base, subbase, and bedding layer, a variation of ±10% around the reference RM values was considered, aiming to achieve better agreement with the obtained results.

Regarding the surface layer, the blocks and the bedding layer were treated together as a segmented layer, due to the distinct mechanical properties and structural responses that characterize these materials (Kim et al. 2024). The linear RM constitutes a parameter equivalent to the EM, which is the property used in the back-analysis process.

2.3 Elastic analysis

After obtaining the elastic properties of each layer, an elastic analysis of the ICBP was carried out. For this analysis, the base, subbase, and subgrade materials were considered non-linear elastic. For the ICBP surface layer (block layer + bedding layer), a linear behavior was assumed, considering the EM obtained from the back-analysis. The AEMC software v.2.4.6 (DNIT 2021) was used. The applied load was 8.2 tf, corresponding to the Brazilian standard axle load (single axle with dual wheels). Full bonding between layers was assumed, since elastic results tend to be more critical under bonded conditions (Bezerra et al. 2024).

In the elastic analysis, a Cartesian coordinate system with orthogonal axes was considered, where the z-axis is aligned with the direction of load application, the y-axis corresponds to the direction of traffic movement, and the x-axis is perpendicular to the y-axis. For this analysis, two points were defined at the top of the subgrade: (x = 0; y = 0; z = 42.01 cm) and (x = 16.2 cm; y = 0; z = 42.01 cm). As a result of the analysis, the vertical strain at the top of the subgrade (εz) was obtained at both points, and the highest value was considered. This approach was adopted because, near the ICBP surface, stresses are higher at the tire–pavement contact area (x = 16.2 cm). However, with increasing depth, the overlap of stress bulbs occurs, leading to higher stresses at the center of the standard axle (x = 0).

2.4 Service life

Subsequently, a mechanistic-empirical verification was performed in order to estimate the number of standard axle load repetitions that the structure can withstand (service life). This analysis was based on the limiting criterion of vertical strain at the top of the subgrade (Rahman et al. 2018), applied through Equation 1. From this approach, it was possible to estimate the percentage of service life consumed by the structure in each analysis period.

$$ESAL_{sl} = \left(\frac{28000}{\varepsilon_z}\right)^4 \times 10^{-2} \quad (1)$$

where, $ESAL_{sl}$ is the number of admissible repetitions of the standard axle load and ε_z is the vertical strain at the top of the subgrade (m/m).

2.5 Residual requests

The service life of the ICBP is directly associated with the vertical strain at the top of the subgrade, and RR is derived from the structural results obtained through mechanistic-empirical analysis. For its calculation, Equation 2 was used, which incorporates the reduction in service life as a function of the degradation caused by traffic, based on the ESAL previously determined by Equation 1.

$$RR_i(\%) = \frac{ESAL_{sl} - ESAL_i}{ESAL_{sl}} \times 100 \quad (2)$$

where, RR_i is the residual service life for year i, $ESAL_{sl}$ is the number of admissible repetitions of the standard axle load under current conditions, and $ESAL_i$ is the number of equivalent single axle load for year i.

2.6 Definition of optimal timing for M&R strategies

For each ICBP section, RR was calculated and a curve representing the structural degradation over the service life was developed. Each curve generated an equation, which was used to define time (variable y) for each level of degradation (variable x). Based on this, scenarios for different M&R strategies in the ICBP were proposed, and the costs over the 20-year design life were calculated. The optimal timing for M&R was defined as the strategy that resulted in the lowest cost. Thus, four distinct scenarios were considered:

a) performing only preventive maintenance at RR = 60%;
b) performing only corrective maintenance at RR = 40%;
c) performing only reinforcement at RR = 20%;
d) performing only reconstruction at RR = 0%.

For each ICBP section, the number of M&R cycles required for the pavement to reach its design service life was determined. After each cycle, it was assumed that the pavement's initial functional and structural conditions were fully restored. Table 4 presents the M&R strategies and costs according to the RR classification, as well as their cost per square meter. The costs were obtained from Brazilian reference tables for the base year 2025 and converted into US dollars.

Table 4 – M&R strategies and costs according RR classification

RR classification (%)		M&R strategy	Specification	Cost/m², in dollar
Very good	80 ≤ RR < 100	Do nothing	No intervention required	-
Good	60 ≤ RR < 80	Preventive maintenance	Grouting with or without vegetation removal	$ 0.64
Fair	40 ≤ RR < 60	Corrective Maintenance	Replacement of damaged blocks, replacement of curbs, correction of finishes, and repair of specific depressions.	$ 28.31
Poor	20 ≤ RR < 40	Reinforcement	Replacement of the block layer and an increase in the block layer thickness.	$ 45.94
Very poor	0 ≤ RR < 20	Reconstruction	Demolition of pavement structure with complete reconstruction	$ 52.28

3. Results and discussion

In this section, the results of the back-analysis and the elastic analysis are first presented. This process results in the estimation of how many repetitions of the standard axle load each ICBP section can withstand at the end of the 20-year service life. Subsequently, the Residual Requests (RR) results for each section are presented. Finally, the cost results for each adopted M&R strategy are presented.

3.1 Back-analysis and elastic analysis

Table 5 presents the Elastic Modulus (EM) values obtained for the block layer in each ICBP section, as well as the relative errors resulting from the back-analysis. In addition, it presents the results obtained from the elastic analysis performed using the AEMC software and number of standard axle load repetitions that the structure can withstand (service life).

Table 5 – Results of back-analysis and elastic analysis

Back-analysis (Blocks layer)			Specific vertical deformation at the top of the subgrade (m/m)	ESAL (service life)
Section	Elastic Modulus (MPa)	Relative error		
1	2778	0,0000	-3.34×10^{-4}	4.94×10^{7}
2	4583	0,0005	-2.96×10^{-4}	8.01×10^{7}
3	3433	0,0007	-3.18×10^{-4}	6.01×10^{7}
4	3391	0,0005	-3.19×10^{-4}	5.94×10^{7}
5	3927	0,0001	-3.08×10^{-4}	6.83×10^{7}
6	432	0,0002	-4.55×10^{-4}	1.43×10^{7}
7	1286	0,0002	-3.90×10^{-4}	2.66×10^{7}
9	10	0,0007	-5.24×10^{-4}	8.15×10^{6}
10	15	0,0050	-5.23×10^{-4}	8.22×10^{6}

Table 5 shows a strong dependence between the increase in deformations and the reduction in ICBP durability. This behavior is mainly associated with the low EM values of the block layer obtained from the back-analysis. In the case of Sections 9 (10 MPa) and 10 (15 MPa), the results indicate low stiffness of this layer, compromising its ability to absorb and redistribute the applied stresses, which increases the demand on the underlying layers and reduces the service life. This performance is also related to the deflection values, as these same sections exhibited the highest vertical displacements, reinforcing the indication of lower structural capacity.

In contrast, Section 2 stood out for presenting the lowest value of vertical deformation at the top of the subgrade and, consequently, the highest service life. This result can be attributed to lower deflection combined with a high EM value of the block layer, indicating greater stiffness and efficiency in dissipating loading stresses, thereby reducing stress propagation to the underlying layers.

Considering the projected traffic over the 20-year design life (ESAL of 5.70×10^{7}), it is observed that Sections 1, 6, 7, 9, and 10 exhibited degradations before reaching the design service life, indicating structural inadequacy under the applied loading. It is worth noting that the AEMC software was developed for asphalt pavements and may not fully represent the elastic analysis. The software assumes homogeneous layers, which constitutes a simplification in the analysis of ICBP.

3.2 Residual requests

After obtaining the results of the vertical strain at the top of the subgrade and the ESAL of service life, it was possible to calculate the RR for each section. Figure 3 shows the deterioration curves for each section.

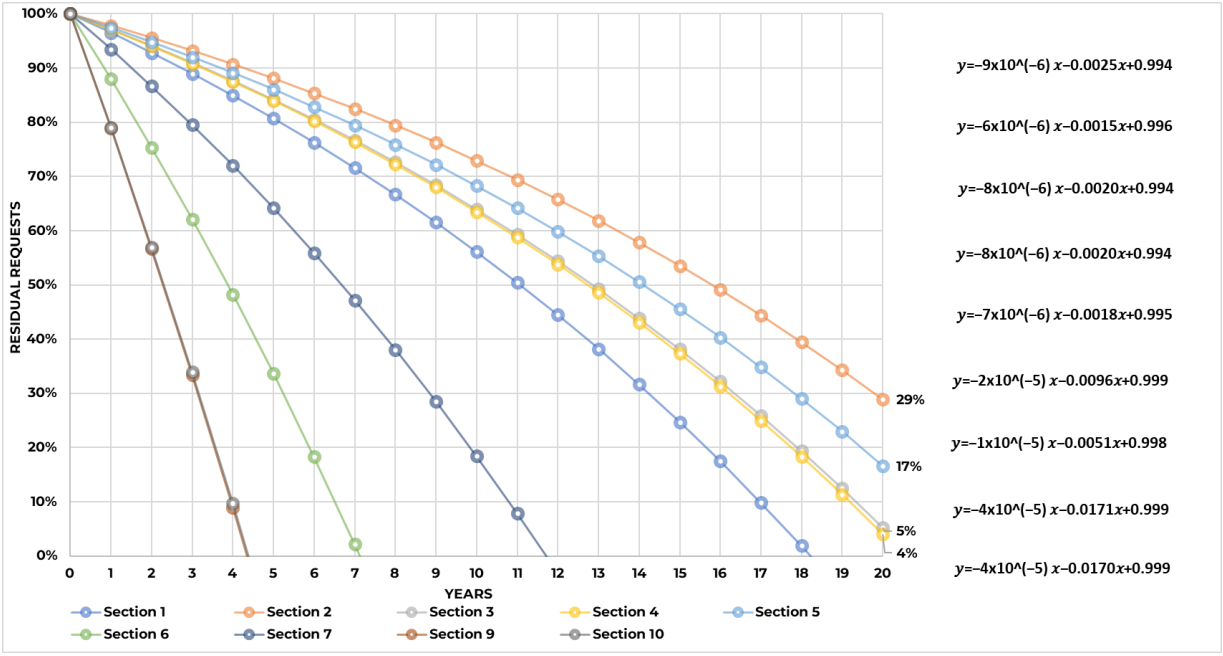

Figure 2 – Results of the residual requests (Authors 2026)

Sections 1, 6, 7, 9, and 10 reach RR values of 0%, indicating that these structures fail before the end of the ICBP design service life. Sections 9 and 10 stand out, as they showed the greatest reductions in RR over the analyzed period, reaching failure conditions approximately four years and four months after the structural evaluation. This behavior is consistent with the low EM values of the block layer in these sections, as well as the high vertical strains observed at the top of the subgrade. As a result, a rapid loss of structural capacity is observed, since the block layer provides limited contribution, transferring most of the stresses to the granular layers.

In contrast, Section 2 presented the highest RR value at the end of the design period (29%). Additionally, Sections 5, 3, and 4 did not reach failure conditions within the analyzed interval, although they were classified as being in very poor condition at the end of the 20 years. These results are associated with lower levels of vertical strain at the top of the subgrade, indicating better structural performance. In general, it is observed that sections with greater capacity to attenuate stresses transmitted to the subgrade exhibited higher service life.

Initially, it is observed that the R^2 values indicate an excellent fit of the models to the deterioration curves. Sections 9 and 10 present higher coefficients associated with x (linear) and x^2 (quadratic), in absolute terms. This indicates a more pronounced deterioration rate. This behavior confirms the previously discussed results, highlighting a rapid loss of RR and, consequently, a shorter service life for these structures. On the other hand, Section 2 presents the lowest coefficients, reflecting a slower degradation rate.

3.3 Definition of optimal timing for M&R strategies

Table 6 shows the M&R timing for each scenario in each section. In addition, it presents the number of M&R cycles required for each section over the 20-year service life, as well as the costs associated with each scenario.

Table 6 – M&R timing, the number of M&R cycles and the costs for each section

RR	M&R strategies	M&R time, in month (cicles of M&R)									Cost, in dollar
		Sections									
		1	2	3	4	5	6	7	9	10	
60%	PM	112 (2.1)	161 (1.5)	130 (1.8)	130 (1.9)	141 (1.7)	38 (6.2)	69 (3.5)	22 (10.8)	22 (10.7)	1,736,171.60
40%	CM	153 (1,6)	214 (1.1)	175 (1.4)	175 (1.4)	190 (1.3)	56 (4.3)	98 (2.4)	33 (7.4)	33 (7.3)	10,776,993.80
20%	RF	189 (1.3)	260 (1.0)	214 (1.1)	214 (1.1)	232 (1.0)	69 (3.5)	126 (1.9)	43 (5.6)	43 (5.6)	13,743,621.10
0%	RC	220 (1.1)	299 (1.0)	247 (1.0)	249 (1.0)	268 (1.0)	87 (2.8)	151 (1.6)	52 (4.6)	52 (4.6)	12,919,322.50

The PM strategy, applied at 60% RR, involves earlier interventions—especially in the most critical sections, such as 9 and 10, which require action as early as 22 months—yet results in the lowest total cost (approximately $1.74 million). This demonstrates that early interventions are more economically efficient over the pavement life cycle. On the other hand, as the RR level decreases, the time to intervention increases, but so do the associated costs. CM, RF, and RC strategies present higher costs compared to the PM strategy (521%, 694%, and 656%, respectively). This behavior indicates that delaying interventions is not economically advantageous. It is worth noting that RF costs were higher than RC, due to the small difference in unit cost and the higher frequency of RF interventions.

Variability in performance among sections is also observed: Sections 6, 7, 9, and 10 require more frequent interventions across all scenarios, confirming their lower structural capacity. In contrast, Section 2 stands out for its higher durability. Furthermore, preventive strategies involve a higher frequency of interventions but result in lower cumulative costs, whereas corrective strategies reduce intervention frequency but increase the cost per intervention.

4. Conclusions

This study aimed to evaluate whether it is possible to define the optimal timing for M&R strategies in ICBP, considering structural performance and the costs associated with interventions. The analysis revealed a strong relationship between the stiffness of the block layer, the vertical strains at the top of the subgrade, and the service life, enabling the identification of sections with critical structural performance and accelerated degradation behavior. The results indicate that, for the analyzed period and considering the imposed constraints and comfort conditions, structures in which stresses are absorbed by the surface layer (block layer + bedding layer) are more suitable for heavy traffic.

From a techno-economic perspective, it was found that preventive strategies, applied at RR = 60%, result in lower life-cycle costs, even with a higher frequency of interventions. In contrast, delaying M&R actions leads to significant cost increases and accelerated loss of structural capacity. It is concluded that the integration of structural analysis, deterioration modeling, and economic evaluation provides a consistent approach to support decision-making in Interlocking Pavement Management Systems. The results reinforce the importance of adopting rational, performance-based strategies, contributing to more efficient use of resources and to the expansion of knowledge on ICBP management, which is still underexplored in the literature.

Abstract: The increasing generation of construction and demolition waste (CDW) and the depletion of natural resources have driven the development of more sustainable cementitious materials. This study evaluates the feasibility of partially replacing natural sand with CDW as fine aggregate in self-compacting mortars (SCM). Four mixtures were produced with replacement levels of 0%, 10%, 20%, and 30% by mass. The materials were characterised through particle size distribution and specific gravity tests. The fresh-state properties were assessed using mini-slump-flow and mini-V-funnel tests, while hardened-state performance was evaluated by measuring compressive strength and estimating the modulus of elasticity at 28 days. All mixtures exhibited adequate self-compactability, maintaining satisfactory flowability and stability. The results indicated that the mixture with 10% CDW replacement achieved the highest compressive strength, slightly outperforming the reference mixture. Higher replacement levels (20% and 30%) resulted in moderate reductions in mechanical performance. The maximum compressive strengths observed were 47.45 MPa (0%), 47.93 MPa (10%), 44.68 MPa (20%), and 39.80 MPa (30%). An increasing trend in stiffness was observed with higher CDW content. The results suggest that partial replacement of natural sand with CDW up to 10% is technically viable, providing environmental benefits without compromising mechanical performance. The findings also highlight the importance of controlling the physical properties of recycled aggregates to ensure consistent performance in self-compacting mortars.

Keywords: self-compacting mortar; construction and demolition waste; recycled aggregates; compressive strength; sustainability.

1. Introduction

The rapid growth of construction activities has significantly increased the consumption of natural resources and the generation of construction and demolition waste (CDW). The extraction of natural aggregates, particularly sand, has led to severe environmental impacts, including river degradation, ecosystem disturbance, and depletion of non-renewable resources (Frazao 2015; John 2000).

At the same time, the accumulation of CDW has become a major environmental challenge, especially in urban areas, necessitating sustainable waste management strategies and material reuse. In this context, the incorporation of CDW as recycled aggregate in cementitious materials has emerged as a promising solution to reduce environmental impacts and promote circular economy practices in the construction industry (Hansen 1992; Leite 2001; Ferreira 2013).

However, the use of recycled aggregates introduces technical challenges, such as higher porosity, increased water absorption, and variability in physical properties, which can directly affect the fresh and hardened behaviour of cementitious composites (Nedeljkovic *et al.* 2021; Han *et al.* 2023; Peiris *et al.* 2025).

In the specific case of self-compacting mortars (SCM), maintaining adequate rheological properties is essential to ensure flowability, stability, and resistance to segregation without mechanical compaction.

Previous studies indicate that moderate replacement levels of natural aggregates with recycled materials can preserve or even improve certain properties, while higher replacement levels tend to reduce mechanical performance due to microstructural changes and weaker interfacial transition zones (ITZ) (Singh *et al.* 2020; Guessoum *et al.* 2023; Zhang *et al.* 2023).

Although recycled aggregates have been widely investigated, most existing studies focus on coarse recycled aggregates in structural concrete. Systematic evidence on the use of CDW as a *fine* aggregate specifically in *self-compacting* mortars remains comparatively scarce, particularly regarding the link between fresh-state behaviour and mechanical performance. Addressing this gap is the central motivation of the present work.

Therefore, this study aims to evaluate the effect of partially replacing natural sand with CDW on the rheological and mechanical properties of self-compacting mortars. Four replacement levels (0%, 10%, 20%, and 30%) were investigated, focusing on flowability, viscosity, compressive strength, and modulus of elasticity. The main original contribution of this work is the identification of an optimal fine-CDW replacement level for self-compacting mortars, at which mechanical performance is enhanced relative to the reference while rheological stability is preserved. The results contribute to advancing the understanding of sustainable cementitious materials and support the development of more environmentally responsible construction practices.

2. Materials and Methods

2.1 Materials and CDW characterisation

The construction and demolition waste (CDW) used in this study was collected from two construction sites in Taubaté, Brazil. The waste originated from structural and non-structural masonry and internal plastering activities; consequently, it consisted predominantly of hardened cementitious mortar and fired-clay (ceramic) fragments, with minor amounts of fine concrete debris. No glass, metal, wood, gypsum, or organic contaminants were retained. The material was manually pre-selected on-site to remove contaminants and coarse particles, transported to the Civil Engineering Laboratory of the Federal University of Itajubá (UNIFEI), and processed in accordance with the applicable Brazilian standard for recycled aggregates from CDW (NBR 15116:2021).

Because masonry- and render-derived CDW is dominated by porous ceramic and adhered mortar, it is expected to exhibit higher water absorption and intra-particle porosity than natural siliceous sand. These compositional features are known to govern the fresh- and hardened-state response of the resulting mortars and are therefore central to interpreting the results reported below. It should be noted that the present characterisation is based on the origin, visual-manual composition, and physical properties of the CDW; a quantitative mineralogical or chemical characterisation was outside the scope of this study and is identified as a limitation in Section 5.

The other materials used in this study were Portland cement (CP II-F-32), metakaolin as a supplementary cementitious material, a polycarboxylate-based superplasticiser (SP), natural river sand, and potable water. The physical characterisation of the aggregates, including particle size distribution and specific gravity, was performed to ensure compatibility between natural and recycled materials and to minimise variability in mixture behaviour.

2.2 Mix design and proportions

The mix design was based on the methodology proposed by Gomes, Gettu, and Agulló (2003), which considers the separate optimisation of the paste phase and the granular skeleton to achieve self-compacting behaviour. This approach is widely adopted in the design of self-compacting cementitious materials due to its effectiveness in balancing flowability and stability. The mix proportions of the four mixtures are summarised in Table 1.

Table 1 – Mix proportions of the evaluated mixtures

Mixture	Cement (g)	Metakaolin (g)	SP (g)	Sand (g)	CDW (g)	Water (g)
B	1201	60.5	13	2022.0	0.0	540
T1	1201	60.5	13	1819.8	202.2	540
T2	1201	60.5	13	1617.6	404.4	540
T3	1201	60.5	13	1415.4	606.6	540

A reference mixture (B) was defined and used as the basis for all compositions. The water-to-cement ratio (w/c) was kept constant at 0.45, and the metakaolin and superplasticiser contents were held constant to isolate the effect of CDW incorporation. Four mixtures were produced with CDW replacement levels of 0%, 10%, 20%, and 30% by mass of natural sand, identified as B, T1, T2, and T3, respectively. Replacement was carried out by mass to ensure direct comparability between mixtures, avoiding distortions arising from differences in material density.

2.3 Test methods

Fresh-state properties were evaluated using the mini-slump-flow and mini-V-funnel tests, which are commonly applied to assess flowability and viscosity in self-compacting systems (EFNARC 2005). The density of the fresh mixtures was also determined. Due to the self-compacting nature of the materials, no mechanical compaction was applied during casting.

For the hardened state, cylindrical specimens 50 mm in diameter and 100 mm in height were moulded. After 24 hours, the specimens were demoulded and cured under water until testing at 28 days. Compressive strength tests were performed to evaluate mechanical performance, and the modulus of elasticity was estimated from the stress-strain relationships obtained during testing. Statistical analysis was carried out using mean values, standard deviations, coefficients of variation, and 95% confidence intervals to assess the consistency and reliability of the experimental results.

3. Results and Discussion

3.1 Particle size distribution

The particle size distribution of the natural sand and CDW is presented in Figure 1. Both materials exhibited similar grading characteristics, with fineness modulus values of 2.24 and 2.26, respectively, indicating that both are classified as medium sand. This similarity indicates that partial replacement of natural sand with CDW does not significantly alter the overall grading of the mixture, which is essential for maintaining adequate packing and workability.

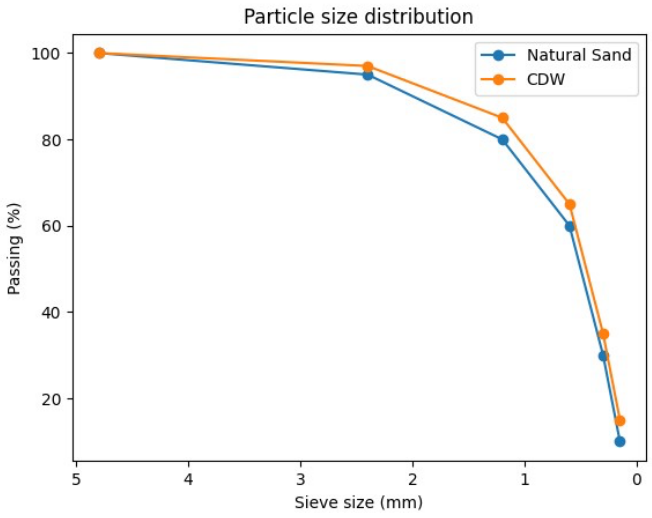

Figure 1 – Particle size distribution of natural sand and construction and demolition waste (CDW)

A slightly higher content of fine particles was observed in the CDW, particularly in the lower sieve sizes. This behaviour is commonly associated with adhered mortar and the intrinsic heterogeneity of recycled materials, in which crushing processes and residual cement paste generate additional fines (Leite 2001; Hansen 1992).

3.2 Fresh-state properties

All mixtures exhibited adequate self-compacting behaviour, maintaining satisfactory flowability and stability. The mini-slump-flow results are presented in Figure 2, with spread values ranging from 300 mm to 310 mm, indicating that the incorporation of CDW did not significantly compromise the flowability of the mixtures.

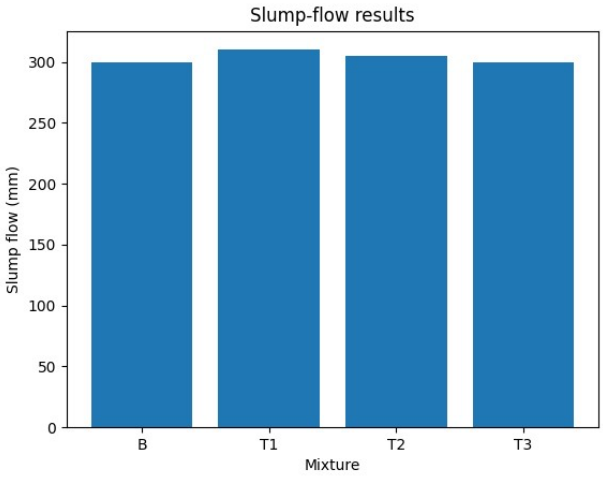

Figure 2 – Mini-slump-flow results for the evaluated mixtures

The mini-V-funnel results are shown in Figure 3, with flow times ranging from 7 to 15 seconds, demonstrating acceptable viscosity levels for self-compacting mortars. A slight increase in flow time was observed with

increasing CDW content, suggesting higher internal friction and viscosity, which can be attributed to the rougher surface texture and higher absorption capacity of the recycled aggregate.

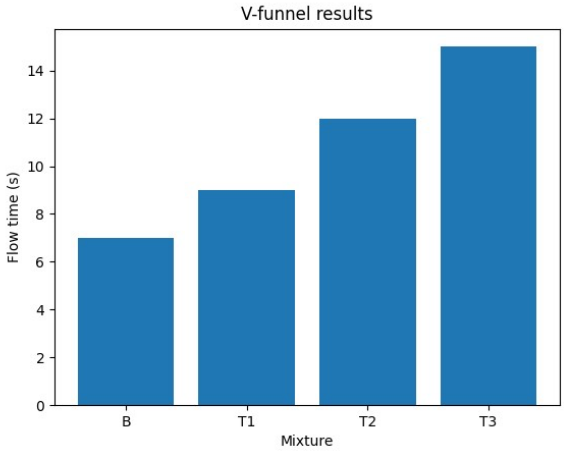

Figure 3 – Mini-V-funnel flow time for the evaluated mixtures

These findings are consistent with previous studies indicating that recycled aggregates can increase the viscosity of cementitious mixtures due to their porous structure and irregular morphology (Nedeljkovic *et al.* 2021; Singh *et al.* 2020).

3.3 Compressive strength

The compressive strength results at 28 days are presented in Figure 4. The reference mixture (B) achieved a maximum strength of 47.45 MPa, while the mixture with 10% CDW replacement (T1) reached 47.93 MPa, representing a slight increase in mechanical performance.

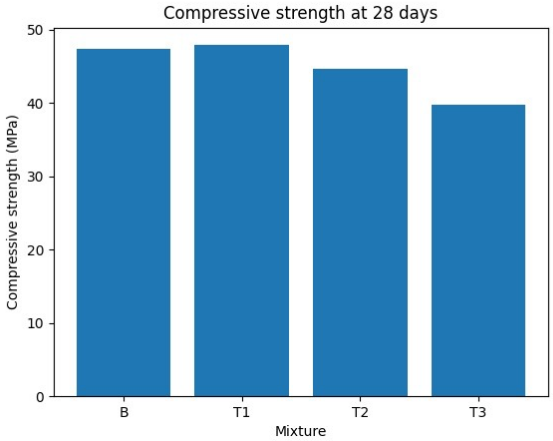

Figure 4 – Compressive strength of mixtures at 28 days

For higher replacement levels, a reduction in compressive strength was observed. The T2 and T3 mixtures presented maximum strengths of 44.68 MPa and 39.80 MPa, corresponding to reductions of approximately 6.8% and 16.1%, respectively, relative to the reference mixture. The microstructural interpretation of this trend is developed in Section 3.5.

3.4 Modulus of elasticity

An increasing trend in the modulus of elasticity was observed with higher CDW content, as shown in Figure 5. Although higher replacement levels reduced compressive strength, the increase in stiffness suggests a change in the mechanical behaviour of the material towards a more rigid, and potentially more brittle, response.

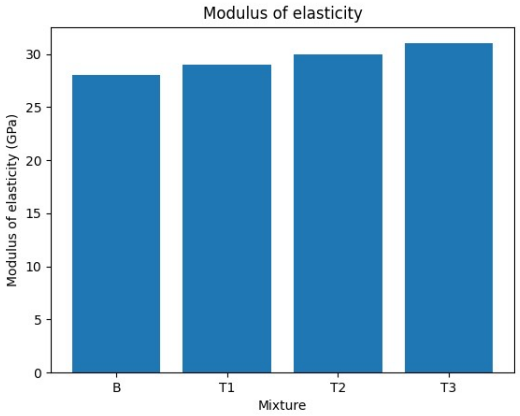

Figure 5 – Modulus of elasticity of the evaluated mixtures

This apparently counter-intuitive combination of decreasing strength and increasing stiffness is consistent with the dual role of recycled fine particles reported in the literature. The rigid ceramic and residual-paste fragments in the CDW raise the overall stiffness of the granular skeleton, increasing the composite modulus, while at the same time the porous, weaker ITZ that they introduce reduces the peak load that the matrix can sustain (Han *et al.* 2023; Zhang *et al.* 2023). Strength and stiffness are therefore governed by different mechanisms and need not vary in the same direction.

3.5 Microstructural interpretation

The strength results can be explained by two competing microstructural mechanisms. At the 10% replacement level, the additional fine fraction supplied by the CDW acts as a micro-filler, improving particle packing, reducing the volume of capillary voids, and densifying the matrix; this filler effect enhances load transfer and accounts for the slight strength gain of T1 over the reference (Zhang *et al.* 2023; Guessoum *et al.* 2023).

At 20% and 30% replacement, the detrimental effects of the recycled aggregate become dominant. The higher porosity and water absorption of the ceramic and adhered-mortar particles weaken the interfacial transition zone (ITZ) between aggregate and cement paste, which is typically the limiting region for crack initiation in cementitious composites. The adhered mortar also introduces a more porous, less homogeneous microstructure, lowering the overall load-bearing capacity. This behaviour is widely reported for cementitious composites containing recycled aggregates (Han *et al.* 2023; Peiris *et al.* 2025; Nedeljkovic *et al.* 2021). The transition from a beneficial filler effect to a dominant ITZ-weakening effect therefore explains the existence of an optimal replacement level near 10%.

Figure 6 shows the variation in compressive strength as a function of CDW replacement level, with an initial increase at 10% followed by a progressive reduction at higher levels. This non-monotonic trend reinforces the interpretation that the interaction between recycled particles and the cementitious matrix, mediated by packing density and ITZ quality, governs both the mechanical and rheological response of the material.

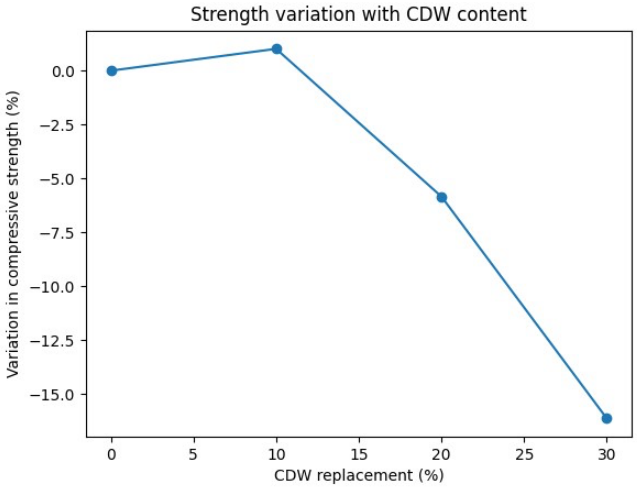

Figure 6 – Variation in compressive strength as a function of CDW replacement level

4. Limitations and Future Work

The present study has limitations that should be acknowledged and that define clear directions for future research. First, the mechanical characterisation was based solely on 28-day results; testing at earlier ages (e.g., 7 and 14 days) would provide a more complete picture of strength development and of how CDW affects the hydration kinetics of the matrix. Second, the microstructural mechanisms invoked here to explain the results, particularly the densification at 10% and the ITZ weakening at higher contents, were inferred from macroscopic behaviour and the literature rather than directly observed; scanning electron microscopy (SEM) and porosity measurements would allow these mechanisms to be confirmed and quantified.

Third, the CDW was characterised in terms of its origin, visual-manual composition, and physical properties, but not through quantitative mineralogical or chemical analysis. Given that the heterogeneity of CDW is a recognised source of variability, a more detailed compositional characterisation, combined with assessment of multiple batches, would strengthen the reliability and generalisability of the findings. Future work will therefore incorporate multi-age testing, SEM-based microstructural analysis, and a fuller characterisation of the recycled aggregate, as well as durability-oriented tests.

5. Conclusions

This study evaluated the use of construction and demolition waste (CDW) as a partial replacement for natural sand in self-compacting mortars. All mixtures maintained adequate self-compacting behaviour, with satisfactory flowability and viscosity, even at higher replacement levels. Among the evaluated compositions, the mixture with 10% CDW replacement presented the best overall performance, achieving slightly higher compressive strength than the reference mixture, an effect attributed to improved particle packing and a filler effect that densifies the cementitious matrix.

Increasing the replacement level to 20% and 30% reduced compressive strength by approximately 6.8% and 16.1%, respectively, mainly due to the higher porosity and water absorption of the recycled aggregate and the consequent weakening of the interfacial transition zone. In contrast, the modulus of elasticity increased with CDW content, indicating a shift towards a stiffer mechanical response governed by the rigidity of the recycled particles.

Overall, the partial replacement of natural sand with CDW up to 10% is technically viable, enabling the production of more sustainable self-compacting mortars without compromising mechanical performance. The novel contribution of this work is the identification of this optimal fine-CDW content for SCM and the mechanistic explanation of the strength-stiffness trade-off observed at higher contents. Given the inherent variability of CDW, controlling the physical properties of the recycled aggregate remains essential for consistent and reliable behaviour in practical applications.

Acknowledgments

The authors would like to thank the Federal University of Itajubá (UNIFEI) for providing the infrastructure and laboratory facilities necessary for this research, and gratefully acknowledge the support of the Civil Engineering Laboratory staff. The authors also acknowledge the financial support provided by CAPES (Coordination for the Improvement of Higher Education Personnel) through the PROAP programme.

Abstract: O concreto pigmentado tem se consolidado como uma solução relevante na arquitetura contemporânea, ao permitir a incorporação da cor diretamente à matriz cimentícia, eliminando a necessidade de revestimentos superficiais. No entanto, a durabilidade cromática desses materiais, especialmente em condições de exposição ambiental, ainda constitui um desafio. Neste contexto, o presente estudo teve como objetivo avaliar o comportamento cromático de concretos autoadensáveis de coloração preta, produzidos com pigmentos à base de magnetita (Fe_3O_4) submetidos ao envelhecimento acelerado por radiação ultravioleta. Foram produzidas três misturas: concreto de referência (sem pigmento), concreto com pigmento A (fabricante A) e concreto com pigmento B (fabricante B), com e sem aplicação de hidrofugante. As amostras foram submetidas a ensaios de envelhecimento acelerado em câmara de radiação ultravioleta (CUV), com ciclos alternados de radiação e condensação. A exposição totalizou aproximadamente 4553 horas de exposição, tempo equivalente a 15 anos de intemperismo natural, considerando que cada 150 horas na câmara representam 6 meses de exposição em condições naturais. A avaliação cromática foi realizada por espectrofotometria, utilizando o sistema CIELAB e o parâmetro ΔE para quantificação das variações de cor ao longo do tempo. Adicionalmente, foram realizados ensaios de resistência à compressão, absorção de água, índice de vazios e capilaridade. Os resultados indicaram baixa variação cromática das amostras, evidenciando boa estabilidade da cor, com desempenho superior dos pigmentos inorgânicos sintéticos. Observou-se que o uso de hidrofugante contribuiu para a redução das variações de luminosidade. Do ponto de vista físico e mecânico, a incorporação de pigmentos resultou em redução da resistência à compressão, especialmente em idades iniciais, além de pequenas alterações nas propriedades de absorção e porosidade. Conclui-se que o uso de pigmentos pretos em concretos autoadensáveis é tecnicamente viável.

Keywords: concreto pigmentado; envelhecimento acelerado; degradação cromática; durabilidade; Fe_3O_4.

1. Introdução

O concreto pigmentado tem se consolidado como uma estratégia relevante na arquitetura contemporânea, especialmente em soluções que exploram o concreto aparente como elemento expressivo. Ao permitir a incorporação da cor diretamente à matriz cimentícia, elimina a necessidade de revestimentos superficiais e amplia as possibilidades projetuais, associando desempenho estrutural e qualidade estética.

Entre os pigmentos utilizados, destacam-se os óxidos de ferro, amplamente empregados devido à sua estabilidade química, disponibilidade e resistência a agentes ambientais. Ainda assim, a manutenção da estabilidade cromática ao longo do tempo permanece como um desafio, sobretudo em elementos expostos à radiação ultravioleta, variações térmicas e ciclos de umidade, que podem provocar alterações perceptíveis na cor. Essa questão é particularmente relevante em concretos de tonalidade escura, como aqueles produzidos com pigmentos à base de magnetita (Fe_3O_4).

Apesar do crescente uso do concreto pigmentado, ainda são limitados os estudos voltados à avaliação sistemática da durabilidade cromática desses materiais, especialmente sob condições de envelhecimento acelerado. Soma-se a isso a ausência de metodologias normatizadas específicas para esse tipo de análise.

Diante desse cenário, este estudo tem como objetivo avaliar o comportamento cromático de concretos pigmentados pretos produzidos com pigmentos inorgânicos de Fe_3O_4, com ênfase na variação de cor sob envelhecimento acelerado por radiação ultravioleta, comparando seu desempenho ao concreto de referência e analisando a influência do tipo de pigmento na estabilidade cromática ao longo do tempo.

2. Fundamentação Teórica

Na arquitetura contemporânea, o concreto pigmentado alia desempenho técnico e valor estético, permitindo a exploração de diferentes tonalidades e superfícies, além de contribuir para a redução de custos de manutenção ao longo da vida útil da edificação (HELENE; TERZIAN, 1992; NEVILLE, 2012; RUSSO, 2024). Sua aplicação reforça a identidade visual dos projetos e estabelece relações com o contexto urbano e paisagístico (MEHTA; MONTEIRO, 2014; CHING, 2024; CONSANI, 2022).

No contexto brasileiro, a Praça das Artes, em São Paulo, destaca-se como exemplo da aplicação do concreto pigmentado em larga escala, evidenciando seu papel na integração entre volumes e na mediação entre o novo e o existente. De forma semelhante, projetos residenciais, como a Casa Terra (MARQUEZ, 2015; ARCHDAILY BRASIL, 2021) e a Residência Montagnola (SYED, 2017), demonstram o uso do concreto pigmentado como elemento estruturador da linguagem arquitetônica, e não apenas como acabamento superficial (Figura 1).

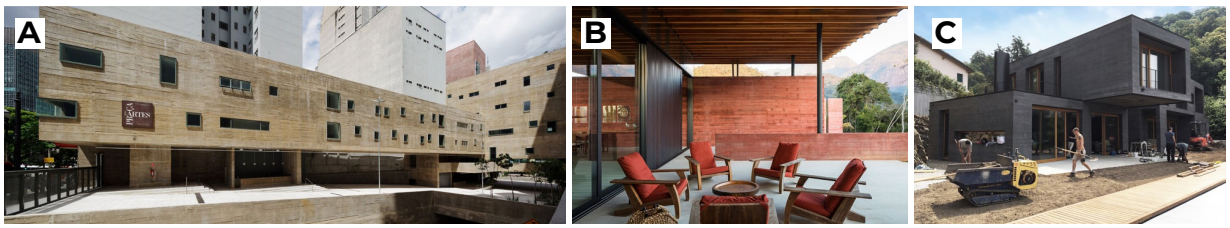

Figura 1 – A, Praça das Artes, Brasil Arquitetura, São Paulo, Brasil; B, residencia Casa Terra, Bernardes Arquitetura, Itaipava, Rio de Janeiro, Brasil; C, Residência Montagnola, Attilio Panzeri & Partners, Lugano, Suíça

Fonte: A, Archdaily Brasil (2012); B, Archdaily Brasil (2021); C, Syed (2017)

A durabilidade estética do concreto pigmentado, entretanto, depende da estabilidade cromática ao longo do tempo. A exposição a agentes ambientais, como radiação ultravioleta, variações térmicas e ciclos de umidade, pode provocar alterações na aparência superficial, resultando em mudanças perceptíveis de cor (NEVILLE, 2016; MEHTA; MONTEIRO, 2014).

Os pigmentos utilizados na coloração de materiais cimentícios podem ser classificados, de forma geral, em orgânicos e inorgânicos, cujas propriedades dependem de sua composição química (PFÄFF, 2022). Os pigmentos orgânicos apresentam cores mais intensas e maior variedade cromática, porém tendem a apresentar menor estabilidade frente à radiação ultravioleta e às condições ambientais, podendo sofrer desbotamento ao longo do tempo, já os pigmentos inorgânicos apresentam maior estabilidade química e térmica, além de menor toxicidade. (BONDIOLI et al., 1998).

3. Metodologia

A metodologia do estudo foi iniciada com a realização de um levantamento bibliográfico de literatura científica e normas técnicas brasileiras, com ênfase no uso de pigmentos pretos e em suas propriedades físico-mecânicas e cromáticas.

3.1 Produção dos concretos e moldagem das amostras

Durante o desenvolvimento da pesquisa, foram acompanhadas as etapas iniciais do processo de produção do concreto pigmentado, que compreenderam a preparação das fôrmas de madeira plastificada, dimensionadas para garantir resistência à umidade, facilitar o desmolde e assegurar adequada distribuição dos agregados (Figura 2).

Na etapa experimental, foram produzidos corpos de prova cilíndricos de concretos autoadensáveis pigmentados, além de um concreto de referência, sem adição de pigmento. A produção das misturas, bem como os ensaios no estado fresco, foi realizada em parceria com a empresa Engemix. Também foram moldados seis corpos de prova prismáticos, com dimensões de 9 × 9 × 4 cm, destinados aos ensaios de envelhecimento acelerado. Adicionalmente, os corpos de prova também foram utilizados para a realização de ensaios de caracterização no estado endurecido.

Figura 2- Formas desenvolvidas para a confecção dos corpos de prova (Fonte: autores)

Em paralelo, foi acompanhado o cálculo do volume de concreto necessário para a moldagem dos corpos de prova, conforme as recomendações técnicas. O traço de referência, definido em parceria com a Engemix, foi composto por cimento CP II E 40, sílica, agregados miúdos e graúdos, aditivo superplastificante e relação água/cimento de 0,5. Para a produção dos concretos pigmentados, foi incorporado 10% (máximo permitido pela norma) de pigmento preto à base de Fe_3O_4, em relação à massa de cimento, resultando em três misturas distintas: concreto de referência (sem pigmento), concreto com pigmento A e concreto com pigmento B (Tabela 1). os valores apresentados correspondem à dosagem laboratorial proporcional.

Tabela 1 – Traços dos concretos de referência e coloridos

Amostra	Água (g)	CP II E 40 SH (g)	Sílica (g)	Brita 0 (g)	Brita 1 (g)	Areia de quartzo (g)	Areia de brita (g)	Aditivo super-plastifi-cante (%)	Pig-mento A (%)	Pig-mento B (%)

(Fonte: autores)

Segundo a composição química observada e a classificação de Bondioli et al., os dois pigmentos analisados podem ser considerados inorgânicos, pois não possuem carbono em sua composição. O pigmento A pode ser classificado como inorgânico natural, por apresentar menor grau de pureza, enquanto o pigmento B corresponde a um pigmento inorgânico sintético, obtido por meio de processamento químico. Em ambos os casos, o principal componente identificado é o Fe_3O_4, óxido de ferro (II, III), embora o pigmento A apresente maiores teores de outros óxidos em comparação ao pigmento B.

Após a concretagem, os corpos de prova foram submetidos à cura inicial em tanque de imersão por 24 horas, assegurando hidratação adequada e preservação da cor superficial. Em seguida, foram desformados e mantidos em ambiente controlado para cura posteriormente, parte das placas recebeu aplicação de hidrofugante à base de silano/siloxano no canteiro experimental da FAU, aplicado em três demãos, com a finalidade de avaliar comparativamente o desempenho estético e a durabilidade de superfícies protegidas e não protegidas (Figura 3).

Figura 3 – Corpos de prova de concreto pigmentado preto sendo aspergidos com hidrofugante (Fonte: autores)

3.2 Caracterização dos materiais

A caracterização do concreto no estado fresco foi realizada conforme as normas ABNT NBR 15823-2:2017 (cone de Abrams), NBR 15823-3:2017 (anel J), NBR 15823-4:2017 (caixa L), NBR 15823-5:2018 (funil V) e NBR 16887:2020 (teor de ar) (Figura 4)

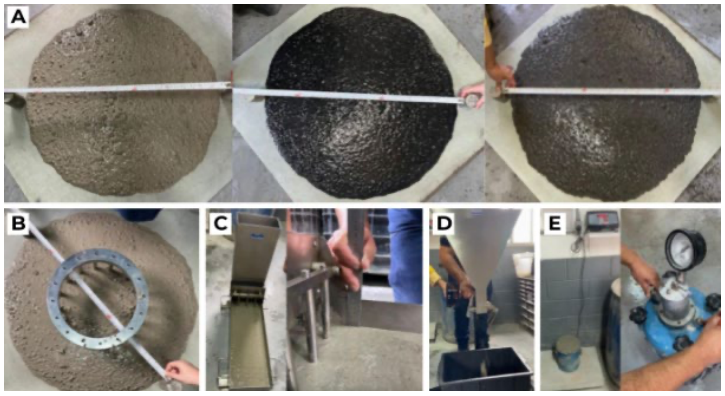

Figura 4 – Caracterização do concreto produzido em estado fresco. A, cone de Abrans; B, anel J; C, Caixa L; D, funil V; E; análise do teor de ar incorporado. (Fonte: autores)

No estado endurecido, foram realizados ensaios de compressão axial aos 7 e 28 dias, conforme a NBR 5739:2018, além de ensaios de absorção de água, índice de vazios e massa específica (NBR 9778:2005) e absorção por capilaridade (ABNT NBR 9779:2012) (Figura 5).

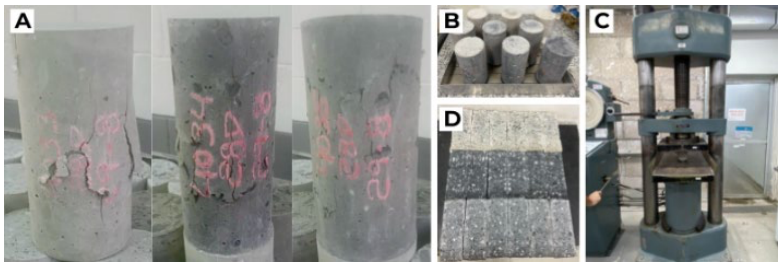

Figura 5 –Caracterização do concreto no estado endurecido: A) corpos de prova rompidos aos 28 dias; B) ensaio de absorção por capilaridade; C) ensaio de compressão diametral; D) corpos de prova após ruptura diametral e linha limite de distribuição. (Fonte: autores)

3.3 Estudo do envelhecimento acelerado e avaliação cromática das amostras

O ensaio de envelhecimento acelerado foi realizado em câmara de radiação ultravioleta (CUV), com o objetivo de simular, em intervalo reduzido, os efeitos da radiação solar e da umidade sobre o concreto pigmentado. O procedimento seguiu a ABNT NBR 15.380:2015, com ciclos alternados de quatro horas de radiação UVB e quatro horas de condensação, em câmara c-UVB, no LMCC/IPT. Os corpos de prova foram submetidos a ciclos de 150 horas, sendo retirados ao final de cada ciclo para estabilização térmica em ambiente protegido da luz e posterior análise por espectrofotometria. A duração total do ensaio foi de

aproximadamente 4553 horas, equivalente a cerca de 15 anos de degradação (Figura 6), permanecendo as amostras ainda em monitoramento.

A avaliação cromática foi realizada por espectrofotometria, utilizando o sistema CIE L*a*b* (CIELAB)[1], com quantificação da variação de cor por meio do parâmetro ΔE. As medições foram realizadas com espectrofotômetro da marca 3nh, operando com o software SQCX Color Quality Control, utilizando observador padrão CIE de 10° e iluminante D65, sem consideração do componente de reflexão especular (SCE) (Figura 6).

Figura 6 – A, placas dispostas na câmara de radiação ultravioleta (CUV), LMCC/IPT; B, Espectrofotômetro 3nh executando medição de placa; C, gabarito empregados nas aferições das placas de concreto com o espectrofotômetro (Fonte: autores)

4. Resultados e Discussões

Com relação ao ensaio de *slump-flow,* o concreto de referência apresentou classe SF2 (750 mm), enquanto os concretos pigmentados atingiram SF3 (≥ 760 mm), conforme a ABNT NBR 15823-1:2017.

Tabela 3 – Média de espalhamento, em mm, e quantidade de aditivo superplastificante, em ml, em cada mistura de concreto

Amostra	Slump flow (mm)			t500 (s)	VSI *		Amostra	Espalhamento médio (mm)	Dosagem de superplastificante (mL)	Classe de espalhamento
	Ensaio 1	Ensaio 2	Média do espalhamento							
Concreto de referência (sem pigmento	730	770	750	4	0		Concreto de referência (sem pigmento)	750	93,3	SF2
Concreto com Pigmento A	760	760	760	3	0		Concreto com Pigmento A	760	165,2	SF3
Concreto com Pigmento B	780	770	775	4	0		Concreto com Pigmento B	775	130,2	SF3

* VSI - sigla em inglês para *Visual Stability Index*, correspondente ao Índice de Estabilidade Visual (Fonte: autores)

Apesar da maior fluidez, todos os concretos apresentaram IEV igual a 0, indicando elevada estabilidade, sem segregação ou exsudação, evidenciando adequado equilíbrio entre fluidez e coesão. No ensaio de

[1] L* (Luminosidade): Controla o claro/escuro. Vai de (0) (preto absoluto) a (100) (branco perfeito); a*: Controla o espectro verde-vermelho. Os ensaios de habilidade passante realizados no concreto de referência (anel J e caixa L) indicaram bom desempenho (PJ1 e PL2) conforme a Tabela A.3 da NBR 15823-1:2017, sugerindo adequada capacidade de escoamento em meios confinados. Considerando a similaridade reológica, infere-se comportamento semelhante para os concretos pigmentados.

A análise do teor de ar incorporado (Tabela 5) evidenciou diferenças relevantes, com destaque para o concreto com pigmento A, que apresentou teor de ar de 6,5% e redução da massa específica. Esse resultado indica possível interferência do pigmento na estabilidade das bolhas de ar, o que pode impactar propriedades no estado endurecido. Já o pigmento B apresentou comportamento mais próximo ao concreto de referência.

Tabela 5 – Massa específica e teor de ar do concreto fresco (método pressométrico)

Amostra	Média de espalhamento "*Slump-flow*" (mm)	Amostra ensaiada – Teor de Ar Aparente (A1)	Massa específica (kg/m³)
Concreto de referência (sem pigmento)	750	SF 2	4
Concreto com Pigmento A	760	SF 3	3
Concreto com Pigmento B	775	SF 3	4

(Fonte: autores)

A Tabela 6 apresenta os resultados dos ensaios de resistência à compressão dos corpos de prova cilíndricos, bem como os valores de massa específica, absorção de água e índice de vazios. Aos 7 dias, o concreto de referência apresentou resistência média de 48,2 MPa, enquanto os concretos pigmentados apresentaram valores inferiores, sendo 37,0 MPa para o concreto com pigmento A e 41,9 MPa para o concreto com pigmento B, evidenciando redução mais acentuada na mistura com pigmento A. Aos 28 dias, observa-se o ganho de resistência em todas as misturas, com o concreto de referência atingindo 66,5 MPa, enquanto os concretos com pigmento A e B apresentaram resistências médias de 54,3 MPa e 54,6 MPa, respectivamente, indicando aproximação entre os concretos pigmentados nessa idade.

De modo geral, os resultados demonstram que a incorporação de pigmentos reduz a resistência à compressão em relação ao concreto de referência, especialmente em idades iniciais, embora essa diferença diminua ao longo do tempo, sugerindo tendência de estabilização do desempenho mecânico.

Tabela 6 – Propriedades mecânicas e físicas do concreto endurecido”

a) Resistência à compressão aos 7 e 28 dias.

Ensaio	Amostra	CP	Resistência à compressão (MPa)	Média (MPa)
Compressão axial 7 dias	Concreto de referência (sem pigmento)	1	47,7	48,2
		2	48,7	
		3	48,2	
	Concreto com pigmento A	4	38,8	37
		5	37	
		6	36,6	
	Concreto com pigmento B	7	41,1	41,19
		8	42,1	
		9	41,9	
Compressão axial 28 dias	Concreto de referência (sem pigmento)	10	66,4	66,5
		11	66,5	
		12	67,9	
	Concreto com pigmento A	13	54,3	54,3
		14	53,2	
		15	54,8	
	Concreto com pigmento B	16	54,4	54,6
		17	54,6	
		18	55,2	

b) Absorção de água, índice de vazios e massa específica

Amostra	CP	Massa específica			Absorção de água (%)	Índice de vazios (%)
		Seca (ρs)	Saturada (ρsat)	Real (ρr)		
Concreto de referência (sem pigmento)	1	2,42	2,49	2,61	2,90	7,10
	2	2,44	2,50	2,60	2,5	6,20
	Média	**2,43**	**2,50**	**2,61**	**2,70**	**6,70**
	Desvio	0,01	0,01	0,01	0,28	0,64

(Fonte: autores)

Com relação a absorção de água e índice de vazios dos corpos de prova, observa-se que os valores de massa específica foram semelhantes entre as misturas, com cerca de 2,61 g/cm³ para o concreto de referência e com pigmento B, e 2,56 g/cm³ para o concreto com pigmento A. Em relação à absorção de água e ao índice de vazios, o concreto com pigmento A apresentou os maiores valores (3,30% e 7,70%), enquanto o concreto com pigmento B apresentou comportamento próximo ao concreto de referência (2,80% e 6,80% contra 2,70% e 6,70%). De modo geral, os resultados indicam que o pigmento A promoveu leve aumento da porosidade, enquanto o pigmento B manteve comportamento semelhante ao concreto de referência.

Os resultados do ensaio de absorção de água por capilaridade indicaram comportamento semelhante entre os concretos analisados, com aumento progressivo da absorção ao longo do tempo. Para o concreto de referência, os valores médios variaram de 0,13 g/cm² (3 h) a 0,33 g/cm² (72 h), com altura média de ascensão capilar de 3,54 cm. O concreto com pigmento A apresentou valores ligeiramente inferiores nas primeiras idades, variando de 0,12 g/cm² (3 h) a 0,36 g/cm² (72 h), e altura média de 3,21 cm. Já o concreto com pigmento B apresentou os maiores valores de absorção, variando de 0,17 g/cm² (3 h) a 0,44 g/cm² (72 h), com altura média de 3,57 cm. De modo geral, observou-se que o concreto com pigmento A apresentou

menor absorção de água, enquanto o concreto com pigmento B apresentou maior capilaridade. Apesar dessas diferenças, os valores obtidos foram próximos, indicando comportamento compatível entre as misturas. Adicionalmente, verificou-se maior variabilidade nos resultados do concreto com pigmento A, com desvio de aproximadamente 0,5 cm na altura de ascensão capilar, enquanto o concreto com pigmento B apresentou comportamento mais uniforme.

Embora não tenham sido aplicados testes estatísticos inferenciais, os valores médios e os desvios obtidos permitem avaliar a tendência de comportamento das misturas. Nos ensaios de compressão, observou-se baixa dispersão entre os corpos de prova de uma mesma composição, o que reforça a consistência dos resultados. A redução da resistência à compressão nos concretos pigmentados foi mais expressiva aos 7 dias, correspondendo a aproximadamente 23% para o pigmento A e 13% para o pigmento B em relação ao concreto de referência. Aos 28 dias, essa diferença diminuiu, com reduções próximas de 18% para ambos os concretos pigmentados, indicando maior aproximação do desempenho mecânico com o avanço da idade.

Conforme apresentado na Figura 7, são ilustradas as placas de concreto utilizadas na análise colorimétrica, correspondentes às amostras avaliadas, incluindo o concreto de referência e os concretos pigmentados com pigmentos A e B, com e sem aplicação de hidrofugante, após os ciclos de envelhecimento acelerado.

Os resultados foram analisados por média e desvio padrão, não sendo aplicados testes estatísticos inferenciais devido ao número reduzido de amostras.

4.1 Análise dos resultados cromáticos pelo sistema CIELAB e da diferença de cor (ΔE)

Os resultados obtidos a partir do sistema CIELAB permitiram avaliar a evolução cromática das amostras ao longo do envelhecimento acelerado, considerando os parâmetros L* (luminosidade), a* (eixo verde–vermelho), b* (eixo azul–amarelo) e a diferença total de cor ΔE*. A análise comparativa entre as amostras com e sem hidrofugante demonstrou que o envelhecimento acelerado influenciou principalmente os parâmetros L* e b*, enquanto o parâmetro a* permaneceu relativamente estável durante todo o período experimental.

4.1.1 Análise das amostras sem hidrofugante

O concreto de referência apresentou os maiores valores de luminosidade (L*) entre todas as amostras, variando aproximadamente de 59,7 a 65,2 ao longo do envelhecimento acelerado. Observa-se tendência gradual de aumento de L*, especialmente após aproximadamente 3000 horas de exposição UVB, indicando clareamento superficial progressivo da matriz cimentícia.

No parâmetro b*, os valores permaneceram positivos e elevados, variando aproximadamente entre 6,4 e 8,0, indicando predominância de tonalidade amarelada característica da pasta cimentícia. Nota-se redução gradual do parâmetro b* ao longo do tempo, sugerindo diminuição da componente amarela superficial devido à exposição à radiação ultravioleta e aos ciclos de condensação.

O parâmetro a* apresentou pequenas variações próximas da neutralidade cromática, mantendo-se entre aproximadamente 0,3 e 0,6, evidenciando baixa influência do envelhecimento sobre o eixo verde–vermelho.

Quanto à diferença total de cor (ΔE*), o concreto de referência sem hidrofugante apresentou aumento progressivo ao longo do envelhecimento, partindo de aproximadamente 0,5 e atingindo valores próximos de 4,2 ao final de 4553 horas. Esse comportamento demonstra que, mesmo sem pigmentação, a matriz cimentícia sofre alterações cromáticas perceptíveis ao longo do envelhecimento acelerado.

O concreto contendo pigmento A apresentou os menores valores de luminosidade (L*), permanecendo predominantemente entre 32,5 e 34,8 durante todo o ensaio, caracterizando superfície visualmente mais escura e com menor tendência ao clareamento quando comparado às demais amostras.

O parâmetro a* apresentou valores muito próximos da neutralidade cromática, oscilando discretamente em torno de 0,0, indicando baixa alteração no eixo verde–vermelho ao longo do envelhecimento.

Já o parâmetro b* apresentou valores negativos, aproximadamente entre -0,5 e 0,0, indicando tendência à tonalidade azulada. Observam-se oscilações mais acentuadas nesse parâmetro quando comparadas ao concreto de referência e ao pigmento B, sugerindo maior instabilidade cromática superficial.

A análise da diferença total de cor (ΔE*) demonstra comportamento relativamente estável nas primeiras etapas do envelhecimento, com valores entre aproximadamente 1,3 e 2,1 até cerca de 3000 horas de exposição. Entretanto, após esse período, observa-se aumento progressivo de ΔE*, atingindo valores próximos de 3,0 ao final do ensaio. Esse comportamento indica que as alterações cromáticas se tornam mais significativas nos estágios mais avançados do envelhecimento acelerado.

O concreto produzido com pigmento B apresentou comportamento intermediário de luminosidade, com valores de L* variando aproximadamente entre 36,5 e 44,5. Observa-se redução inicial significativa de L* nos primeiros ciclos de envelhecimento, seguida de relativa estabilização e posterior aumento gradual da luminosidade ao longo do tempo.

O parâmetro a* permaneceu praticamente constante, com valores próximos de 0,3 a 0,5, indicando elevada estabilidade no eixo verde–vermelho.

No parâmetro b*, os valores permaneceram próximos da neutralidade cromática, variando aproximadamente entre 0,0 e 1,0. Comparativamente ao pigmento A, o pigmento B apresentou menores oscilações no eixo azul–amarelo, evidenciando maior estabilidade cromática superficial.

Em relação à diferença total de cor (ΔE*), o concreto com pigmento B apresentou os maiores valores iniciais entre os concretos pigmentados, atingindo aproximadamente 7,8 nas primeiras 500 horas de envelhecimento. Contudo, observa-se redução progressiva de ΔE* ao longo do tempo, alcançando valores próximos de 3,0 ao final do ensaio. Esse comportamento sugere que as alterações cromáticas iniciais foram mais intensas, seguidas de estabilização gradual da superfície pigmentada.

4.1.2 Análise das amostras com hidrofugante

Nas amostras protegidas com hidrofugante, o concreto de referência apresentou aumento contínuo do parâmetro L*, variando aproximadamente de 65 para 69, indicando clareamento superficial mais pronunciado quando comparado às amostras sem proteção.

O parâmetro b* apresentou redução gradual de aproximadamente 6,6 para valores próximos de 5,3, demonstrando diminuição da componente amarela ao longo do envelhecimento.

O parâmetro a* permaneceu estável, com pequenas oscilações próximas de 0,3.

Quanto à diferença de cor ΔE*, observa-se crescimento contínuo durante o envelhecimento acelerado, atingindo valores próximos de 4,1 ao final do ensaio, comportamento semelhante ao observado nas amostras sem hidrofugante.

O concreto com pigmento A protegido com hidrofugante apresentou valores de L* entre aproximadamente 34 e 38, com leve aumento de luminosidade ao longo do envelhecimento acelerado.

O parâmetro a* permaneceu próximo da neutralidade cromática, enquanto o parâmetro b* manteve valores negativos, variando aproximadamente entre -1,6 e -0,8, indicando persistência da tonalidade azulada superficial.

Em relação ao ΔE*, observa-se comportamento relativamente estável durante grande parte do envelhecimento, com valores inferiores a 2,0 até aproximadamente 3000 horas de exposição. Entretanto, após esse período, ocorre aumento gradual dos valores, atingindo aproximadamente 2,9 ao final do ensaio. Comparativamente às amostras sem hidrofugante, não se observa redução significativa das alterações cromáticas totais, indicando limitada eficiência do tratamento superficial nesse sistema pigmentado.

O concreto contendo pigmento B e protegido com hidrofugante apresentou o comportamento cromático mais estável entre todas as amostras analisadas.

Os valores de L* permaneceram relativamente estáveis, variando aproximadamente entre 41 e 46, com menores oscilações ao longo do envelhecimento quando comparados às amostras sem proteção superficial.

O parâmetro a* apresentou elevada estabilidade próximo da neutralidade cromática, enquanto o parâmetro b* permaneceu entre aproximadamente -0,1 e 0,4, indicando mínima alteração no eixo azul–amarelo.

A diferença total de cor ΔE* apresentou redução progressiva ao longo do envelhecimento acelerado, passando de aproximadamente 3,8 nas primeiras 500 horas para valores próximos de 1,1 ao final do ensaio. Esse comportamento evidencia elevada estabilidade cromática superficial e demonstra que a aplicação do hidrofugante contribuiu significativamente para minimizar as alterações cromáticas do concreto pigmentado com pigmento B.

4.1.3 Análise comparativa geral

A análise integrada dos resultados demonstra que o envelhecimento acelerado afetou principalmente os parâmetros L* e b*, enquanto o eixo a* permaneceu relativamente estável em todas as misturas.

O concreto de referência apresentou tendência de clareamento progressivo da superfície, com aumento de luminosidade e redução gradual da componente amarela ao longo do tempo. Entre os concretos pigmentados, o pigmento A apresentou maior instabilidade cromática no parâmetro b* e maiores oscilações superficiais durante o envelhecimento.

Por outro lado, o pigmento B apresentou o comportamento cromático mais estável, especialmente quando associado à aplicação do hidrofugante. A redução progressiva dos valores de ΔE* ao longo do envelhecimento indica maior estabilidade óptica e menor susceptibilidade às alterações superficiais induzidas pela radiação UV e pela umidade.

De forma geral, os resultados demonstram que a durabilidade cromática dos concretos pigmentados depende da interação entre composição mineralógica do pigmento, estabilidade dos parâmetros CIELAB, porosidade da matriz cimentícia e eficiência da proteção superficial. Entre os materiais analisados, o sistema contendo pigmento B associado ao hidrofugante apresentou o melhor desempenho global quanto à estabilidade cromática e resistência às alterações superficiais provocadas pelo envelhecimento acelerado (Figura 8).

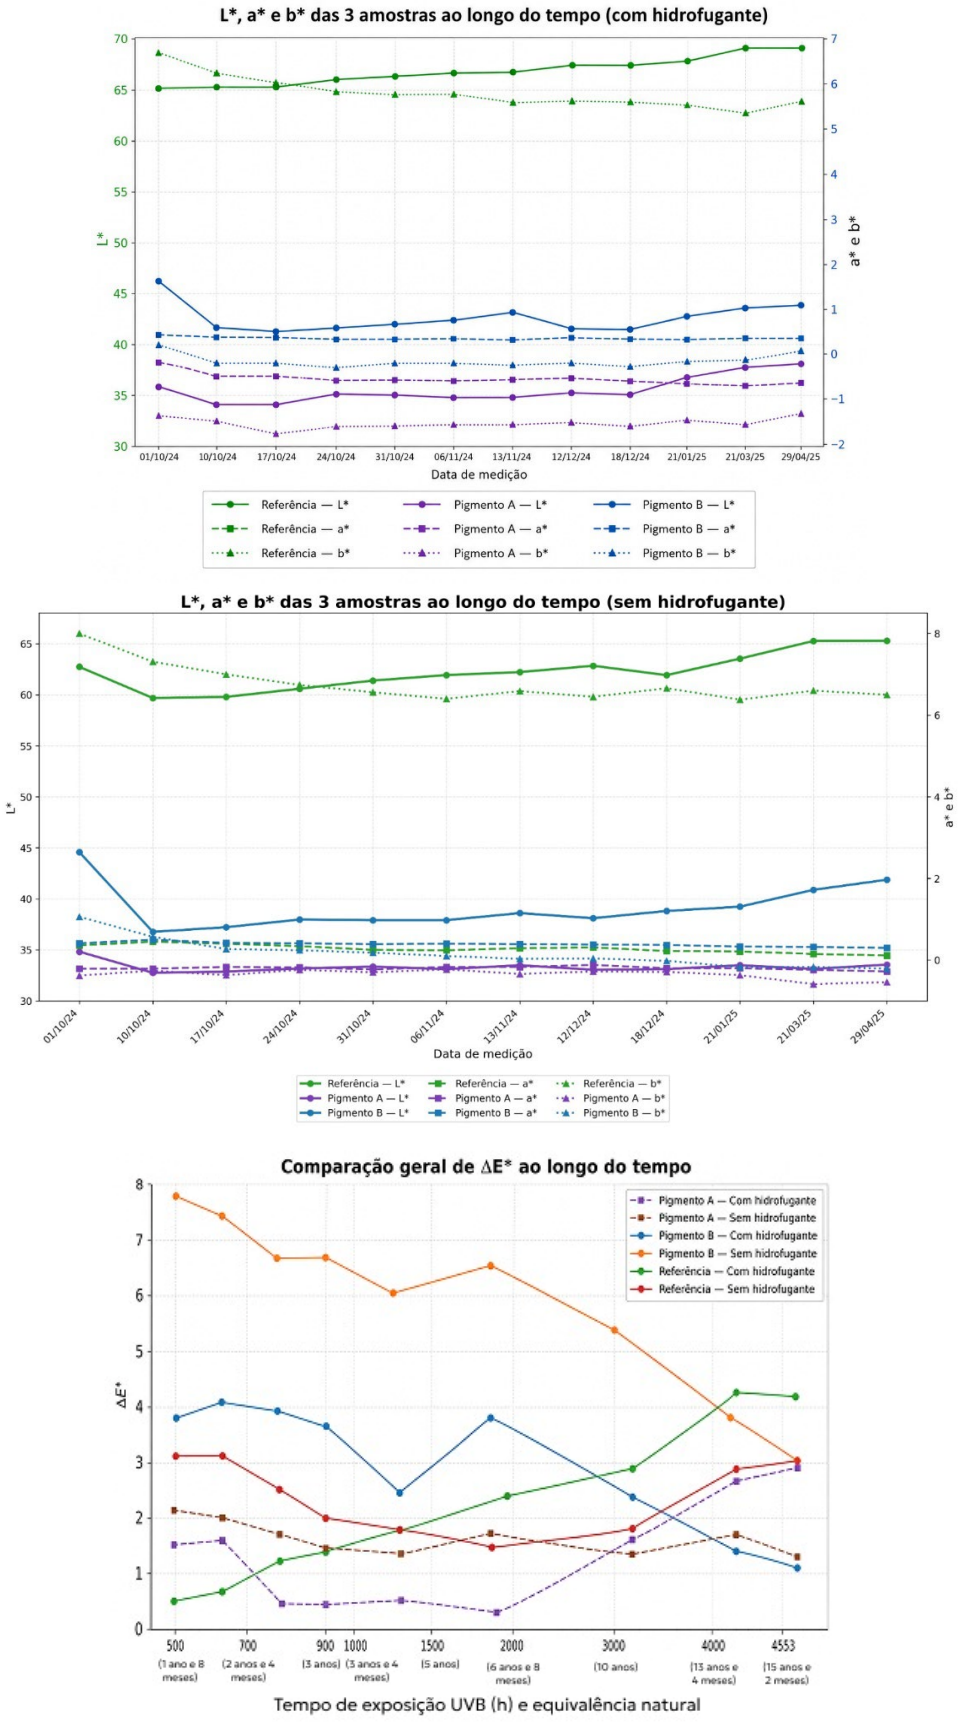

Figura 8 – Análise do envelhecimento acelerado das placas de concreto. (Fonte: autores)

5. Conclusões

Conclui-se que a incorporação de pigmentos pretos à base de Fe_3O_4 em concretos autoadensáveis apresentou desempenho satisfatório quanto à durabilidade estética e viabilidade tecnológica para aplicações arquitetônicas aparentes expostas ao intemperismo. Os ensaios de envelhecimento acelerado, realizados durante aproximadamente 4553 horas em câmara UV - equivalentes a cerca de 15 anos de exposição natural simulada - demonstraram que as alterações cromáticas variaram conforme a composição química dos pigmentos e a aplicação do hidrofugante.

A análise pelo sistema CIELAB indicou que os parâmetros mais afetados pelo envelhecimento foram L* e b*, enquanto o parâmetro a* permaneceu relativamente estável em todas as amostras, com variações inferiores a aproximadamente ±0,5. O concreto de referência apresentou aumento gradual da luminosidade (L*), variando aproximadamente entre 59,7 e 69,1, associado ao clareamento superficial da matriz cimentícia, enquanto o parâmetro b* reduziu de aproximadamente 7,8 para 5,3, indicando diminuição da componente amarelada ao longo do envelhecimento.

Entre os concretos pigmentados, o pigmento A apresentou os menores valores de luminosidade, com L* variando aproximadamente entre 32,5 e 38,2, além de maior instabilidade no parâmetro b*, cujos valores oscilaram entre -1,6 e 0,0. Já o pigmento B apresentou comportamento cromático mais estável, com L* variando entre aproximadamente 36,5 e 46,3 e b* próximo da neutralidade cromática, entre -0,1 e 1,0.

A análise da diferença total de cor (ΔE*) demonstrou comportamentos distintos entre os sistemas analisados. O concreto com pigmento B sem hidrofugante apresentou os maiores valores iniciais de ΔE*, atingindo aproximadamente 7,8 nas primeiras 500 horas de envelhecimento, porém com redução progressiva até cerca de 3,0 ao final do ensaio. Nas amostras contendo pigmento B com hidrofugante, o ΔE* reduziu de aproximadamente 3,8 para 1,1, evidenciando elevada estabilidade cromática e maior eficiência da proteção superficial. Em contrapartida, o concreto com pigmento A apresentou ΔE* relativamente estável até aproximadamente 3000 horas, seguido de aumento gradual até valores próximos de 3,0, independentemente da aplicação do hidrofugante.

As diferenças de desempenho observadas estão associadas à composição química dos pigmentos. O pigmento B apresentou teor de Fe_3O_4 de 97,3%, enquanto o pigmento A apresentou 74,1% e maior presença de óxidos secundários, o que provavelmente contribuiu para maior instabilidade óptica e maior susceptibilidade às alterações cromáticas superficiais.

Do ponto de vista mecânico, os concretos pigmentados apresentaram redução da resistência à compressão em relação ao concreto de referência. Aos 7 dias, as resistências médias foram de 48,2 MPa para o concreto de referência, 37,0 MPa para o concreto com pigmento A e 41,9 MPa para o concreto com pigmento B. Aos 28 dias, os concretos pigmentados atingiram aproximadamente 54 MPa, enquanto o concreto de referência apresentou 66,5 MPa.

Os ensaios físicos indicaram maior absorção de água e índice de vazios no concreto com pigmento A (3,5% e 8,2%) em comparação ao concreto de referência (2,7% e 6,7%), enquanto o concreto com pigmento B apresentou desempenho intermediário, com absorção próxima de 3,0% e índice de vazios de 7,2%.

De forma geral, os resultados demonstram que o concreto produzido com pigmento B associado ao hidrofugante apresentou o melhor desempenho global, combinando menores variações de ΔE*, maior estabilidade dos parâmetros L*, a* e b*, menor absorção de água e comportamento mecânico mais próximo ao concreto de referência, demonstrando maior potencial para aplicação em concretos arquitetônicos aparentes submetidos à exposição ambiental prolongada.

Band Gap Tuning of 1D Phononic Crystals for Subway Vibration Mitigation: A Parametric Study of Periodic Foundations and Barriers

Lucas L. SANTOS[1], Carlos H. COSTA[2]

[1] Federal University of Ceará, Russas, Brazil, lucasls.engcivil@gmail.com
[2] Federal University of Ceará, Russas, Brazil, carloshumberto@ufc.br

Abstract: Increasing urban expansion has intensified the challenges associated with subway-induced vibrations, which compromise human comfort and the structural integrity of adjacent buildings. As an innovative solution, one-dimensional phononic crystals (1D-PnCs) have been applied as periodic foundations and barriers, leveraging their ability to block elastic wave propagation within specific frequency ranges known as band gaps. This paper presents a parametric study of 1D-PnCs composed of alternating layers of concrete and rubber for structural vibration mitigation. Using the Transfer Matrix Method (TMM), the dispersion relations and the Frequency Response Function (FRF) of the system were analytically modeled. The methodology investigated the sensitivity of the band gaps to variations in elastic properties and geometric parameters. For practical application purposes, the optimized design was evaluated against real-world experimental Vibration Acceleration Level (VAL) spectra from two distinct subway lines. The results reveal that the dynamic behavior is predominantly governed by the impedance of the flexible inclusion and the unit cell dimensions. Calibrating the lattice constant to 0.48 m demonstrated efficacy in mitigating global low-frequency peaks below 30 Hz. Additionally, adjusting the rubber's elastic modulus enabled targeted spectral modulation: stiffening the material isolated the 6.3 Hz and 12.5 Hz peaks in Line 3, whereas reducing its stiffness optimized the blockage of a highly energetic 16 Hz peak in Line 5. It is concluded that the parametric manipulation of 1D-PnCs enables customized isolation designs, ensuring efficient vibration attenuation in civil engineering applications.

Keywords: Transfer Matrix Method; Bragg Scattering; Acoustic Impedance Contrast; Elastic Wave Propagation; Ground-Borne Vibration.

1. Introduction

Structural integrity and human comfort in civil buildings are frequently compromised by anthropogenic vibrations, particularly those induced by subway and railway traffic (Erkal; Kocagöz, 2020). With the rapid expansion of transit-oriented development (TOD) and the growing construction of buildings over or adjacent to subway stations, the control of secondary indoor vibrations has become a critical challenge in urban engineering (Xing, Zhu and Chen, 2025). Operating predominantly in low-frequency ranges from 4 to 20 Hz, these vibrations can cause issues ranging from progressive structural fatigue and material damage to severe occupant discomfort and direct interference with sensitive equipment (Jakubczyk-Galczynska; Jankowski, 2014; Zhu et al., 2014).

Over the last three decades, phononic crystals (PnCs) have emerged as a revolutionary solution for the control and manipulation of mechanical wave propagation, whether acoustic waves in fluids or elastic waves in solids (Fabro et al., 2021; Jin et al., 2025). PnCs can be defined as artificial periodic structures characterized by the spatial periodic variation of their material properties, such as density and elastic modulus (Liu; Guo; Wang, 2020). According to Maldovan and Thomas (2009) the fundamental characteristic of PnCs is the existence of acoustic band gaps (ABGs) or phononic band gaps. These ABGs consist of forbidden spectral ranges where the propagation of mechanical waves is completely suppressed, a phenomenon analogous

to the photonic band gaps (PBGs) observed in photonic crystals (Laude et al., 2009). Outside these stop bands, elastic waves can propagate freely, allowing the periodic structure to act as a natural harmonic filter (De Lima et al., 2025).

The physics behind the formation of these forbidden bands allows distinguishing two main categories of periodic structures: conventional phononic crystals and acoustic metamaterials. In conventional PnCs, band gaps are physically induced by the Bragg scattering effect. This phenomenon occurs due to the coupling between waves propagating in opposite directions, which are resonantly excited when the wave vector satisfies the Bragg condition. This leads to destructive interference in specific frequency ranges. For this mechanism to be effective, the wavelength (λ) must be comparable to the lattice constant (a), meaning $\lambda \approx 2a$. In contrast, acoustic metamaterials operate in the subwavelength regime, where $\lambda \gg a$. In these structures, the formation of gaps does not depend on spatial periodicity at the wavelength scale, but rather on local resonances within the scatterers, causing the material to exhibit effective negative properties in certain frequency ranges (Liu; Guo; Wang, 2020).

The width and position of the ABGs depend intrinsically on the geometry of the structure and, crucially, on the acoustic impedance contrast ($Z=\rho \cdot c$) between the constituent materials (Liu; Guo; Wang, 2020). Impedance is a fundamental concept that describes a material's resistance to acoustic or elastic waves (Geng; Zhu; Chong, 2018). The greater the impedance mismatch between the matrix and the scatterer, the more intense the reflections at the interfaces, functioning on the principle of destructive interference of multiple reflected waves that prevent wave transmission (Jain; Pujari; Laskar, 2021; Li et al., 2023). In this context, Kee et al. (2000) highlight that both mass density contrast and elastic constant contrast play vital roles in the formation of ABGs, as the modulation of these properties scatters the waves and impedes their transmission, resulting in sound absorption and vibration isolation effects.

Unlike traditional base isolation systems, which rely fundamentally on energy dissipation through damping or on increasing the structure's natural period, periodic foundations and barriers function as geometric filters acting at the building's base or directly within the soil (Xiong; Shi; Xiang, 2012).

However, the effectiveness of this advanced protection system relies strictly on the precise alignment (tuning) between the designed band gap frequencies and the predominant excitation frequencies of the vibration source. This tuning is achieved by manipulating the geometric and elastic properties of the unit cell (Jia; Shi, 2010).

Within this context, this paper presents an analytical-parametric study for band gap modulation in 1D-PnCs designed as periodic foundations and barriers for subway vibration mitigation. The dynamic response and dispersion relations of the periodic structure, composed of a rigid concrete matrix and flexible rubber inclusions, are analytically modeled using the Transfer Matrix Method (TMM). To validate the efficacy and practical applicability of the proposed geometric and material optimization, the design of these foundations and barriers is directly applied and evaluated against real-world experimental Vibration Acceleration Level (VAL) spectra. These spectra were recorded on Lines 3 and 5 of a subway system analyzed by Xing, Zhu and Chen (2025) demonstrating how the manipulation of internal parameters can be efficiently tuned to block critical frequencies and acceleration peaks generated by passing trains.

2. Methodology and Theoretical Model

This research adopts an analytical-parametric approach for the design of one-dimensional phononic crystals (1D-PnCs) applied as periodic foundations and barriers. The main objective is to determine, through a parametric study, the optimal combination of materials and geometries capable of mitigating subway-induced vibrations, as illustrated by the practical conceptual scheme in Figure 1(a).

The methodological procedure is divided into four main stages: (1) definition of the physical model; (2) mathematical formulation of wave propagation; (3) evaluation of the reference model against experimental spectra; and (4) parametric study for band gap tuning.

2.1 Physical Model Conception

The system was modeled as a 1D-PnC, which is characterized by the periodic spatial repetition of two layers of homogeneous solid materials: a rigid matrix (Concrete, Material A) and a flexible inclusion (Rubber, Material B). This periodic arrangement defines a fundamental unit cell of lattice constant a ($a = d_A + d_B$), as detailed in Figure 1(c). The geometric and theoretical configuration of this system is detailed in Figure 1(b).

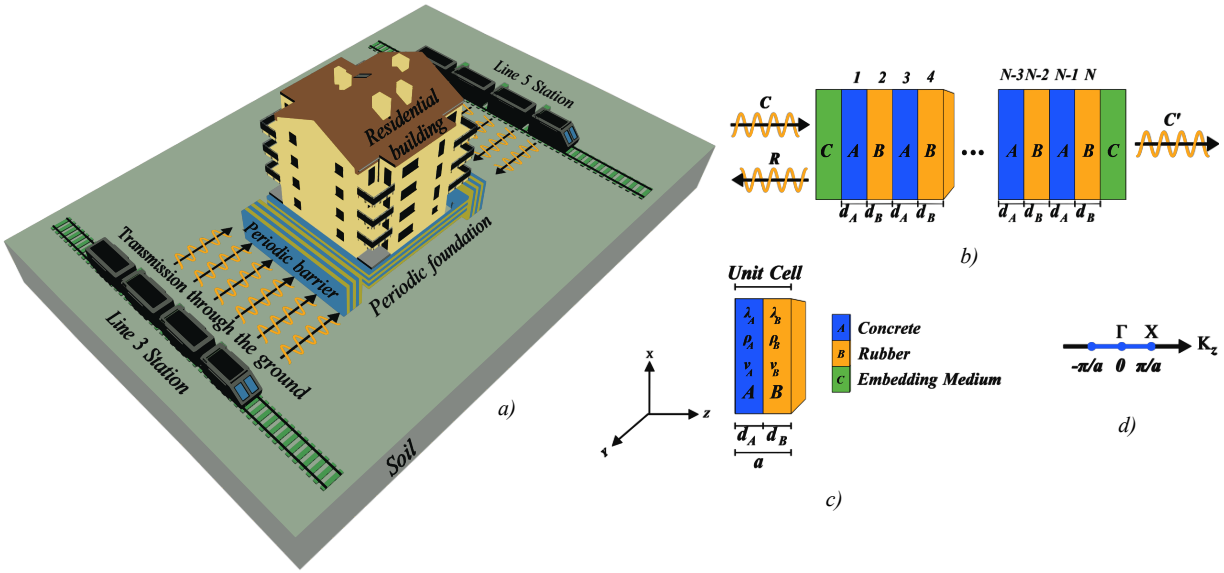

Figure 1 – Conceptual application and theoretical modeling of one-dimensional phononic crystals (1D-PnC) in civil engineering: (a) Conceptual scheme illustrating their use as periodic barriers and foundations for mitigating subway vibrations; (b) Multilayered periodic structure subjected to incident waves; (c) Fundamental two-component unit cell (concrete and rubber) highlighting material properties; (d) First irreducible Brillouin zone representation.

The performance of this system in blocking normal or oblique incident elastic waves is based on the acoustic impedance mismatch ($Z=\rho \cdot c$) between the two media, where ρ is the density and c is the wave propagation velocity in the respective material. This dynamic behavior is mapped in the first Brillouin Zone (Figure 1(d)). The velocities $c_T = \sqrt{\mu/\rho}$ and $c_L = \sqrt{(\lambda+2\mu)/\rho}$, at which transverse and longitudinal elastic waves propagate, are determined by the mechanical properties of the solid materials in question. Here $\lambda = E\nu/((1+\nu)(1-2\nu))$ and $\mu = E/(2(1+\nu))$ are the Lamé constants, where E is the Young's Modulus and ν is the Poisson's ratio, which describe the mechanical properties of the homogeneous solid material.

2.2 Transfer Matrix Method (TMM)

The dynamic response of the 1D-PnC was analytically modeled using the Transfer Matrix Method (TMM), which relates the amplitudes of elastic waves along continuous periodic media.

For the propagation of longitudinal (L) or transverse (T) waves along the z-direction, the displacement dynamics ψ in a medium j is described by the wave equation (De Lima et al., 2025).

$$\nabla^2 \psi_{\gamma,j} = \frac{1}{{c_{\gamma,j}}^2} \frac{\partial^2 \psi_j}{\partial t^2} \quad (1)$$

here $\gamma \in \{L, T\}$ and the velocity $c_{\gamma,j}$ depends on the density (ρ_j), and Lamé constants (λ_j, μ_j) of the material. The general solution superimposes the transmitted wave and the reflected wave in medium j, with amplitudes ϕ_j and $\overline{\phi}_j$.

$$\psi_j(x,y,z) = (\phi_j e^{ik_{zj}z} + \overline{\phi}_j e^{-ik_{zj}z})\, e^{i(k_{xj}x - 2\pi f t)} \quad (2)$$

The TMM establishes the continuity conditions for displacement and the stress tensor at the material interfaces, given by $\tau_{\gamma,j}(z) = \Lambda_{\gamma,j} \frac{\partial \psi_j}{\partial z}$. The term $\Lambda_{\gamma,j}$ depends on the propagation mode, where $\Lambda_{L,j} = \lambda_j + 2\mu_j$ for longitudinal waves and $\Lambda_{T,j} = \mu_j$ for transverse waves. For the transition from layer A to layer B, the interface transmission matrix (M_{AB}) is defined as:

$$\begin{pmatrix} \phi_B \\ \overline{\phi}_B \end{pmatrix} = M_{AB} \begin{pmatrix} \phi_A \\ \overline{\phi}_A \end{pmatrix} \tag{3}$$

$$M_{AB} = \frac{1}{2} \begin{pmatrix} 1 + \frac{\Lambda_{\gamma,A} K_{zA}}{\Lambda_{\gamma,B} K_{zB}} & 1 - \frac{\Lambda_{\gamma,A} K_{zA}}{\Lambda_{\gamma,B} K_{zB}} \\ 1 - \frac{\Lambda_{\gamma,A} K_{zA}}{\Lambda_{\gamma,B} K_{zB}} & 1 + \frac{\Lambda_{\gamma,A} K_{zA}}{\Lambda_{\gamma,B} K_{zB}} \end{pmatrix} \tag{4}$$

Within layer j of thickness d_j, the geometric phase shift is governed by the homogeneous propagation matrix (M_j):

$$\begin{pmatrix} \phi'_j \\ \overline{\phi'}_j \end{pmatrix} = M_j \begin{pmatrix} \phi_j \\ \overline{\phi}_j \end{pmatrix} = \begin{pmatrix} e^{-ik_{zj}d_j} & 0 \\ 0 & e^{ik_{zj}d_j} \end{pmatrix} \begin{pmatrix} \phi_j \\ \overline{\phi}_j \end{pmatrix} \tag{5}$$

The global transfer matrix of the finite structure (M) is constructed by the sequential product of the matrices representing each layer and interface. When evaluating a finite 1D-PnC with N unit cells embedded in a medium C, the boundary conditions at the entrance and exit must be accounted for. For a single unit cell (N=1), the wave transmits from medium C into layer A, propagates through layers A and B, and emerges back into medium C, yielding the global matrix $M_1 = M_{CA} M_A M_{AB} M_B M_{BC}$. For a periodic structure composed of N unit cells, the internal reflections and transmissions repeat. This periodic repetition is analytically generalized by raising the transfer matrix of the internal interfaces to the power of N-1. Thus, the generalized global transfer matrix M_N for any number of cells is defined as:

$$M_N = M_{CA} M_A M_{AB} M_B (M_{BA} M_A M_{AB} M_B)^{N-1} M_{BC} \tag{6}$$

The relationship between the wave amplitudes propagating through the entire finite structure is governed by the global transfer matrix M_N. Assuming the wave is incident from medium C, passes through the periodic structure, and exits into a semi-infinite medium C, there is no backward-propagating wave at the exit boundary. Thus, the state vectors comprising the forward (ϕ) and backward ($\overline{\phi}$) wave amplitudes at the entrance and exit are related as:

$$\begin{pmatrix} \phi'_c \\ 0 \end{pmatrix} = M_N \begin{pmatrix} \phi_c \\ \overline{\phi}_c \end{pmatrix} = \begin{pmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{pmatrix} \begin{pmatrix} \phi_c \\ \overline{\phi}_c \end{pmatrix} \tag{7}$$

By expanding this matrix equation, the boundary condition at the exit (0) allows us to solve for the reflected wave amplitude at the entrance as $\overline{\phi}_c = -(M_{21}/M_{22})\,\phi_c$. Substituting this relation back into the upper equation eliminates the reflected component, yielding the absolute ratio of the transmitted (ϕ'_c) to the incident (ϕ_c) wave amplitude:

$$\left| \frac{\phi'_c}{\phi_c} \right| = \left| M_{11} - \frac{M_{12} M_{21}}{M_{22}} \right| \tag{8}$$

Finally, to evaluate the vibration attenuation levels in practical engineering terms, the Frequency Response Function (FRF) is calculated in decibels (dB), following the methodologies of Cheng et al. (2020) and Zhao et al. (2021). The FRF represents the transmission loss and is defined as the logarithmic ratio of these amplitudes:

$$FRF = 20log\left(\left| \frac{\phi'_c}{\phi_c} \right| \right) = 20log \left| M_{11} - \frac{M_{12} M_{21}}{M_{22}} \right| \tag{9}$$

A negative FRF value indicates that the periodic material successfully attenuates the dynamic response, whereas a positive value represents a response amplification.

To analyze the behavior of an infinite structure, the Bloch-Floquet theorem is applied to the global matrix of a single unit cell (M'). Unlike the finite model, this matrix does not account for the external host medium, but rather the internal wave propagation cycle from one cell to the adjacent one. It encompasses the

propagation through both layers and the crossing of their internal interfaces, mathematically expressed by the product $M'= M_A M_{AB} M_B M_{BA}$. The relationship between the state vectors of adjacent cells is given by:

$$\begin{pmatrix} \phi_{l+1} \\ \dot{\phi}_{l+1} \end{pmatrix} = M' \begin{pmatrix} \phi_l \\ \dot{\phi}_l \end{pmatrix} = \begin{pmatrix} M'_{11} & M'_{12} \\ M'_{21} & M'_{22} \end{pmatrix} \begin{pmatrix} \phi_l \\ \dot{\phi}_l \end{pmatrix} \quad (10)$$

Here M' represents the global transfer matrix of a single unit cell. Therefore, the dispersion relation is obtained by applying Bloch's theorem:

$$cos(ka) = 1/2\, Tr[M'] \quad (11)$$

The dynamic spectrum of the structure is evaluated by Equation (11) at frequencies where $|1/2Tr[M']| \leq 1$, the wave vector k is real, indicating free propagation (passbands). Conversely, when $|1/2Tr[M']|>1$, k assumes a complex value, rendering the wave evanescent. These spectral regions constitute the band gaps, resulting in the blockage of vibrations.

2.3 Definition of the Reference Model

A reference unit cell model was established to evaluate the initial performance of the periodic structure against a real-world excitation scenario. The material properties adopted for the concrete and rubber are summarized in Table 1.

Table 1 – Material properties of 1D-PnC

Material	Young's Modulus	Poisson's ratio	Density
	E (Pa)	ν	ρ (kg/m³)
Concrete	25 x 10^9	0.33	2300
Rubber	0.147 x 10^6	0.463	1300

Geometrically, the reference unit cell was modeled with identical thicknesses for both layers, where d_A=d_B=0.2 m, resulting in a lattice constant a=0.4 m. To evaluate the effectiveness of this configuration, the band structures for S and P waves were calculated, and the results are illustrated in Figure 2.

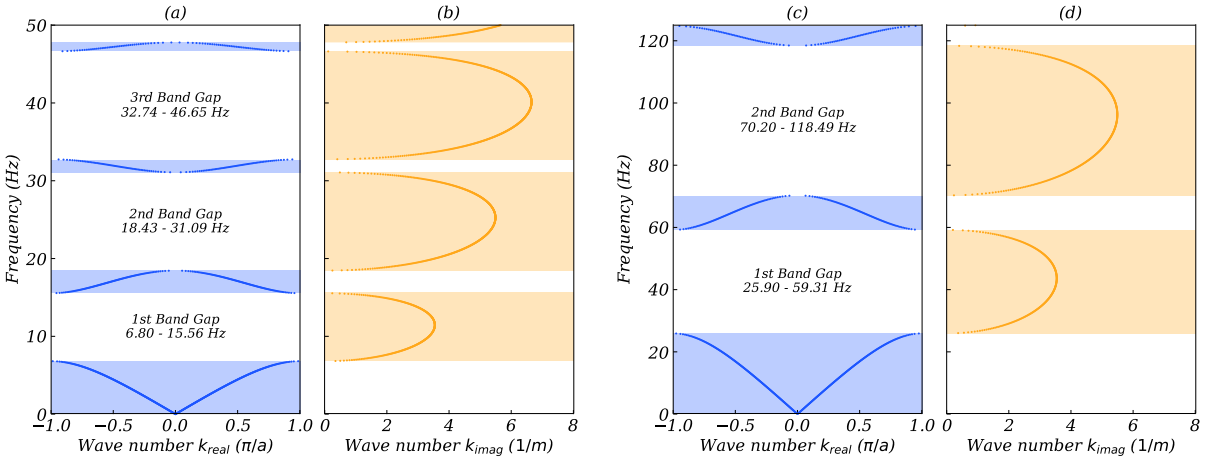

Figure 2 – Dispersion relations of the 1D phononic crystal: (a) real part (k_{Real}) and (b) imaginary part (k_{Imag}) of the wavenumber for S-waves; (c) real part (k_{Real}) and (d) imaginary part (k_{Imag}) of the wavenumber for P-waves

The objective of this evaluation was to verify whether the limits of the first two theoretical S-wave band gaps were capable of covering the predominant excitation frequencies as solution for the vibration problem. For this purpose, the experimental Vibration Acceleration Level (VAL) spectra obtained by Xing, Zhu and Chen (2025), measured on Lines 3 and 5 of a subway system in Chengdu, China, were used as the mitigation target. According to Xing, Zhu and Chen (2025), for Line 3, two peaks were observed in the vertical direction near 6.3 Hz and 12.5 Hz, with amplitudes of 85.4 dB and 84.7 dB, respectively. In the longitudinal direction, the peak occurs at 6.3 Hz with 84.8 dB, and in the horizontal direction at 8 Hz with an amplitude of 80.2 dB. For

Line 5, when the train enters the station, the highest vibration amplitude is found in the 4 Hz to 20 Hz range, reaching a peak of 86.6 dB at 16 Hz. In the 1-4 Hz and 20-80 Hz ranges, the maximum level is 70.9 dB, with a peak at 3.15 Hz.

Comparing these predominant excitation frequencies with the theoretical dispersion relations of the reference model as seen in Figure 2(a) and (b), it is observed that the initial configuration is only partially effective. The first S-wave band gap, spanning from 6.80 Hz to 15.54 Hz, successfully encompasses the horizontal peak at 8 Hz and the vertical peak at 12.5 Hz from Line 3, theoretically providing attenuation for these specific components. However, the reference structure fails to cover some critical frequency ranges. The peaks at 3.15 Hz from the Line 5 and 6.3 Hz fall entirely within the first propagation band, meaning they would pass through the structure without mitigation. Consequently, while the reference 1D-PnC demonstrates foundational potential for vibration mitigation, its band gaps are not adequately tuned to completely block the most severe train-induced vibrations. This gap in performance highlights the necessity of the proposed optimization.

2.4 Parametric Study and Target Frequency Tuning

Considering the limitations of the reference model, the core stage of the methodology consisted of a parametric study to tune the frequency ranges of the band gaps. The objective was to investigate the sensitivity of the band gaps to variations in the physical and geometric parameters. The procedure was carried out in two stages. Initially, keeping the unit cell geometry fixed (a=0.4 m), the influence of the elastic properties (E, ν) and the density (ρ) of the constituent materials was investigated. Subsequently, the internal geometric configuration of the structure was analyzed, evaluating the impact of varying the layer thickness ratio ($r = d_{Rubber}/d_{Concrete}$), the lattice constant ($a = d_{Concrete}+d_{Rubber}$), and the filling fraction ($f = d_{Rubber}/a$).

3. Results and discussion

3.1 Sensitivity Analysis of the Band Gaps to Parametric Variations

To understand how the material properties govern the behavior of the band gaps, this section presents a parametric study similar to those conducted by Jia and Shi (2010), Li et al. (2023), Witarto et al. (2016). In Figure 3, it is observed that as the value of E_{Rubber} increases, there is an upward shift in the lower and upper frequency limits of both band gaps. This occurs because an increase in E_{Rubber} raises the Lamé constants (λ e μ), consequently increasing the wave velocities c_T and c_L and the wave propagation frequencies.

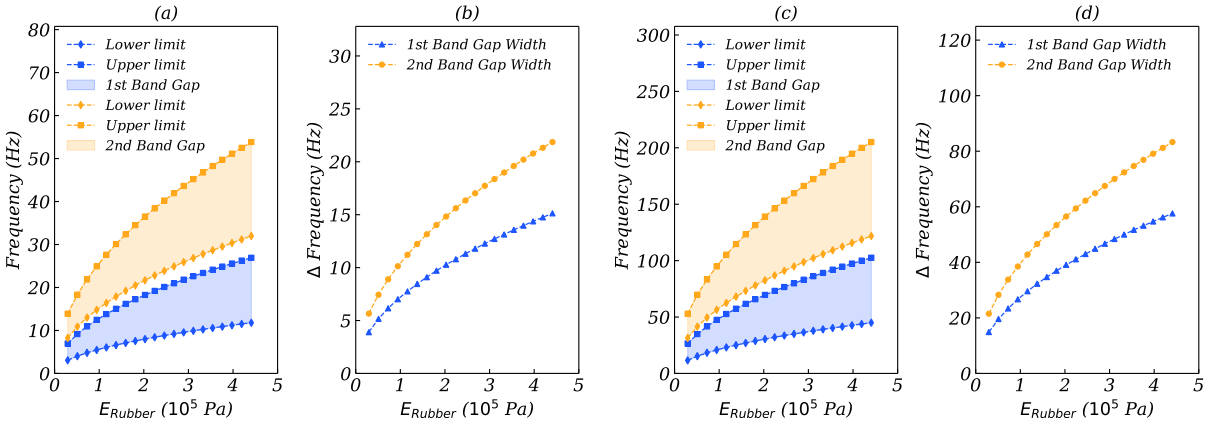

Figure 3 – Influence of the rubber Young's modulus (E_{Rubber}) on the band gap properties. (a) Frequency limits and (b) band gap width for S-waves; (c) frequency limits and (d) band gap width for P-waves

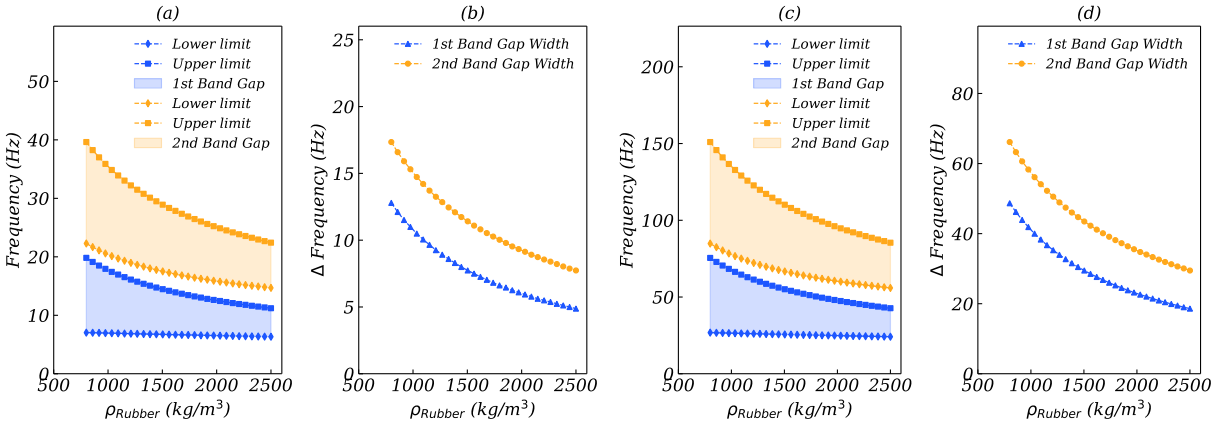

Figure 4 – Influence of rubber density (ρ_{Rubber}) on the band gap properties. (a) Frequency limits and (b) band gap width for S-waves; (c) frequency limits and (d) band gap width for P-waves

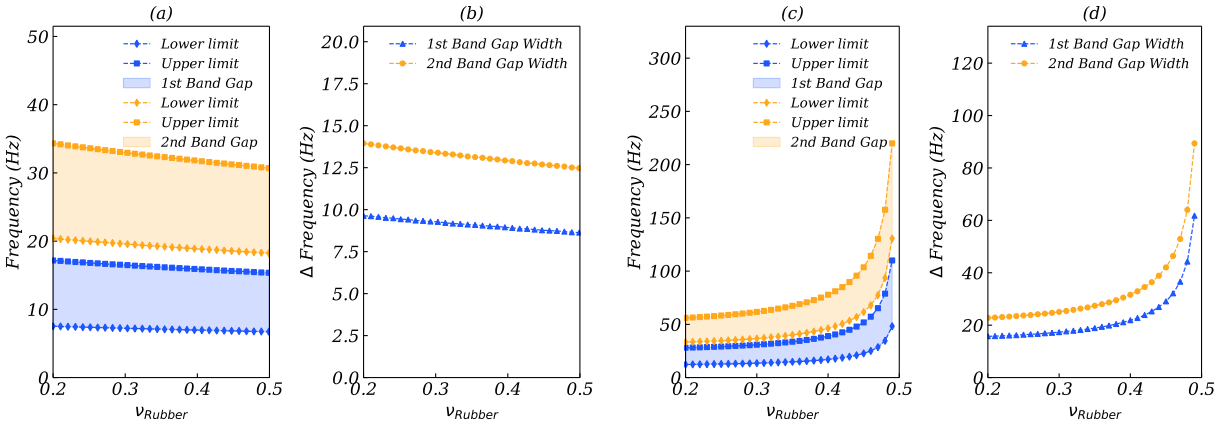

Figure 5 – Influence of rubber Poisson's ratio (ν_{Rubber}) on the band gap properties. (a) Frequency limits and (b) band gap width for S-waves; (c) frequency limits and (d) band gap width for P-waves

Increasing ρ_{Rubber} shifts the band gaps to lower frequencies (Figure 4). This occurs because an increase in ρ_{Rubber} decreases the wave velocities c_T and c_L thereby reducing the propagation frequencies. For S-waves, the influence of ν_{Rubber} is relatively small, causing a slight reduction in both the lower and upper boundary frequencies (Figure 5a).

On the other hand, for P-waves, the sensitivity is extremely high as ν_{Rubber} approaches the incompressibility limit of rubber at 0.5. As illustrated in Figure 5(c), both the frequencies and the band gap width increase exponentially.

When varying the Young's modulus of the concrete ($E_{Concrete}$), the upper and lower limit frequencies, as well as the widths of the first two band gaps, remained constant for both S-waves and P-waves (Figure 6). The same behavior was observed in the analysis of the Poisson's ratio (Figure 8) which demonstrates that the elastic properties of the rigid layer (concrete) exert less influence on the limits and widths of the band gaps than the properties of the inclusion material (rubber). Conversely, increasing the concrete density ($\rho_{Concrete}$), lowers the frequency ranges of the band gaps (Figure 7).

As shown in Figure 9, and increase in the thickness ratio ($r = d_{Rubber}/d_{Concrete}$), shifts both the lower and upper frequency limits to lower values, but results in narrower band gaps.

Figure 10 demonstrates an inversely proportional relationship between the unit cell size (a) and the band gap position. This behavior is intrinsic to the diffraction physics in PnCs, where the condition for destructive interference (Bragg reflection) is met when the wavelength becomes comparable to the spatial periodicity of the structure ($\lambda \approx 2a$) (Jin; Djafari-Rouhani; Torrent, 2019).

Figure 11 shows that as the filling fraction $f = d_{Rubber}/a$ approaches 1, the band gap width tends to zero, since the periodic structure and the impedance contrast cease to exist.

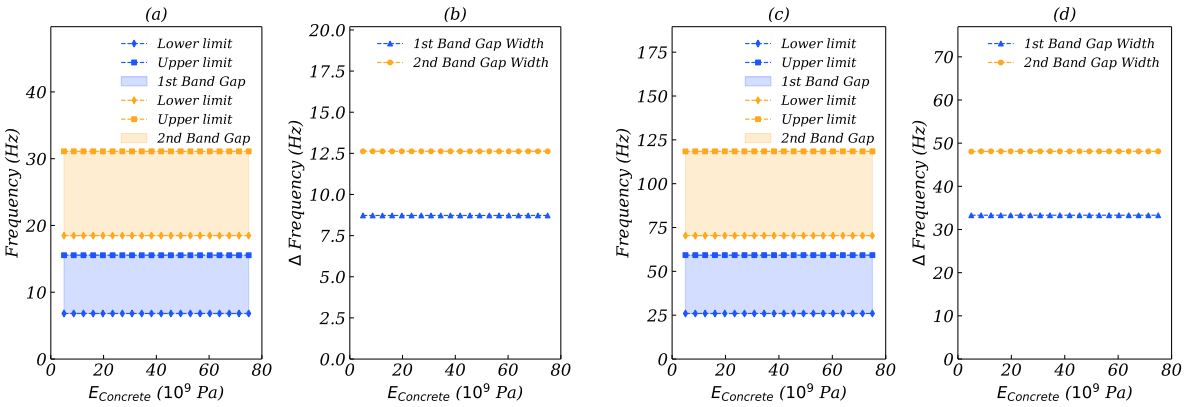

Figure 6 – Influence of the concrete Young's modulus ($E_{Concrete}$) on the band gap properties. (a) Frequency limits and (b) band gap width for S-waves; (c) frequency limits and (d) band gap width for P-waves

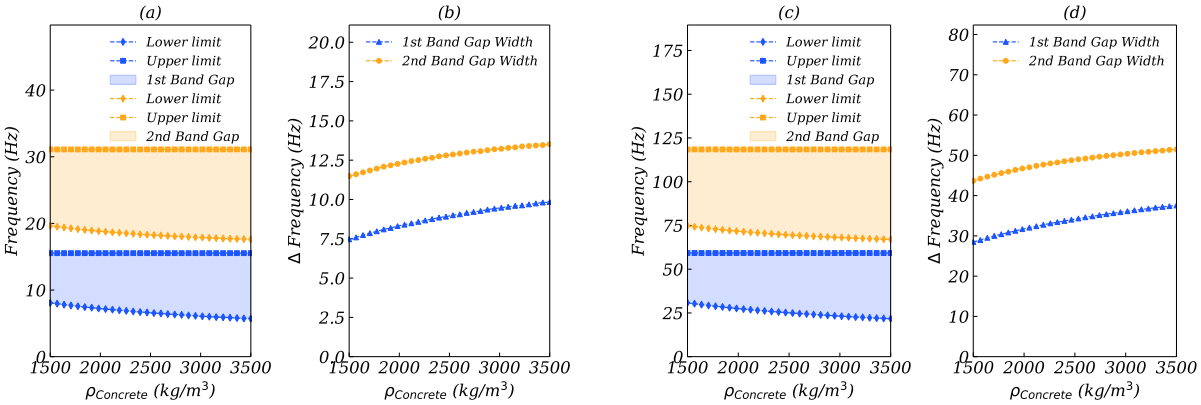

Figure 7 – Influence of the concrete density ($\rho_{Concrete}$) on the band gap properties. (a) Frequency limits and (b) band gap width for S-waves; (c) frequency limits and (d) band gap width for P-waves

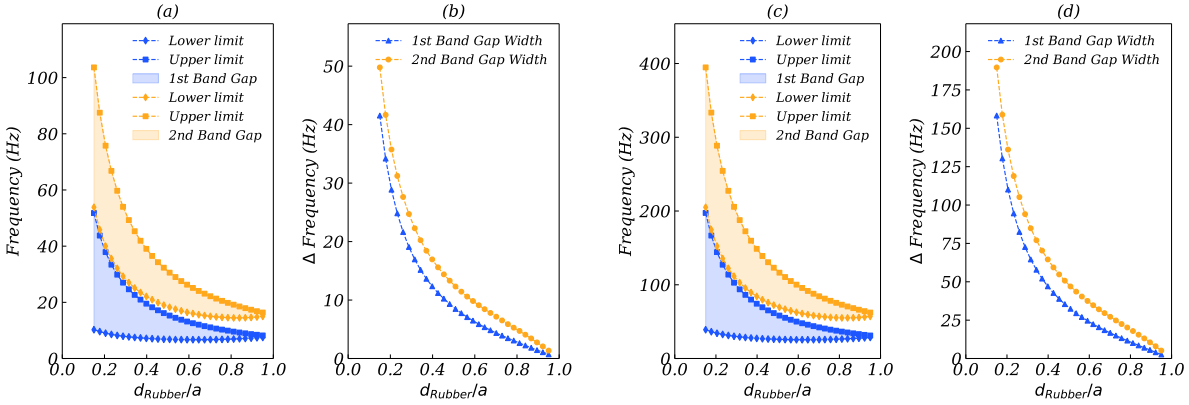

Figure 11 – Influence of the filling fraction (f=d_{Rubber}/a) on the band gap properties. (a) Frequency limits and (b) band gap width for S-waves; (c) frequency limits and (d) band gap width for P-waves

3.2 Design of the Optimized Periodic Structures and Optimal Tuning for Lines 3 and 5

Figure 12 illustrates the behavior of the periodic foundation after optimizing the geometric lattice parameter to a = 0.48 m. The band structure analyzed for S and P waves, represented in Figure 12(b) and (d), shows the formation of the band gaps. In Figure 12(a) and (c), it is possible to observe that significant transmission drops occur exactly within the theoretically predicted band gap frequencies. The arrangement with four unit cells exhibits deeper attenuation levels compared to the two unit cell arrangement.

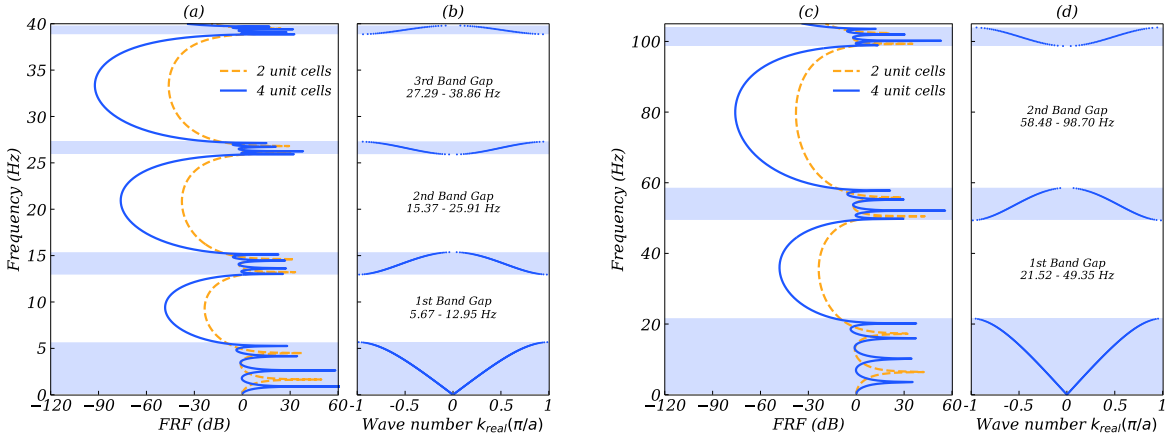

Figure 12 – Dynamic properties of the optimized unit cell (adjusted lattice constant a = 0.48 m). The behavior for S-waves is presented on the left: (a) Frequency Response Function (FRF) for finite arrangements; (b) band structure. The corresponding behavior for P-waves is detailed on the right: (c) FRF; (d) band structure

It was observed that the first band gap, which extends from 5.67 to 12.95 Hz, effectively encompasses the low-frequency peaks, such as those observed around 6.3 Hz and 12.5 Hz in all directional components. Furthermore, the second band gap, ranging from 15.37 to 25.91 Hz, covers the secondary excitation peaks. This is evident for Line 5, where the Periodic Foundation (PF) successfully isolates the peak occurring at 16 Hz. Figure 13 presents the dynamic response of the periodic barrier after adjusting E_{Rubber} = 1.16 x 10^5 Pa.

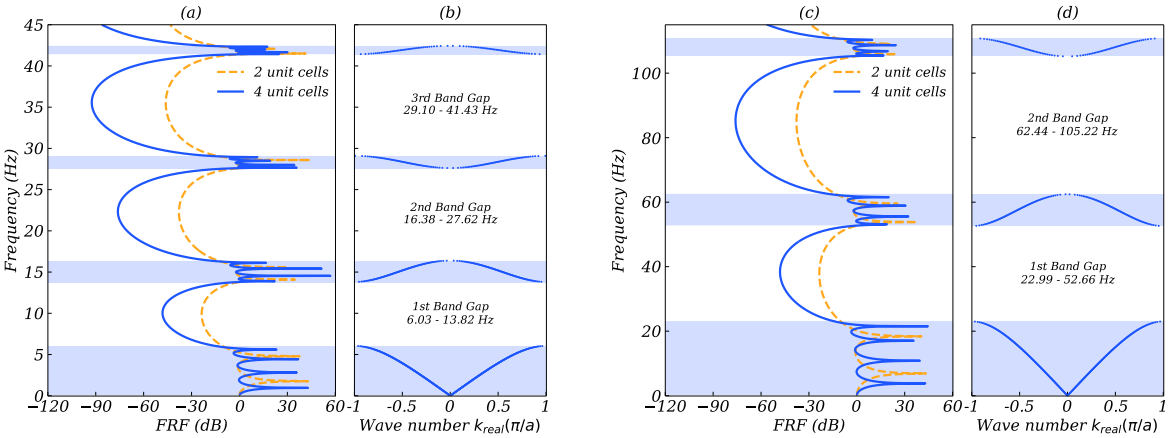

Figure 13 – Dynamic properties of the optimized unit cell (adjusted rubber Young's modulus E_{Rubber} = 1.16 x 10^5 Pa). The behavior for S-waves is presented on the left: (a) Frequency Response Function (FRF) for finite arrangements; (b) band structure. The corresponding behavior for P-waves is detailed on the right: (c) FRF; (d) band structure

As illustrated by the band structure graph Figure 13(b) and (d) and confirmed by the FRF Figure 13(a) and (c), the new band gap zones are shifted to slightly higher frequencies.

The first band gap, ranging from 6.03 to 13.82 Hz, can effectively mitigate the frequency peaks at 6.3 Hz and 12.5 Hz present in Line 3. For Line 5, the second band gap, in the range of 16.38 to 27.62 Hz, was shifted to the right. Consequently, the secondary energetic peak occurring exactly at 16 Hz in the longitudinal direction falls outside the attenuation zone. Thus, this limitation directly motivates the subsequent optimization step, which aims to perform a new adjustment in the material properties to encompass this 16 Hz peak once again. The next objective was to identify a configuration that could offer targeted isolation specifically for Line 5. Figure 14 presents the behavior of the periodic structure when the rubber's elastic modulus is reduced to E_{Rubber} = 0.94 x 10^5 Pa.

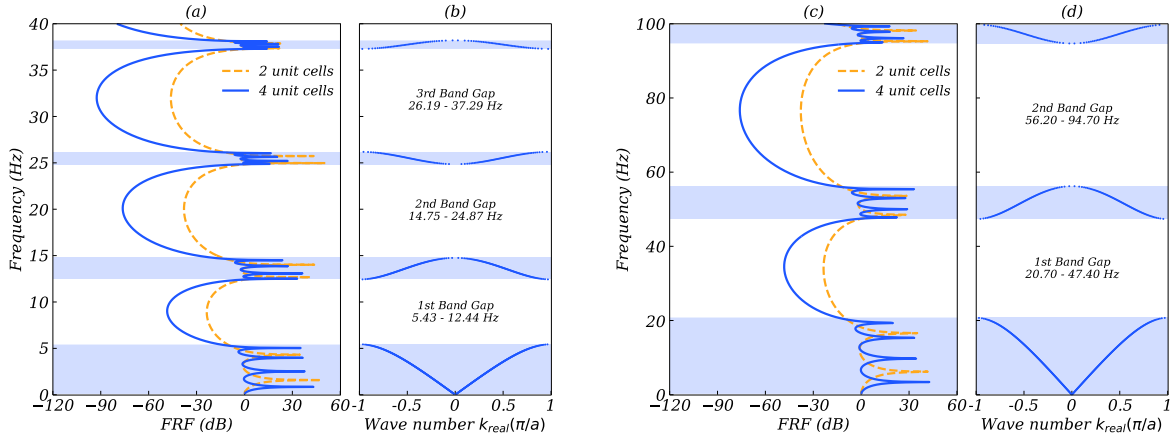

Figure 14 – Dynamic properties of the optimized unit cell (adjusted rubber Young's modulus E_{Rubber} = 0.94 x 10^5 Pa). The behavior for S-waves is presented on the left: (a) Frequency Response Function (FRF) for finite arrangements; (b) band structure. The corresponding behavior for P-waves is detailed on the right: (c) FRF; (d) band structure

As observed in the FRF (Figure 14(a) and (c)) and the band structure (Figure 14(b) and (d)), this reduction in stiffness shifts the band gap frequencies downward. This modification, when superimposes the adjusted band gaps onto the VAL spectra of (a) Line 3 and (b) Line 5, exhibits varying performance depending on the specific railway line. For Line 5, this adjustment proves to be effective. The resulting second band gap successfully encompasses the main peaks occurring at 12.5 and 16 Hz in the longitudinal direction. However, when applied to Line 3 although the first band gap manages to cover the 6.3 Hz peak, the second peak at 12.5 Hz falls outside the attenuation range.

4. Conclusions

This paper demonstrated the feasibility and effectiveness of applying one-dimensional phononic crystals (1D-PnCs) as periodic foundations and barriers for mitigating subway-induced vibrations. Through an analytical-parametric approach based on the Transfer Matrix Method (TMM), it was possible to map the dynamic response of the structure and strategically modulate the attenuation ranges (band gaps). The sensitivity analysis revealed that the dynamic behavior of the system is predominantly governed by the unit cell dimensions and the impedance contrast imposed by the rubber inclusion. It was found that geometry dictates the overall position of the attenuation bands. Adjusting the lattice constant to 0.48 m proved highly efficient in encompassing the global energy peaks concentrated at low frequencies, below 30 Hz, which are typical of the railway excitations studied. Furthermore, calibrating the elastic properties of the rubber layer enabled targeted spectral optimization, validated against real-world Vibration Acceleration Level (VAL) spectra. Stiffening the rubber proved ideal for isolating the critical peaks at 6.3 Hz and 12.5 Hz recorded on Line 3. Conversely, reducing its elastic modulus reconfigured the mechanical filter, precisely blocking the energetic 16 Hz peak characteristic of Line 5. It is concluded that the design of 1D-PnCs should not be generic, but rather customized to the vibrational signature of each specific site. The predictive methodology proposed herein provides civil engineering with a tool for designing tailor-made passive isolation systems.

Abstract: The structural assessment of rubble stone masonry is inherently complex because its constituent materials, stones and mortar, exhibit significant heterogeneity and uncertain properties, along with well-known variability in stone geometry, size, and positioning. A micro-modelling strategy based on a detailed particle model (PM) that follows a discrete element method (DEM) has been applied in the modelling and evaluation of traditional stone masonry unreinforced walls, transversally confined walls and walls reinforced with sprayed micro-concrete layers with external steel mesh and transverse confinement. Simulations of axial and shear–compression loading show that DEM-based PMs accurately reproduce the behaviour of ancient masonry, albeit at high computational demand. In this work the proposed DEM-based PM has been optimized to reduce computational cost. Coarser mortar particle representations are adopted to assess its impact on the overall predicted response. The results, including uniaxial compression and compression-shear tests, show that the adopted micro-modelling approach can be optimized without compromising its predictive capability and overall performance.

Keywords: Rubble-stone masonry; particle model; optimization.

1. Introduction

In Portugal, ancient buildings represent nearly 50% of the built heritage and their structural walls are mostly constructed using rubble stone masonry. Moreover, these masonry buildings were built before the existence of structural safety codes and regulations, and were designed to solely resist vertical loads, and therefore are particularly vulnerable to seismic actions. The structural assessment of rubble stone masonry is inherently complex because its constituents, the filler material such as limestones, and a binder such as lime, exhibit significant heterogeneity and uncertain properties, along with well-known variability in stone geometry, size, and arrangement, Pinho and Lúcio (2017). Traditional continuum-based methods often fail to capture key failure mechanisms such as cracking, sliding and progressive collapse, Roca et.al (2010), particularly under seismic loading. To address this limitations, micro-modelling strategies have been increasingly adopted, with Discrete Element Method (DEM) approaches proving particularly effective for masonry. Lemos (2017) showed that DEM is particularly well suited for capturing nonlinear behaviour and collapse mechanisms in masonry under static and dynamic loading conditions. Similarly, Gobin et al. (2021) demonstrated that DEM is capable of effectively capturing the behaviour of masonry under seismic action, with crack patterns and resulting collapse mechanisms emerging directly from the analysis.

A micro-modeling strategy based on a detailed particle model (PM) that follows a discrete element method (DEM) has been applied to the modelling and evaluation of traditional unreinforced stone masonry walls Azevedo et al. (2022), transversally confined walls Cismaşiu et al. (2023) and walls reinforced with sprayed micro-concrete layers with external steel mesh and transverse confinement, Azevedo et al. (2025). The studies have shown that the 2D DEM-based PMs reliably reproduced the response of the ancient masonry under uniaxial compression and compression-shear loading conditions, though they entail high computational demand. Devanand et al. (2025) adopted a similar DEM-based particle micro-modelling approach for brick masonry and demonstrated that it can accurately reproduce masonry behaviour under compression-loading conditions. Chen et al. (2024) modelled rubble masonry walls using a coupled finite–discrete element micro-modelling approach employing a coarser masonry representation when compared to those adopted in this paper.

In this work the DEM-based PM has been optimized to reduce its known computational cost. Coarser mortar particle representations were adopted to assess their impact on the overall predicted response. The results presented, namely uniaxial compression and monotonic compression-shear tests, show that the adopted micro-modelling approach can be optimized without compromising its predictive capability and overall performance. Ongoing work is focused on an optimization strategy based on a hybrid finite element/discrete element algorithm as proposed by Azevedo and Lemos (2022) that reduces the number of particles and contacts required to properly represent the stone behaviour by replacing the internal particle discretization with a coarser finite element mesh and retaining only the boundary particles.

2. Discrete Element-Based Particle Model (PM)

2.1 Fundamentals

The masonry elements (stones and mortar) are represented by rigid circular particles with three degrees of freedom (two translations and one rotation) that interact at the point of contact (Figure 1). At the contact point normal (k_n) and shear stiffness (k_s) springs are assigned which allow elastic deformations. Complex macroscopic nonlinear responses can be obtained if brittle or simple contact softening-based laws are adopted at the contact level. The calculation cycle of a discrete element algorithm is based on two principles: the force–displacement law, the forces acting on each particle are related to the particle's displacement relative to neighboring particles, and the law of motion, given the forces applied to the centroid of the particle, the new position of the particle is determined by applying Newton's second law, that are sequentially applied, see Cundal and Stark (1979) and Azevedo *et al.* (2010).

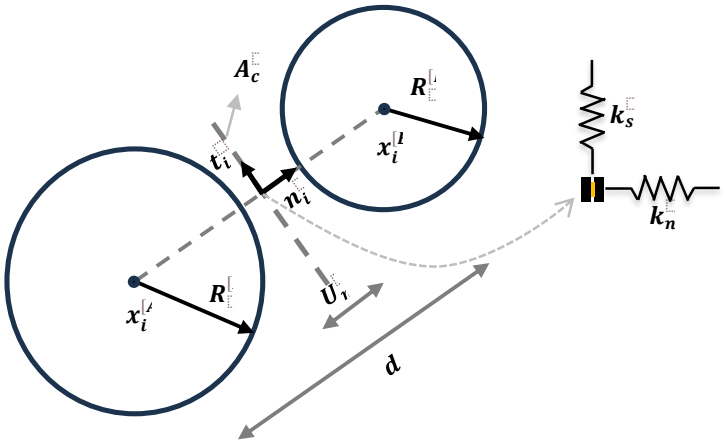

Figure 1 – PM contact model

At a given time increment, the contact normal force ($\Delta F_n\ (t)$) and the shear contact force ($\Delta F_s\ (t)$) increments are defined based on a linear force–displacement relationship, given the contact normal ($\Delta x_n\ (t)$) and shear ($\Delta x_s\ (t)$ displacement increments and the contact stiffnesses:

$$\Delta F_n\ (t) = -k_n\ \Delta x_n\ (t) \tag{1}$$

$$\Delta F_s\ (t) = -k_s\ \Delta x_s\ (t) \tag{2}$$

2.2 Contact stiffness and contact strength

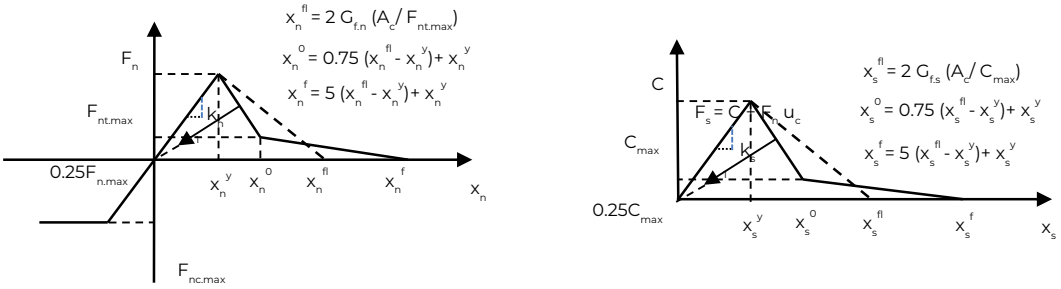
The normal and shear contact stiffnesses are defined using the following expressions:

$$k_n\ = A_c\ \frac{\bar{E}}{d} \tag{3}$$

$$k_s\ = \alpha\quad k_n \tag{4}$$

where $\bar{E}$ is the modulus of elasticity of the equivalent continuous material; d is the distance between the centers of gravity of the circular particles in contact (Figure 1); A_c is the contact area (Figure 1) and α is the shear stiffness to the normal stiffness ratio.

The total tensile strength ($F_{n.max}$), the maximum cohesion (C_{max}), the maximum shear strength ($F_{s.max}$) and the total compressive strength ($F_{nc.max}$) are defined given the maximum tensile stress ($\sigma_{n.t}$), the maximum cohesive stress (τ), the normal force acting on the contact (F_n), the friction term (μ_c), the maximum compressive stress, ($\sigma_{n.c}$) and the contact area, it is possible to define, as shown in Equations (5)–(8):



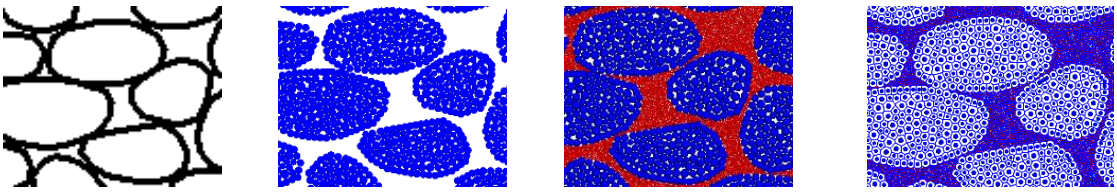
$$F_{n.max} = \sigma_{n.t}\ A_c \tag{5}$$

$$C_{max} = \tau\ A_c \tag{6}$$

$$F_{s.max} = C_{max} + F_n\ \mu_c \tag{7}$$

$$F_{nc.max} = \sigma_{n.c}\ A_c \tag{8}$$

A bilinear softening damage model is adopted for the contact point in the normal (tensile) and shear directions, see Azevedo *et al.* (2010) and Azevedo *et al.* (2022), Figure 2.



a) Normal direction b) Shear direction

Figure 2 – Contact model: Bilinear softening damage model in the normal (tensile) and shear directions and a yield plateau in compression, Azevedo et al. (2010) and Cismaşiu et al. (2023)

In this constitutive model, the maximum values of tensile strength and cohesion are reduced according to the total damage value, which is defined by the sum of tensile and shear damage. The contact damage value at a given direction is defined as a function of the maximum contact displacement in that direction. In the normal direction, the maximum contact displacement is defined given the adopted contact fracture energy in the normal direction ($G_{f.n}$), similarly, the maximum shear displacement is defined given the contact fracture energy in the shear direction ($G_{f.s}$). For stone masonry walls modelling it is necessary to adopt a yield plateau in the normal direction (compression), Azevedo *et al.* (2022) and Cismaşiu *et al.* (2023).

2.3 Model generation

The arrangement and geometry of the stones in the masonry wall are determined through a mapping process of the stone units (Figure 3a). Following, each stone unit is discretized with particles (Figure 3b). Subsequently, the void space surrounding each stone, representing the mortar, is also discretized with circular particles (Figure 3c). The mortar particle size distribution was chosen to match the material's granular structure; however, this led to high computational demand. Nevertheless, computational constraints may require the adoption of coarser particle distributions. The contacts are established using the Voronoi-Laguerre tessellation of the gravity centers of each circular particle (Figure 3d). Three types of contacts are present in a PM model of a rubble-masonry wall: mortar-mortar (m-m), mortar-stone (m-s) and stone-stone (s-s).

a) Masonry specimen b) Stone discretization c) Mortar discretization d) Particle contacts

Figure 3 – Rubble stone masonry wall model generation, Azevedo et al. (2022) and Cismaşiu et al. (2023)

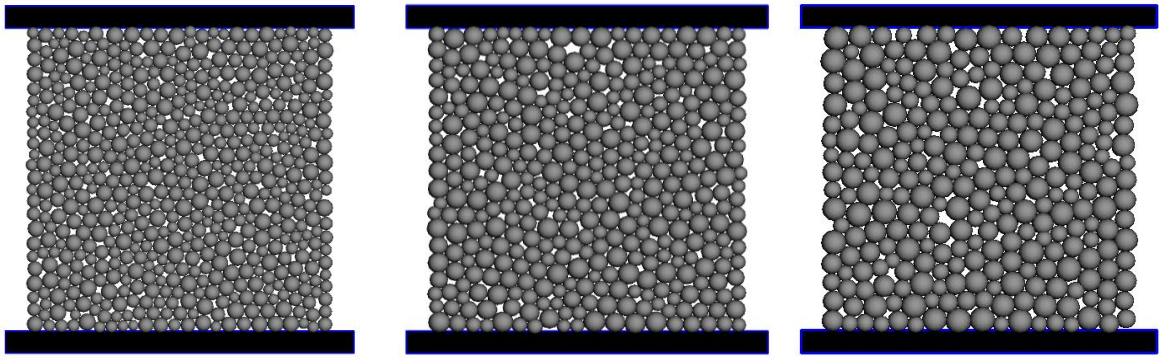
3. PM Parameter Calibration

One particular feature of PMs is that the elastic and strength contact properties cannot be assigned directly from laboratory test results. Instead, these parameters are calibrated at the assembly level so that the particle system reproduces the macroscopic behaviour of the material they represent in known experimental tests such as uniaxial tensile and compression tests, and biaxial or triaxial tests. In the absence of experimental test results, the strength parameters of the m–s contacts are adopted as 50% of the calibrated m–m contact strength parameters., Azevedo et al. (2022); Cismaşiu et al. (2023).

The macroscopic elastic response of a PM is related to the adopted Young's modulus of the equivalent continuous material ($\bar{E}$) and to the adopted stiffness factor (α) that relates the shear stiffness and normal stiffness. The macroscopic strength response of a PM is controlled by six contact parameters, namely the maximum tensile stress ($\sigma_{n.t}$), the maximum cohesion stress (τ), the friction coefficient (μ_c), the tensile contact fracture energy ($G_{f.n}$), the shear contact fracture energy ($G_{f.s}$), and to the maximum compression stress value ($\sigma_{n.c}$) that defines the yield plateau in the normal direction under compression.

A simple trial and error calibration procedure based on user experience is carried. The elastic contact parameters are initially set to match the macroscopic Young modulus and Poisson coefficient, followed by setting the contact strength parameters to match the known macroscopic parameters, such as the tensile and the compression strength of the masonry element (mortar, stone) being calibrated. Research efforts on

the automation of the calibration of the micro-mechanical parameters, Kibriya et. al (2024) make PMs more appealing, as some experimental data may not be available for existing masonry structures.



The contact properties of the stone and mortar were calibrated based on the experimental tests carried out for stones and mortar, Pinho (2007), see Table 1. Other authors have also provided experimental values for the mechanical properties of the stone masonry components, which could be used for calibration purposes of the mortar and stone contacts properties, see D'Altri et al. (2020) and Saloustros et al. (2023). It is worth mentioning that databases compiling results from experimental studies on the mechanical properties of stone masonry walls can provide significant support for PM parameter calibration, Murano et al. (2020).

Table 1 – Elastic and strength macroscopic values: experimental values, Pinho (2007)

Material	$\mathbf{E}$ (GPa)	υ	σ_c (MPa)
Stone	6.0	0.29	47.8
Mortar	0.075	0.16	0.65

The properties of the s–s contacts, representative of stone, were calibrated on 0.20 m × 0.20 m numerical models. The properties of the m–m contacts, representative of mortar, were calibrated on 0.04 m × 0.04 m numerical models. The model size should be chosen to match the size adopted in the experimental tests. The numerical models were subjected to pure compression and pure tension tests using the Parmac2d PM implementation.

For the stone units with an average dimension of 16.7 cm, a PM model with a uniform radius distribution between 0.003 m and 0.005 m was adopted in all models. In the reference model (R), PM model with a uniform radius distribution between 0.000714 m and 0.00119 m was adopted for the mortar, Azevedo et al. (2022). Note that the adopted maximum radius value corresponds to the maximum size of the sand used in the laying mortar, Pinho (2017). To assess the impact of mortar particle size on the overall predicted response, different coarser mortar particle representations are adopted, namely: PM model (M2) with a uniform radius distribution between 0.0008568 m and 0.001428 m; and PM model (M3) with a uniform radius distribution between 0.0009996 m and 0.001666 m. Figure 4 presents the developed mortar PMs adopted for the calibration of the contact properties for uniaxial compression and tensile strength. When compared with the reference PM model, in the PM model M2 a radius multiplier of 1.2 was adopted for the minimum and maximum radius distributions, whereas a radius multiplier of 1.4 was adopted in the PM model M3.

a) PM model R c) PM model M2 d) PM model M3

Figure 4 – Uniaxial compression PMs - 0.04 m × 0.04 m

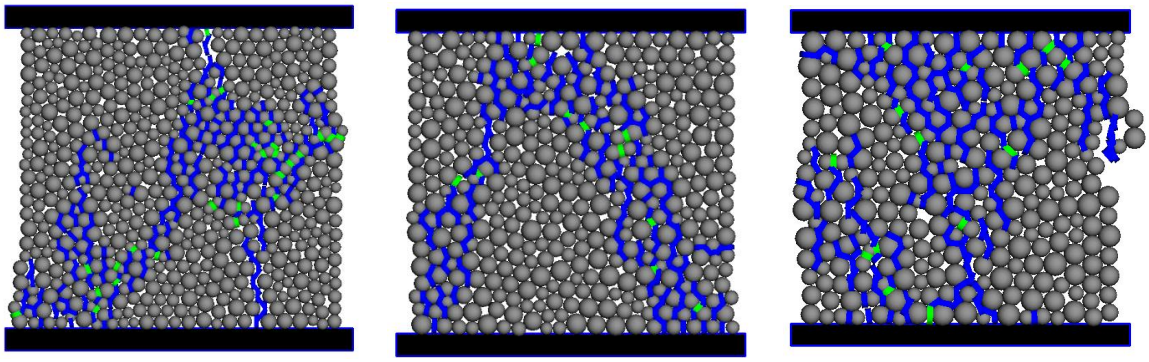


Table 2 presents calibrated PMs contact properties obtained through a trial and error procedure. The s-s and m–m (R) contacts were calibrated as part of the work presented in Azevedo et al. (2022). In all PMs

representing the mortar, a maximum compression value of 0.80 MPa was adopted in the normal direction, close to the maximum uniaxial compression value of the laying mortar, Pinho (2007). The m–m (M2) and m–m (M3) contacts were calibrated within the framework of this work. As shown in Table 2 the calibrated contact properties values for PM models with different particle assemblies, see Figure 4, are very similar. The similarity is mainly due to the fact that the contacts areas and the contact interactions are established using the Voronoi-Laguerre tessellation of the circular particle gravity centers (Figure 3d).

Table 2 – Elastic and strength PMs contact calibrated properties

Contacts	$\bar{E}$ (GPa)	α	$\sigma_{n.t}$ (MPa)	τ (MPa)	μ_c	$G_{f.n}$ (N/m)	$G_{f.s}$ (N/m)
s-s	8.6	0.11	8.9	35.7	1.0	0.3838	56.1403
m-m (R)	0.090	0.43	0.171	0.171	1.0	0.0014	0.0033
m-m (M2)	0.0905	0.40	0.179	0.179	1.0	0.0019	0.0046
m-m (M3)	0.0910	0.39	0.169	0.169	1.0	0.0019	0.0049

Figure 5 presents the final contact cracking distribution predicted in uniaxial compression for the different assessed mortar PM models. The obtained final crack patterns are the expected failure patterns when the loading plates have zero friction. Figure 6 presents the stress-deformation for the uniaxial compression test for the calibrated m-m contact properties. It can be observed that the PM models representing mortar have a very similar behaviour close to the observed in hydrated air lime mortar.

a) PM model R c) PM model M2 d) PM model M3

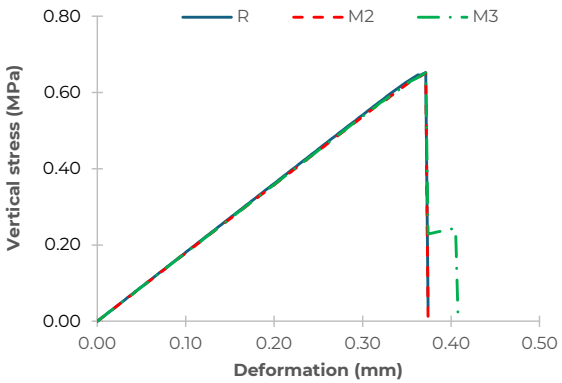

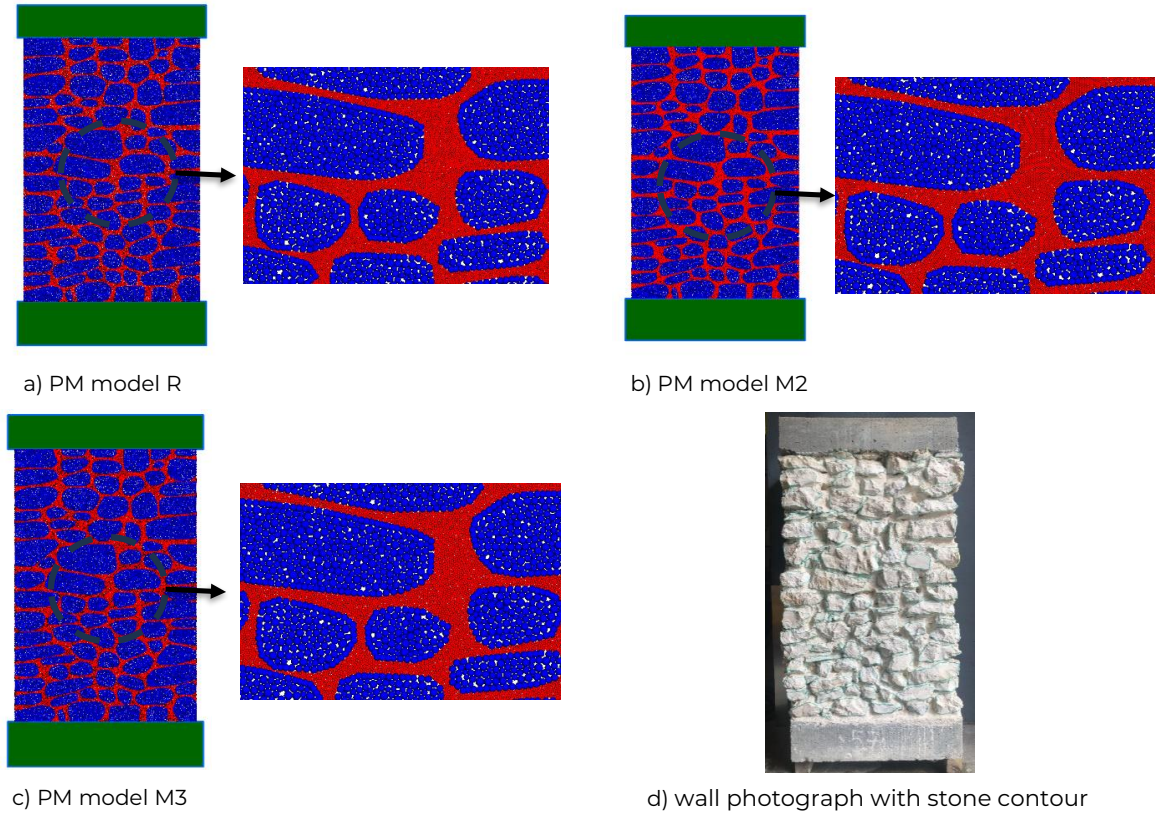

Figure 6 – Stress-displacement diagram for compression tests

4. Numerical uniaxial compression and shear-compression tests of the specimen M57

4.1 Experimental setup

The PM numerical models developed in this work are built based on the experimental studies conducted by Pinho (2007) which evaluated the effectiveness of different strengthening techniques by subjecting several rubble-stone masonry specimens to two specific testing conditions: axial compression and shear-compression tests. The 2D PM numerical models are defined from the frontal faces of the tested walls with 0.40 m width, Pinho (2007). In this work one unreinforced rubble-stone masonry specimens: M57 with dimensions 1.20 m x 0.80 m x 0.40 m is adopted, Figure 7.

a) PM model R

b) PM model M2

c) PM model M3

d) wall photograph with stone contour

Figure 7 – Frontal wall PMs and photograph with stone contour of specimen M57

Table 3 presents, for the different mortar adopted, mortar particle size distributions, the total number of particles and contacts used in the discretization of specimen M57.

Table 3 – PMs number of particles and number of contacts

Model	Particles		Contacts		
	Stone	Mortar	s-s	m-m	s-m
M57 (R)	14997	94131	39842	264660	21338
M57 (M2)	14822	65747	39545	182094	18801
M57 (M3)	14650	48542	39205	132323	16919

As shown the PM model based on a M2 mortar discretization, M57 (M2), enables when compared with the reference mortar discretization, M57 (R), a 31% reduction in the total number of particles and contacts, whereas, the PM model based on a M3 mortar discretization, M57 (M3), enables when compared with the reference mortar discretization, M57 (R), a 50% reduction in the total number of particles and contacts.

4.2 Results and discussion

4.2.1 Uniaxial compression tests

The numerical prediction of the uniaxial compression test for models M57 (R), M57 (M2), and M57 (M3), along with the experimental results, is shown in Figure 8. The m–m and s–s contact parameters for each PM model are presented in Table 2, while the m–s contact parameters are defined as 50% reduction of the m-m calibrated contact strength. As shown in Figure 8an excellent agreement with the experimentally observed behaviour is predicted, both in terms of peak strength and residual strength, for all the adopted mortar discretizations.

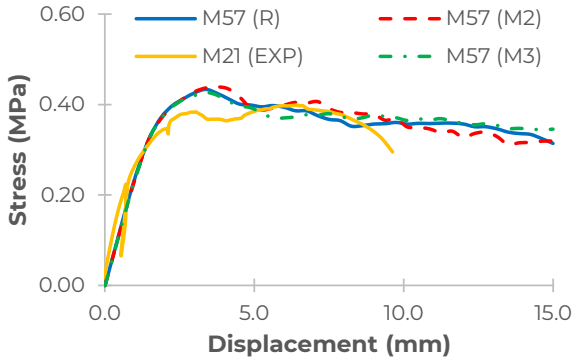

Figure 8 – Vertical Stress-Vertical displacement curve of model 57 (PM Numerical models) and experimental response of tested specimen M21 with similar geometry, Pinho (2007)

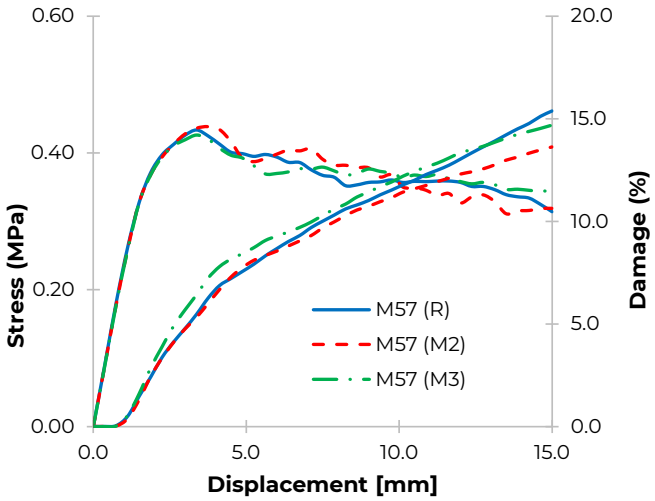
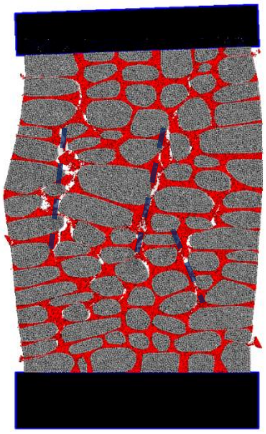
Figure 9 presents the damage evolution throughout the uniaxial compression test for the PM's with different mortar discretizations. All PMs predict a similar behaviour, meaningful damage initiates at around 40% of the peak strength with a steady growth up to the peak strength, after peak strength the damage evolution is slightly more restrained.





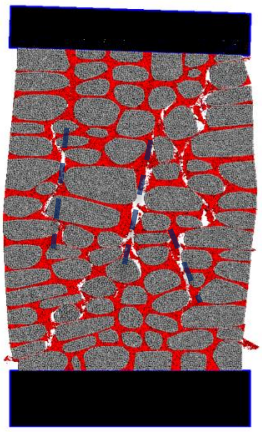


Figure 9 – PMs predicted Stress-displacement curve of model M57 including damage evolution

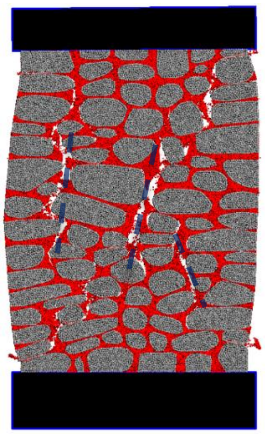

Figure 10 presents the PMs predicted failure modes along with the failure mode observed experimentally for a wall with similar geometry (M43), Pinho (2007). As shown, the PMs predicted failure modes are very similar to each other, with the principle macroscopic cracks having similar locations and extensions, and to the failure mode observed experimentally.

a) PM M57 (R)

b) PM M57 (M2)

c) PM M57 (M3)

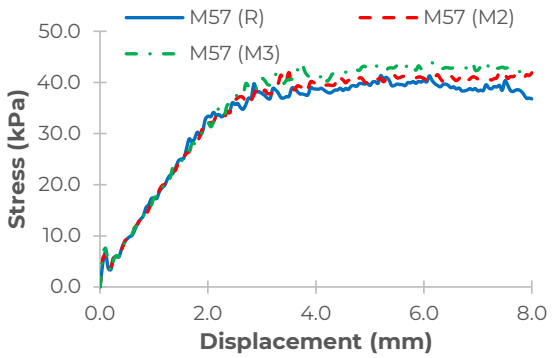
d) M43 Experimental model

Figure 10 – Uniaxial compression failure mode - PMs Numerical prediction versus experimental observation

The running time of the PM M57 (R) is approximately 65 hours on a 12th Gen Intel ® Core i9-12900 KF–3.19Hz. The PM M57 (M2) enables a 25% reduction cost, whereas the PM M57 (M3) enables a 50% reduction cost, with similar predictions under uniaxial loading.

4.2.2 Monotonic shear-compression tests

The M57 based PM models were also evaluated under shear-compression. A vertical pre-compression stress of 0.23 MPa, identical to the experimental value adopted by Pinho (2007). Note that, in the experimental program carried out by Pinho (2007) only the walls with dimensions 1.20 m x 0.80 m x 0.40 m were assessed under shear-compression. As shown in Figure 11, the PM models with different mortar discretizations predict similar responses under a shear-compression loading condition. With the M57 (M3) PM the peak strength value is 6% higher than that predicted with the M57 (R) PM model. The M57 (M2) PM predicts an even closer peak strength value, only 2% higher than that predicted with the reference model, M57 (R).



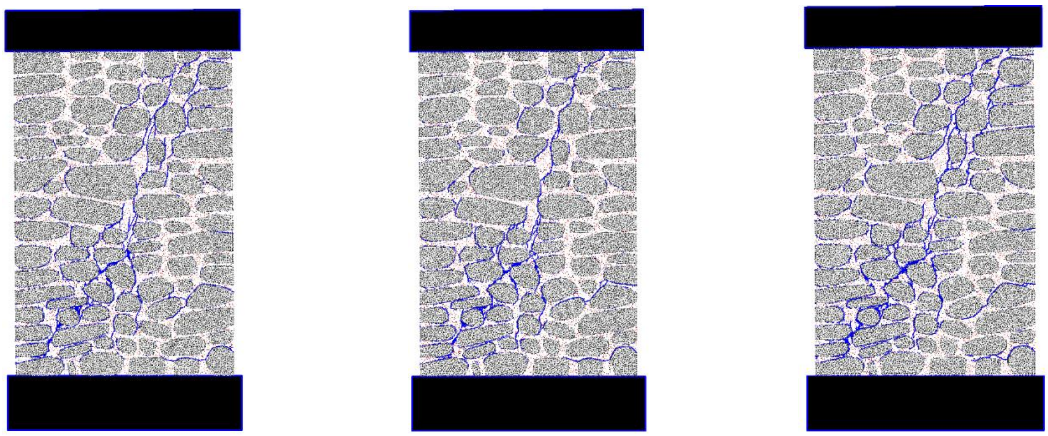


Figure 11 – Horizontal stress-horizontal displacement curve of M57 PM numerical models

Figure 12 presents the PMs predicted final contact damage distribution. As shown, the PMs predicted contact damage distributions are similar to each other. Figure 12 also shows that damage initially occurs at the s-m contacts, latter propagating to form the final macroscopic final cracks.

a) PM model M57(R) c) PM model M57(M2) d) PM model M57(M3)

Figure 12 – Shear-compression PMs predicted final contact damage distribution

The running time of the PM M57 (R) is approximately 50 hours on a 12th Gen Intel ® Core i9-12900 KF–3.19Hz. The PM M57 (M2) enables a 27% reduction cost, whereas the PM M57 (M3) enables a 44% reduction cost, with similar predictions under shear-compression loading.

5. Conclusions

The results presented show that the adopted 2D micro-modelling approach can be optimized without compromising its predictive capabilities and overall performance by coarsening the mortar discretization. The coarsened mortar PMs have an excellent agreement with the reference PM that adopts a finer discretization. The maximum strength, the failure mode, and the overall mechanical behaviour observed experimentally in rubble-stone masonry walls under uniaxial compression and under shear-compression are well predicted with the coarsened mortar discretizations. Work is underway to replace the particle discretization adopted in the stone discretization with a coarser finite element mesh adopting only the boundary particles.

Abstract: This paper presents the CIB Student Chapter of Instituto Superior Técnico (IST), University of Lisbon, affiliated with the Research Group "Studies on Construction", of the Civil Engineering Research and Innovation for Sustainability (CERIS) research unit. Originally established in 2004 as the first CIB Student Chapter in Portugal, it was relaunched in 2025 to foster international exchange and research excellence among students, especially those in PhD programs. By aligning academic research with innovation, the Chapter intends to prepare future leaders in the construction sector. This article describes the internal organization of the Chapter and outlines its action plan based on the scope of CIB Working Commissions addressing: Heat and Moisture Transfer in Buildings; Facilities Management and Maintenance; Prediction of Service Life of Building Materials and Components; and Building Pathology. The importance of engaging with this Student Chapter is discussed through testimonies from former and current members, highlighting the initiative's impact on their academic and professional development.

Keywords: CIB Student Chapter, PhD Students, International Cooperation, Research and Innovation, Built Environment.

1. Introduction

Global challenges require international collaboration in research, benefiting from multiple perspectives, players (Haley *et al.*, 2024) and approaches. In this context, research networks are expanding and increasingly including emerging research economies (Adams, 2012). In Civil Engineering, combining efforts with researchers, policymakers and industry stakeholders is fundamental to pursuing sustainable construction practices, seeking environmental responsibility and social well-being (Khan, McNally, 2023).

Aligned with these needs, the International Council for Research and Innovation in Building and Construction (CIB) is a worldwide network created in 1953 that currently comprises more than 40 Technical Commissions. The Council fosters international cooperation to improve the quality and impact of research and innovation in the building and construction sector. CIB scope covers technical, economic, environmental and organizational aspects across all stages of the built environment life cycle, from research to implementation.

Within the CIB structure, there are several Student Chapters, representing organized groups of students enrolled at CIB Member universities having common interests in the work of CIB Commissions and Priority Themes: sustainable construction, integrated design and delivery solutions and resilient urbanization. These students are envisioned as future leaders of building research and innovation, participating in an environment that fosters engagement and inspiration while promoting international cooperation.

Following this educational framework, the CIB Student Chapter from Instituto Superior Técnico (IST), University of Lisbon (UL), was originally inaugurated in 2004, being the first CIB Student Chapter in Portugal (Flores-Colen, de Brito, 2004). After more than a decade of activities that lasted until 2020, the Student Chapter IST/UL was officially relaunched in 2025. The Chapter is associated with Research Group 5 (RG5), "Studies on Construction", of Civil Engineering Research and Innovation for Sustainability (CERIS).

The objective of this paper is to share perspectives on research and collaboration under the scope of the CIB Student Chapter IST/UL. This Chapter is structured around the United Nations Sustainable Development Goals (SDGs), mainly SDGs 4 (Quality Education), 9 (Industry, Innovation and Infrastructure), 11 (Sustainable Cities and Communities) and 17 (Partnerships for the Goals). Furthermore, it is devoted to priorities highlighted during the 26th United Nations Climate Change Conference (COP26), such as the urgent need for resilience and action against climate change impacts in the built environment.

The internal organization of the Chapter is detailed, together with its action plan and promoted activities. The thematic framework that characterizes the core pillars of expertise of the Chapter are outlined, combined with their alignment with CIB Working Commissions. Finally, the importance of engaging in the CIB Student Chapter IST/UL regarding academic and professional development is reported based on information shared by former and current members. The purpose of the discussion is to introduce our Chapter under the scope of the CIB Community, contributing to the CIB Vistas Program foundational values: people, the planet, global collaboration and the future.

2. Internal organization

Figure 1 illustrates the categories of participants involved in the management and benefiting from the actions of the CIB Student Chapter IST/UL. The dashed arrows represent an open line for communication and contribution among the different levels, allowing for cooperation, exchanges and collaborative inputs.

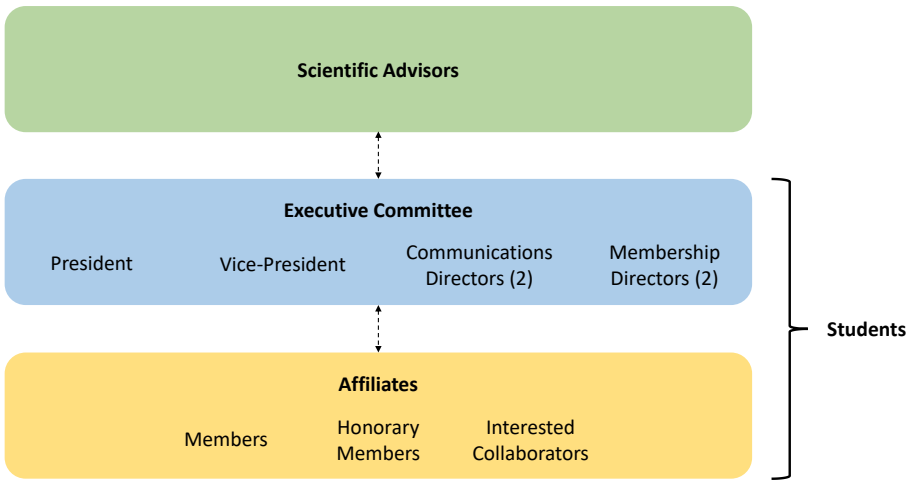

Figure 1 - Internal organization of the CIB Student Chapter IST/UL

The Scientific Advisors are faculty members from the Department of Civil Engineering, Architecture and Environment (DECivil) at IST who provide institutional and scientific support to the Chapter. Their names and contact details are communicated to the CIB General Secretariat, thereby ensuring the continuity of the Chapter, the formal connection with the university and the official point of contact between the Student Chapter and CIB.

Regarding the governance of the Chapter, the Executive Committee is composed of students who take on internal management responsibilities. The positions made available in the relaunch of the group are President, Vice President, two positions for Communications Directors and two positions for Membership

Directors, with the possibility of adding others in the future as needed.

Student president and Vice-President duties include the overall coordination of the Chapter, the strategic definition of activities and institutional representation within CIB and the academic community. The Communications Directors are responsible for the internal and external dissemination of the Chapter's activities, ensuring the maintenance of communication channels and the visibility of initiatives among students and the scientific community. The Membership Directors are responsible for supporting the recruitment of new participants and implementing strategies to ensure their continued and active participation within the Chapter.

The members of the CIB Student Chapter IST/UL are master's students with research grants, PhD students and researchers from RG5 of CERIS who actively collaborate on the initiatives organized. Honorary members are former students who participated as a member from the Chapter during their period at CERIS. Finally, interested collaborators are students and researchers willing to participate in the Chapter, but unable to become members due to their affiliation with research areas or institutions other than CERIS RG5.

The relaunch of the CIB Student Chapter IST/UL relies on Professors Inês Flores-Colen and Jorge de Brito as Scientific Advisors, whose experience is particularly relevant as they participated in the founding of this first CIB Student Chapter in Portugal and have since remained active members of CIB. Presidency and Vice-Presidency positions are currently held by Jéssica Bersch and Giovanna Bartels; Renato Neves and Nicollas Moreira serve as Communications Directors, while Isobel Andrews and Fernanda Magalhães are the Membership Directors.

3. Action plan and activities

An Action Plan was defined upon the relaunch of the CIB Student Chapter IST/UL for the upcoming years. For this purpose, the main actions planned by the group were distributed as yearly or continuous activities, as illustrated in Figure 2.

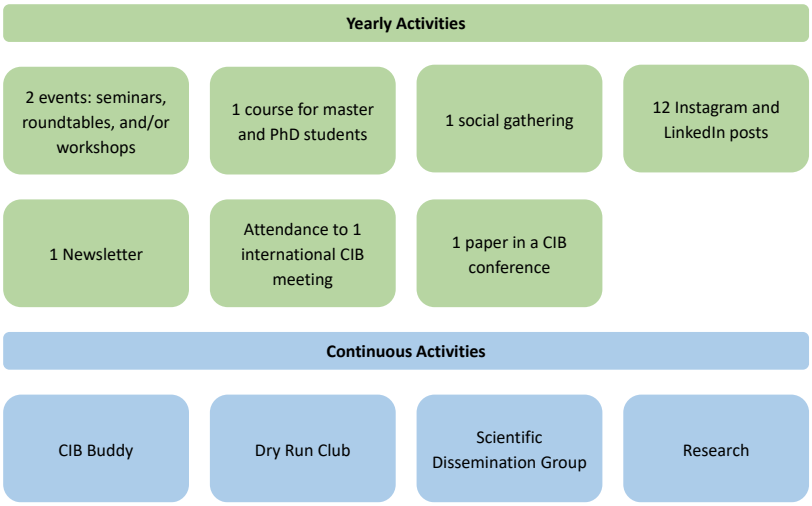

Figure 2 - Action plan of the CIB Student Chapter IST/UL

Regarding yearly tasks, seminars, workshops and roundtables are envisioned to disseminate the activities carried out within the scope of the CIB Student Chapter and promote knowledge sharing and transfer among its members, considering the associated thematic framework, themes of interest for the affiliates and research developed by students. The first seminar was held in October 2025 and was attended by more than 30 participants. In addition to the presentation of the Chapter, the event featured a keynote titled "Decarbonization in the construction sector: Educational approaches in the Netherlands," by Thais Varella, MSc in Environmental

Studies and Lecturer in Environmental Science at Avans University of Applied Sciences, Netherlands.

Courses for master's and PhD students are structured as training sessions planned to cover topics of interest to the Chapter. The objective for the sessions is for members to share their expertise with one another. Training on the development and presentation of graphs, machine learning, or specific Civil Engineering software is considered relevant, for example.

At least at the end of each academic year, CIB Student Chapter members who are pursuing their PhD studies are invited to a social gathering, beginning with a pitch-style presentation on the status of their theses, followed by networking and social activities. This event is designed to foster collaboration and friendship among students.

The digital presence of the Student Chapter is maintained through Instagram (@cibstudentist), YouTube (https://www.youtube.com/channel/UCqh9u2cKfn1eHC7xmL0oKnA) and its own website (https://cibsc.wordpress.com/). Additionally, an annual newsletter synthesizes the outputs of the Chapter to be sent to the affiliates. For the digital presence of the Chapter, a custom logo was developed within the Communications Directory, based on the CIB and IST logos, as presented in Figure 3.

Figure 3 - Logo of the CIB Student Chapter IST/UL

As part of the international engagement, opportunities for integration with other CIB Student Chapters throughout the world are pursued during Chapter members' attendance at national and international conferences, especially those supported by CIB, through the presentation of activities and discussions of potential collaborations. Knowledge dissemination is planned through paper publications and presentations at CIB partner events, such as the International Conference on the Durability of Building Materials and Components (DBMC).

Regarding the Chapter's ongoing activities, the CIB Buddy program intends to support students of DECivil/IST within the academic environment in Lisbon. International or new students may connect with the Student Chapter and receive support from members, who are responsible for highlighting opportunities to engage in research, sharing PhD experiences and assisting with contact with professors.

The Dry Run Club's purpose is to provide scheduled meetings whenever the members need to present their papers at conferences or for thesis and dissertation defences. These sessions allow practicing the presentation of scientific work to colleagues in a peer-based environment, contributing to the improvement of the work and the development of confidence.

Research is a core activity of the CIB Student Chapter, enabling the development of innovations that address resilience and climate change impacts in the built environment. Each member pursuing a master's or PhD conducts research with potential impact, seeking, where possible, collaboration with the CIB Commissions considered in this work, such as Hygrothermal Science, Facilities Management, Service Life Prediction or Building Pathology.

Finally, the scientific dissemination group is an open communication channel operating through the Student Chapter mailing list to disseminate scientific papers, events and other materials that contribute to the knowledge and development of the group. The pieces of news shared by the cibstudent@tecnico.ulisboa.pt e-mail address are those perceived as relevant by the members, Scientific Advisors and other academic or industry professionals.

4. Thematic framework

The CIB Student Chapter IST/UL was relaunched with a focus on the themes approached by the CIB Commissions “W040 - Heat and Moisture Transfer in Buildings”, “W070 - Facilities Management and Maintenance”, “W080 - Prediction of Service Life of Building Materials and Components” and “W086 - Building Pathology”, mainly due to the Executive Committee and Scientific Advisors expertise. Table 1 summarizes the thematic framework of the Chapter.

Table 1 - Thematic framework of the CIB Student Chapter IST/UL

Alignment with CIB Commission	Expertise	Focus
W040	Hygrothermal Science	Heat, moisture, air and salt transfer
W070	Facilities Management	Asset management, relationship between technical, financial and sociological aspects of building facilities
W080	Service Life Prediction	Durability design and service life prediction methodologies
W086	Building Pathology	Inspections, diagnosis and rehabilitation

Beyond addressing the individual scope presented by each commission of interest, the Chapter promotes an integrated approach to the built environment. Within the scope of W040, the focus respects the physical laws governing heat and moisture transfer to optimize building performance. Hygrothermal assessments in walls contribute to building resilience and adaptability to a changing climate, long-term sustainability and more efficient costs (Palani *et al.*, 2023). Hygrothermal simulations can even be used to predict and prevent mould growth (Sukop, Ostrý, 2025). Therefore, the focus on W040’s topics is complemented by W086 under the Student Chapter framework, where systematic pathology surveys provide diagnostic data necessary for sustainable rehabilitation and maintenance. Building pathology refers to the causes, mechanisms and consequences of failures that compromise structural integrity, hygrothermal performance and indoor air quality (Freitas, 2021).

Furthermore, the Chapter explores durability and service life (W080) and the socioeconomic challenges of asset management (W070). As service life is the period during which construction can meet changing performance requirements without reaching unacceptable levels (Silva *et al.*, 2021) and facility services intend to ensure better condition, quality and durability of building assets (Baniya, 2023), the focus on the operational phase is crucial for optimizing strategies for circularity, resilience and global cost prediction in buildings.

By fostering collaboration between academia and industry, the group seeks to translate theoretical models into practical maintenance strategies that enhance the long-term value and resilience of construction. For that purpose, the integrated thematic framework adopts a life cycle perspective of the built environment and building materials, envisioning reduced environmental impacts during their construction, use and end of life phases (Pedroso *et al.*, 2022). In this context, reliable reference service life datasets of building materials become crucial to contribute to reducing uncertainties (Sadeghi *et al.*, 2025).

Deriving from the expertise shown in Table 1, when approaching the themes, the Chapter seeks to expand by including current and pressing trends. The role of digital transformation in these fields is recognized, thereby encouraging the integration of artificial intelligence (AI) and digital tools in the promoted activities to enhance inspection, management and maintenance (Torres-Gonzáles *et al.*, 2023, Valença *et al.*, 2024). By structuring and gathering data generated throughout the whole life cycle of buildings, AI can improve construction processes (Abioye *et al.*, 2021).

Moreover, climate change effects on buildings need to be addressed (Barrelas *et al.*, 2023, Lacasse *et al.*, 2020) and, for that purpose, the Chapter seeks to contribute to the understanding of these impacts, the decarbonization of the construction sector (Bartels *et al.*, 2025) and the promotion of sustainable rehabilitation practices (Rucha *et al.*, 2026), in line with global sustainability agendas. Circular economy is also under the scope of the Student Chapter, including concerns over bio-based (Bellei *et al.*, 2025, Moreira *et al.*, 2024), innovative (Bersch *et al.*, 2023) and recycled (Neves *et al.*, 2025) materials, especially in areas at risk (Magalhães *et al.*, 2024).

5. Engagement and professional growth

Figure 4 shows a word cloud developed based on a survey answered by six members belonging both to the current Executive Committee of the CIB Student Chapter IST/UL or that were its former Presidents. The responses corresponded to the five words that the experience on the Chapter reminded them of. In summary, the Chapter appears to connect students to a global scientific ecosystem, thus working as expected from its foundational objectives. Beyond technical expertise, terms like 'Engagement', 'Motivation' and 'Friendship' suggest that the Chapter also fosters a sense of belonging and soft skills development.

Figure 4 - Word cloud for engaging in the CIB Student Chapter IST/UL

Concerning the skills developed during active participation in the Executive Committee of the Chapter, as shown in Figure 5, leadership and team management were highlighted. Organizing projects and events, combined with the communication associated to them appeared second.

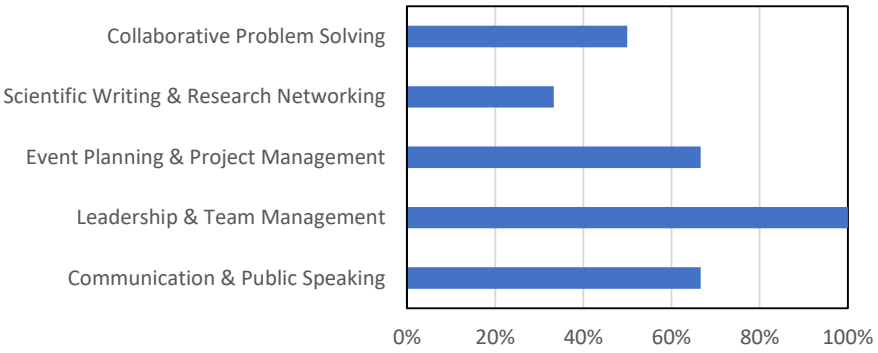

Figure 5 - Skills developed during active participation in the Executive Committee of the CIB Student Chapter IST/UL

The active functioning of the Chapter also involves challenges. These are related to recruiting new members, keeping them motivated over time and inspiring them to collaborate with the team. Identifying opportunities for international cooperation and research fields were also raised by the survey participants. Furthermore, organizing high-impact technical events and balancing the Chapter activities with PhD and research workloads are part of the more demanding tasks.

The engagement in the CIB Student Chapter IST/UL is reported by its members as a transformative experience for both academic and professional development. Participation in the Chapter facilitates the creation of national and international research networks, expanding beyond the academic sphere. Moreover, it provides scientific exposure and interactions between PhD students from different fields, allowing them to share their journeys. For leadership roles, the experience is particularly impactful, fostering the development of soft skills, such as strategies to keep members active and motivated.

Ultimately, the Chapter serves as a bridge to the global CIB Community, introducing the members to its structure and experts. When discussing how to foster international cooperation in science, members emphasized the importance of seeking connections with other institutions and Student Chapters, CIB Working Commissions and Task Groups and foreign peers in innovative research topics. For some respondents, participating in the Student Chapter allowed them to join Working Commissions meetings, collaborate in reports and understand the challenges and demands in specific CIB areas.

6. Conclusions

The relaunch of the CIB Student Chapter IST/UL in 2025 reaffirms its role as an educational platform for international cooperation in building and construction research. The thematic framework fosters an integrated research approach that aligns traditional construction, including hygrothermal behaviour and building pathology, with service life prediction and facilities management. This synergy tackles the built environment's life cycle, essential for addressing climate change and promoting technological and sustainable rehabilitation.

Qualitative evidence from members highlights that the Chapter goes beyond technical training, allowing the development of leadership skills for members, especially those involved in the Executive Committee, including team management, strategic communication and institutional representation. The Chapter can open the doors to the CIB international community through synergies with Working Commissions and other Student Chapters. Besides academia-industry interactions, belonging to the group allows sharing of PhD research journeys, resulting in an active, collaborative and friendly environment.

The benefits in terms of networking, scientific exposure and soft skills development outweigh the challenges of maintaining engagement within the group. Future efforts will focus on expanding digital integration and strengthening partnerships, ensuring that the CIB Student Chapter IST/UL continues to prepare leaders for the construction sector who are committed to people, the planet, global collaboration and the future.

Acknowledgments

This research was funded in whole by the *Fundação para a Ciência e a Tecnologia*, I.P. (FCT, https://ror.org/00snfqn58) under Grant UID/6438/2025 (https://doi.org/10.54499/UID/06438/2025) of the research unit CERIS.
